203 CHAPTER • 203 Primary Myocardial Disease in the Dog

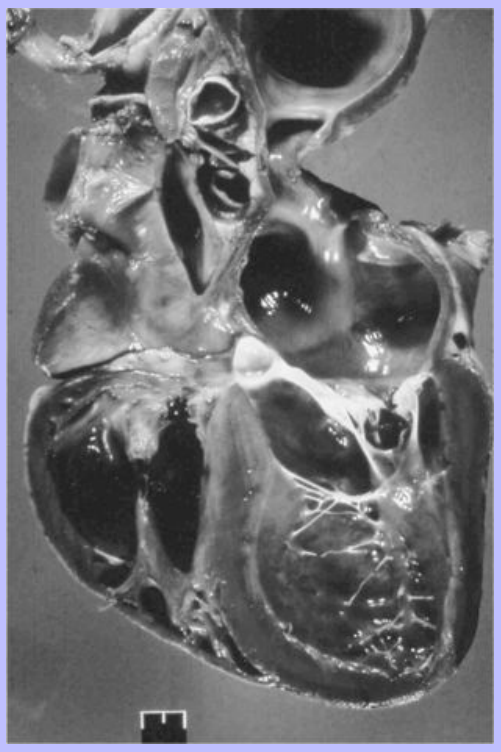
Kathryn M. Meurs

Canine myocardial disease is one of the most common forms of acquired heart disease in the dog.[1] The most common form of myocardial disease in the dog is dilated cardiomyopathy, but arrhythmogenic right ventricular cardiomyopathy, hypertrophic cardiomyopathy and myocarditis, among others, are also reported.

203.1 CANINE DILATED CARDIOMYOPATHY

Dilated cardiomyopathy (DCM) is a primary myocardial disease characterized by cardiac enlargement and impaired systolic function of one or both ventricles (Figure 203-1). Diastolic dysfunction may also be observed.[2] An increased understanding of the etiology of both the human and canine disease has lead to the development of the theory that DCM is the final result of a variety of myocardial insults including viral, nutritional, toxic, and genetic.[3] In human beings, the disease has been shown to be familial in almost 50% of the cases, caused by mutations in nine different genes.[4] The etiology in many cases is never determined and they are considered idiopathic.

Figure 203-1 Heart from a Doberman pinscher with dilated cardiomyopathy. The left ventricle and left atrium are grossly dilated. (Courtesy Bruce Keene.)



Although canine DCM is described as one disease, significant variation in the presenting complaint, clinical evaluation, and rate of progression has been observed depending on the breed of dog.[5–11]

Generally DCM is a disease of large and medium-sized dog breeds. Some breeds are clearly overrepresented, particularly in specific geographic regions. Surveys in North American publications find an increased incidence in the Doberman pinscher, Irish wolfhound, Great Dane, and Cocker spaniels.[12,13] European sources suggest an increased incidence of the Airedale terrier, Doberman pinscher, Newfoundland, and English cocker spaniel.[14] This difference may suggest an influence of environmental factors on the development of DCM, but more likely it is related to the strong genetic influences of certain popular dogs within an area.

203.1.1 Clinical Presentation

Dilated cardiomyopathy is an adult onset disease, with the exception of the Portuguese water dog.[11] The clinical presentation may be subtle and include the gradual development of exercise intolerance and weight loss.[15] However more commonly, early indications of disease may be overlooked. A diagnosis is not made until CHF develops and the patient is presented for coughing, dyspnea, tachypnea, and occasionally, ascites.

203.1.2 Physical Examination

A soft systolic murmur consistent with mitral valve regurgitation and/or a gallop rhythm (S_3) may be ausculted at the left apex. A tachyarrhythmia may be noted. In some cases, these may be the first signs of the disease in an otherwise healthy dog. Since primary valvular disease is relatively uncommon in large breed dogs, and the detection of DCM before the development of CHF may be beneficial in the long-term management of the case, identification of a new murmur, gallop or tachyarrhythmia in suspect breeds may warrant a thorough cardiac work-up. Although canine DCM is predominantly a left ventricular disease, biventricular involvement and heart failure with jugular venous distension and ascites is frequently noted, particularly in the giant breeds.

203.1.3 Electrocardiography

Left atrial and ventricular enlargement and sinus tachycardia, atrial fibrillation, or ventricular tachyarrhythmias are common.

203.1.4 Radiography

Left atrial and ventricular enlargement with or without pulmonary venous distension and pulmonary edema may be observed. In some cases, biatrial and biventricular enlargement may be noted. If the disease is diagnosed in the early stages, radiographic findings may be subtle.

203.1.5 Echocardiography

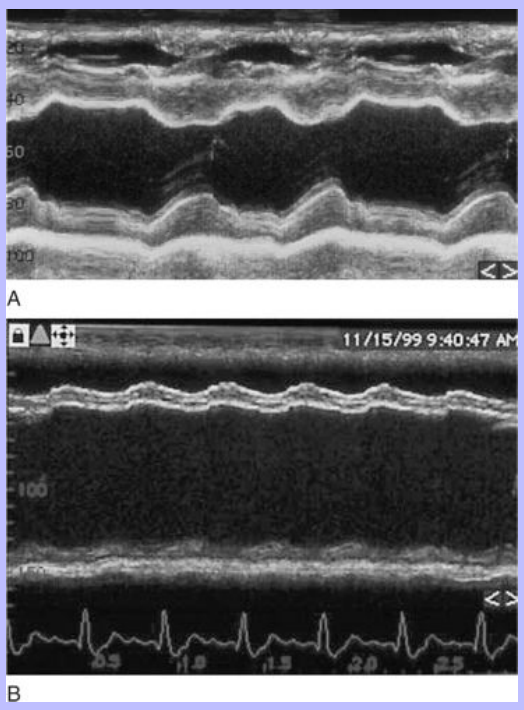
Echocardiography is the diagnostic test of choice for canine DCM and is also an important part of detection of occult disease. Echocardiographic findings in the symptomatic patient should include left and sometimes right atrial and ventricular dilation as quantified by M-mode and two-dimensional measurements (Figure 203-2). The measurements should be compared with the normal values for that particular breed or size (body surface

area) of dog. In some cases, the ventricular wall thickness may appear thin during diastole, but more often it is within normal limits. An important part of the diagnosis is usually concurrent left ventricular systolic dysfunction based upon decreased fractional shortening, ejection fraction, or shortening area and increased end-systolic volume.[16] Doppler echocardiography may be used to document a central jet of mitral regurgitation that may be associated with dilation of the ventricle.

A differential diagnosis for DCM is severe atrioventricular (AV) valve disease since severe ventricular dilation and systolic dysfunction may be observed. Consideration of the breed of dog may be helpful in differentiation between DCM and AV valve disease since it is uncommon for many of the large breed dogs to develop primary valve disease. An exception to this may be the Cocker spaniel, a breed that has a high incidence of primary valve disease and also is at increased risk of DCM.

Unfortunately, the diagnosis of the affected dog in the occult (asymptomatic) stage is much more difficult. In some cases, dilation of the ventricle precedes the development of systolic dysfunction and is an early indicator of DCM.[17] However, this is not always the case and systolic dysfunction may precede dilation. Annual two-dimensional and M-mode echocardiography is recommended for adult dogs of at risk breeds or if early signs (e.g., heart murmur, gallop, tachyarrhythmias) are detected. Suggested additional studies for additive information when evaluation of borderline cases include measurement of the mitral valve annulus motion, systolic time intervals, systolic and diastolic performance index, and stress echocardiography.[18–20]

Figure 203-2 **A,** M-mode echocardiogram from a normal dog with adequate contractility. **B,** M-mode echocardiogram from a Great Dane with a dilated left ventricle with a markedly decreased systolic function.



203.2 BREED VARIATIONS

There is an increasing amount of breed specific information about canine DCM. Because of differences the specific breed should be considered when considering etiology, developing treatment plans, and providing prognostic information.

Occasionally, atypical breeds of dogs develop DCM. The etiology of the disease in these cases is unknown.

203.2.1 Cocker Spaniels

Dilated cardiomyopathy has been reported in both American and English cocker spaniels; however, DCM occurs less commonly in this breed than valvular endocardiosis.[5,21,22]

An association between the development of DCM and low plasma taurine levels has been reported in some American cocker spaniels.[5] Dogs provided taurine and L-carnitine supplementation showed an increase in FS% and a decrease in LVEDD and LVESD over a 4-month period, although myocardial function did not return to normal.[23] This study suggests that at least some Cocker spaniels with DCM may benefit from supplementation with taurine and, perhaps L-carnitine. The current recommendations for American cocker spaniels with DCM are to measure plasma taurine levels (normal >50 ng/ml) and to treat with 500 mg of taurine orally every 12 hours and 1.0 gram of L-carnitine orally every 12 hours.[23] Additional treatment should be given as needed to address such conditions as CHF and arrhythmias. The investigators suggest that supportive cardiovascular medications can be gradually withdrawn after the FS% increases to more than 20% (usually 3 to 4 months of supplementation). Supplementation with taurine, and L-carnitine if possible, should be continued for life. If taurine deficiency is not identified the prognosis is poorer.

English cocker spaniels also get a form of DCM but a relationship to taurine or carnitine levels has not been well studied. Many reported dogs were from the same kennel, which may suggest a heritable component.[24,25] Profound evidence of left ventricular enlargement on the electrocardiogram with R wave amplitudes more than 3.0 mV in lead II was frequently observed.[22,26] Some of the reported dogs died suddenly, but many have had a prolonged, fairly asymptomatic course of disease, or a long survival (years) with medical management.[24–26]

203.2.2 Dalmatians

Male dogs appear to be over represented in Dalmatian DCM, although large studies have not been performed.[6] All dogs had adult onset disease and presented for signs consistent with left heart failure (cough, dyspnea) or syncope. None of the dogs had evidence of biventricular heart failure. Electrocardiography frequently demonstrated sinus rhythm or sinus tachycardia with occasional ventricular ectopy. Atrial fibrillation was not observed in any of the dogs. Duration of survival ranged from 1.5 to 30 months with euthanasia due to refractory CHF. None of the dogs died suddenly. Interestingly, the majority (8/9) of reported dogs had been fed a low protein diet for all or part of their lives for prevention or treatment of urate stones. The cause and effect of these diets on the development of DCM is not known, but Dalmatians that develop DCM that are being fed a low protein diet should be switched to a more balanced diet if possible.

Occasionally Dalmatians develop acquired AV valve disease, so this should be considered as an important differential diagnosis.

203.2.3 Doberman Pinschers

The Doberman pinscher is one of the most commonly reported breeds of dogs to be affected with DCM in North America.[7,13,27] It is characterized as an adult disease that results in the development of left and/or biventricular failure, often with atrial fibrillation. However, about 30% of the dogs develop ventricular tachyarrhythmias and may present for syncope or die of sudden death before the development of heart failure, and in some cases, before the development of ventricular dilation and systolic dysfunction.[28,29]

Dilated cardiomyopathy in this breed is believed to be familial, although the pattern of inheritance is not well documented.[30]

The clinical stage of DCM in the Doberman pinscher appears to be malignant in comparison to the disease in other breeds. The median survival time for dogs once heart failure has developed is 9.6 weeks. Atrial fibrillation and bilateral CHF are poor prognostic signs.[7] However, the occult stage appears to be slowly progressive (2 to 3 years), and some affected dogs die from noncardiac disease before they become symptomatic from DCM. Although there is only a small amount of evidence, there may be some benefit to early diagnosis and initiation of treatment in the occult stage (as discussed below).[31]

Some Doberman pinschers develop syncope or die suddenly before left ventricular dilation or systolic dysfunction ever develops. In most cases, these symptoms are associated with the presence of ventricular tachyarrhythmias. However, bradycardia-associated episodic weakness and syncope has also been observed in cardiomyopathic Doberman pinschers. Therefore Holter monitoring should be performed on the syncopal dog to document the causative arrhythmia before treatment is initiated.[32]

The timing and procedure for treatment of ventricular arrhythmias in the affected dog is not clear cut. Rapid ventricular tachycardia, complex ventricular arrhythmias, or the combination of ventricular arrhythmias, ventricular dilation, and systolic dysfunction is thought to be associated with a higher risk of sudden cardiac death and to be indications for treatment, but this has not been well documented. Additionally, some dogs die suddenly without having any of these arrhythmias documented. If treatment is warranted, consideration might be given to the use of one of several ventricular antiarrhythmics. Sotalol, a combination beta-blocker and potassium channel blocker, may be beneficial in some cases but should be used with caution if systolic dysfunction is present. Amiodarone has been studied in the affected Doberman pinscher at a dose of 10.0 mg/kg orally every 12 hours for 1 week, followed by 8.0 mg/kg every 24 hours.[28] After 6 months the dose may be reduced to 5.0 mg/kg every 24 hours. Careful evaluation of serum concentrations, complete blood counts (neutropenia has been reported), and liver enzymes monthly is suggested.[28] Although the goals of treatment include decreasing the number of VPCs, decreasing symptoms, and decreasing the risk of sudden death. The ability of any antiarrhythmic to reach these goals for these cases has not been proven.

Evidence that the disease is familial and that early intervention may increase survival has lead to significant interest in screening asymptomatic dogs for signs of early disease. Annual echocardiography and ambulatory electrocardiography (Holter monitoring) are believed to be the best predictors of early DCM.[33,34] Criteria that are believed to be indicators of occult disease include an echocardiographically determined LVEDD more than 4.6 cm and a LVESD more than 3.8 cm, even in the absence of systolic dysfunction.[17] These numbers are

based on average sized dogs and may not be valid for very large dogs. Annual Holter monitoring has also been recommended to detect Doberman pinschers that may develop ventricular arrhythmias before ventricular dilation and systolic dysfunction (Figure 203-3). Adult Doberman pinschers with greater than 50 ventricular premature complexes (VPCs) per 24 hours, or with couplets or triplets are suspect for the development of DCM.[34] Owners should be advised that since this is an adult onset disease with variability in the age of onset, screening tests should be performed annually.

Figure 203-3 Adult Doberman pinscher with a Holter monitor used for screening for occult disease.

203.2.4 Great Danes

Dilated cardiomyopathy in the Great Dane appears to be a familial disease.[8] Affected male dogs were overrepresented, which suggests an X-linked pattern of inheritance in at least some families. If this is true, sons of affected females are at high risk of developing the disease; daughters of affected fathers are likely to be silent carriers.

Affected Great Danes presented most commonly for weight loss and/or coughing. Left-sided heart murmurs, gallops, and ascites were frequently observed. The most common electrocardiographic findings included atrial fibrillation with occasional ventricular premature complexes. In some cases, atrial fibrillation may develop before any other evidence of underlying myocardial disease (chamber enlargement or systolic dysfunction). These dogs should be carefully followed for the possible development of DCM.

203.2.5 Irish Wolfhounds

Atrial fibrillation frequently preceded the development of a heart murmur, clinical signs, and CHF in the Irish wolfhound with DCM and was present in the majority of dogs by the time they developed DCM.[9,35] The progression of the disease is not well understood but appears to be slow, with the development of atrial fibrillation preceding the development of CHF by an average of 24 months.[9] Occasionally, additional

electrocardiographic abnormalities have been described, which include ventricular premature complexes and left anterior fascicular block patterns. Echocardiography is useful for separation of normal dogs, dogs with occult disease, and dogs with clinical evidence of heart failure.[36] Affected Irish wolfhounds occasionally died suddenly but more commonly were euthanized due to heart failure, most commonly biventricular and sometimes with chylothorax.[35,36]

203.2.6 Newfoundlands

Adult-onset DCM without a gender predisposition has been reported in the Newfoundland.[10,20] Clinical presentation included dyspnea, cough, inappetance, and ascites with left or biventricular heart failure. Interestingly a heart murmur was auscultable in a very small percentage of the dogs (4 out of 37).[10]

1079

1080

The most common electrical abnormality was atrial fibrillation, but isolated ventricular premature complexes were also observed.

203.2.7 Portuguese Water Dogs

A juvenile form of familial DCM has been reported in the Portuguese water dog.[11,15] Affected puppies were from apparently unaffected parents. Puppies died from CHF at an average age of 13 weeks after a very rapid course of disease.

203.2.8 Treatment of the Dog with Occult Dilated Cardiomyopathy

Administration of angiotensin converting enzyme (ACE) inhibitors may have some benefit for the dog with early ventricular dilation, with or without systolic dysfunction. Specifically, the use of ACE inhibitors (enalapril, lisinopril, captopril) in the Doberman pinscher with ventricular dilation was found to prolong the amount of time before the onset of CHF.[31] Although this study was limited to evaluation of Doberman pinschers, the use of ACE inhibitors for other breeds of dogs with occult DCM may be considered. This information provides additional support for the practice of screening adult dogs that are at increased risk of developing DCM because of their breed, and perhaps a family history, to allow early medical intervention.

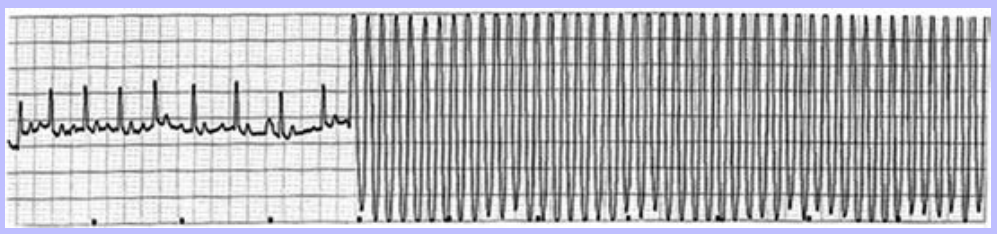
Administration of beta-blockers at this stage is still being evaluated. The addition of low-dose beta-blockers to the treatment of human patients with DCM and stable heart failure has demonstrated a reduction in both mortality and morbidity.[37] However, many human patients with DCM cannot tolerate even very low doses of beta-blockers and demonstrate rapid cardiac decompensation. The use of beta-blockers for the canine patient with DCM has not yet been well studied and a consensus opinion on use of these drugs for patients is not yet available.

Beta-blockers might be considered for the patient with occult disease, but they should be very carefully monitored and should not be given once there is evidence of fluid retention and heart failure until it is very well stabilized. The optimal beta-blocker for this purpose appears to be carvedilol because of its effects on both alpha and beta-receptors. It cannot be overemphasized that the addition of beta-blockers in canine DCM patients should be done very cautiously with gradual increases in dosing after a 2-week period and careful monitoring of heart rate, blood pressure, and symptomology.

203.2.9 Treatment of the Dog with Dilated Cardiomyopathy and CHF

There are no specific therapeutic recommendations for the treatment of DCM other than those mentioned above. Nonspecific treatments, including surgery and nutritional supplementation, have been reported but have not yet been shown to have significant long-term benefits for most dogs.[38–40] As discussed above, early diagnosis and intervention may be of the most benefit. A thorough discussion of treatment of the dog with CHF is provided elsewhere in this textbook.

Figure 203-4 An electrocardiogram from a syncopal Boxer with ARVC. Sinus rhythm with a sudden onset of ventricular tachycardia is present. (Courtesy Alan Spier.)



203.3 ARRHYTHMOGENIC RIGHT VENTRICULAR CARDIOMYOPATHY IN THE BOXER

Since the early 1980s, the term *boxer cardiomyopathy* has been used to describe adult boxer dogs that present with ventricular arrhythmias, and sometimes, syncope.[41] Recent studies have demonstrated that the disease has many similarities to a human disease called *arrhythmogenic right ventricular cardiomyopathy* (ARVC). The similarities between the diseases include clinical presentation, etiology, and a fairly unique histopathology that includes a fibrous fatty infiltrate of the right ventricular free wall.[42] The disease is most commonly characterized by ventricular arrhythmias, syncope, and sudden death. However, systolic dysfunction and ventricular dilation are seen in a small percentage of cases.

Arrhythmogenic right ventricular cardiomyopathy is a familial disease in the boxer and appears to be inherited as an autosomal dominant trait.[43] Unfortunately, the disease also appears to be a disease of variable genetic penetrance and affected dogs can have many different presentations including asymptomatic, syncope, sudden death, and systolic dysfunction with CHF.

The most common presenting complaint is syncope. Episodes of syncope may be but are not always associated with a period of exercise or excitement. Some dogs present for exercise intolerance or lethargy and others die suddenly without ever developing symptoms. Infrequently (approximately 10% of affected dogs), a dog may present with signs of left or biventricular heart failure.

Most affected Boxers have a completely normal physical examination. However, a tachyarrhythmia may be ausculted. In the small percentage of cases with ventricular dilation and systolic dysfunction, a systolic murmur and/or gallop (S_3) may be ausculted at the left apex. Infrequently, signs of right heart failure (ascites and jugular venous distension) may be observed. The Boxer breed also has a very high incidence of left basilar systolic murmurs. These murmurs may be associated with aortic stenosis, or potentially may be physiologic. Many

boxers with ARVC have these murmurs in addition to their arrhythmic disease, but left basilar systolic heart murmurs are not an indication of boxer ARVC.

A 2-to 5-minute electrocardiogram is frequently normal in the affected Boxer. However, ventricular premature complexes (VPCs) may be present singly, in pairs, and in runs of paroxysmal ventricular tachycardia (Figure 203-4). The VPCs typically have a left bundle branch block morphology in leads I, II, III, and AVF, consistent with the right ventricular origin of this arrhythmia.[44] In some cases, the ventricular arrhythmias that cause syncope may not be observed on the electrocardiogram and a 24-hour Holter monitor should be performed to evaluate for arrhythmias. Interpretation of the Holter results can sometimes be challenging because strict criteria for this diagnosis do not exist. However, since it is unusual for a normal dog to have any VPCs in a 24-hour period, the observation of more than 100 VPCs, or periods of couplets, triplets, or runs of ventricular tachycardia 1080 are abnormal and may be diagnostic in a dog with clinical signs.[45] Supraventricular premature 1081 complexes may also be observed, particularly in boxers with ventricular dilation and systolic dysfunction.

Thoracic radiographs are usually within normal limits. However, in the small number of cases with left ventricular dilation and systolic dysfunction, generalized cardiomegaly with pulmonary edema and/or pleural effusion may be noted.

Echocardiography is an important part of the evaluation because ventricular dilation and systolic dysfunction may occur, but in most cases affected dogs have normal chamber sizes and systolic function. In some cases, careful evaluation will allow the identification of right ventricular enlargement.

The familial etiology of ARVC has led to a widespread interest in screening dogs before selection of them as breeding animals. Since ARVC presents as an electrical abnormality more often than one of myocardial dysfunction, screening efforts should be based on annual Holter monitoring as well as annual echocardiography. Unfortunately, clear criteria for the diagnosis of occult ARVC do not exist. However, dogs that are symptomatic (syncope, heart failure) or have evidence of ventricular tachycardia on a Holter should not be used for breeding. Additionally, dogs that have over 100 left bundle branch block morphology VPCs in 24 hours are probably highly suspicious of being affected. However, not all affected dogs will ever develop clinical signs and many may live a normal lifespan.

It is likely that there are multiple factors that may influence which dogs become symptomatic for the disease. To help decrease the risk of making an error when adding or removing a dog from a breeding program, owners should be encouraged to screen annually rather than putting significant emphasis on a single Holter monitor reading. Since the disease is adult onset and an increase in VPCs has been observed with age in affected animals, an animal that is clear at the age of 2 is not guaranteed to stay clear. Additionally, an animal with a few hundred VPCs at the age of 2 years may have more, less, or the same number the next year. Until a greater understanding of disease inheritance and disease progression exists, caution should be used when advising breeders to remove dogs from breeding programs. Overzealous removal of animals based on the results of a single Holter monitor may have a significant negative impact on the breed.

At this time, there is no evidence that treatment will significantly alter the outcome for affected dogs. However, treatment has been shown to decrease the number of syncopal episodes.[46]

If an arrhythmia is detected on routine examination in an asymptomatic dog a Holter monitor should be performed to evaluate for the frequency and complexity of the arrhythmia. Although a strict relationship between the development of symptoms and the number of VPCs does not exist, treatment is generally started if more than 1000 VPCs occur in 24 hours, runs of ventricular tachycardia occur, or evidence of the R on T phenomenon

exist. Owners should be advised that ventricular antiarrhythmics have the potential for proarrhythmic effects and that treatment is not known to decrease risk of sudden death.

Dogs with syncope and ventricular arrhythmias are generally started on treatment. There are two choices for treatment that are well tolerated and have been shown to decrease VPC number and complexity: sotalol at a dose of 1.5 to 3.5 mg/kg, every 12 hours, orally or the combination of mexiletine at a dose of 5 to 8 mg/kg, every 8 hours, orally and atenolol at a dose of 12.5 mg/DOG, every 12 hours, orally.[46] It is likely that there is individual variation for drug response and if a poor response is observed with one drug, a different one may prove to more effective. Ideally, a Holter monitor would be placed before starting therapy and repeated 2 to 3 weeks after starting therapy to prove that the therapy is helping. Significant day-to-day variation in VPC number exists and a therapeutic effect is likely to exist if at least an 85% reduction in VPC number while on medication is observed.[47]

If echocardiography demonstrates systolic dysfunction and ventricular dilation treatment for DCM (ACE inhibitors, etc.) may be warranted. Additionally, supplementation with L-carnitine might be considered at a dose of 50 mg/kg, every 8 to 12 hours, orally since a small number of affected Boxers have demonstrated improvement in systolic function and prognosis after supplementation.[48]

Dogs with ARVC are always at risk of developing sudden death. However, many dogs may live for years on antiarrhythmics without symptoms, some of these may eventually develop ventricular dilation and systolic dysfunction.

203.4 MYOCARDITIS

Myocarditis is defined by the presence of myocardial necrosis or degeneration and inflammation.[49] A variety of physical, chemical, and infectious agents can damage the myocardial tissue and evoke an inflammatory response. In the dog, protozoal and viral organisms are reported most commonly.

Chagas' disease, caused by the protozoan parasite *Trypanosoma cruzi*, has been reported in the dog, particularly in the southern part of North America. Three stages of infection have been described: acute, latent, and chronic. The acute stage is characterized by lethargy, generalized lymphadenopathy, pale mucous membranes, increased capillary refill time, and hepato-splenomegaly.[50] This stage is associated with a variety of electrocardiographic (ECG) abnormalities, including sinus tachycardia, prolonged PR interval, decreased R wave amplitude, axis shifts, and conduction disturbances.[51] Sudden death may be observed. Dogs that survive the acute stage may enter a prolonged latent period during which the clinical signs appear to regress.[50] The chronic stage of Chagas' disease is associated with signs of progressive right-sided cardiac dysfunction, ascites, pleural effusion, hepatomegaly, and jugular venous distention.[50] Occasional ventricular tachycardias have been reported.[51] Diagnosis is most commonly performed by serology, although the acute form can sometimes be diagnosed by the presence of circulating trypomastigotes on thick blood smears. In general, treatment of Chagas disease is directed at palliation since destruction of the intracellular form of the parasite may result in severe exacerbation of the host inflammatory response.

Additional protozoan parasites that have been associated with the development of myocarditis include *Neopsora caninum* and *Toxoplasmosis gondii*.[52,53]

Parvovirus myocarditis is an uncommon form of myocardial disease. It may present with a peracute form that affects puppies between 3 and 8 weeks of age. Puppies present with acute dyspnea consistent with severe left heart failure and die within hours.[54] At necropsy, the hearts are found to be dilated with multifocal myofiber

necrosis, mononuclear cell infiltrate, and intranuclear inclusion bodies in the myocardial nuclei.[54,55] A second form of the disease in juvenile dogs (generally less than 1 year of age) may be very similar to DCM.[54,56]

Infrequently, infectious organisms including bacteria *Bacillus piliformis, Citrobacter koseri,* and the spirochete *Borrelia burgdorferi* have been associated with the development of myocarditis.[57,58]

203.5 HYPERTROPHIC CARDIOMYOPATHY

Hypertrophic cardiomyopathy is a primary myocardial disease characterized by concentric hypertrophy of the IVS and LV free wall. Hypertrophic cardiomyopathy (HCM) and the variant hypertrophic obstructive cardiomyopathy (HOCM) are infrequent forms of canine myocardial disease. There appear to be significant differences between the canine disease and the disease more commonly observed in cats and human beings with regard to etiology and pathologic findings.[59,60] An inheritable form of hypertrophic obstructive cardiomyopathy has been observed in the Pointer dog, but most canine cases appear to be sporadic.[59–62] Because of the relative infrequency that hypertrophic and hypertrophic obstructive cardiomyopathy is observed in the dog, suspect patients should be carefully evaluated for other reasons that might result in concentric hypertrophy of the LV, including the much more common left ventricular outflow tract obstruction observed with subvalvular and valvular aortic stenosis.

1081 1082

203.6 HYPOTHYROIDISM

Some dogs with hypothyroidism have been observed to have a reduction in fractional shortening % and an increase in LVESD; however, the values had significant overlap with normal dogs.[63] Thus, although evaluation of thyroid levels might be considered in dogs that have minor echocardiographic changes in addition to other signs of hypothyroidism, it should not be considered a common cause of myocardial dysfunction nor ventricular dilation.[64]

203.7 MYOCARDIAL INFARCTION

Acute myocardial infarctions are an uncommon form of myocardial disease and appear to be most commonly associated with concurrent systemic or cardiac disease that has lead to a thromboembolic state. These conditions might include endocarditis, neoplasia, renal disease, immune mediated hemolytic anemia, and pancreatic disease. Dogs with infarcts were very rarely diagnosed with atherosclerosis as opposed to human beings who have a high incidence of infarcts associated with atherosclerosis.[65]

204 CHAPTER • 204 Feline Myocardial Disease

Mark D. Kittleson

204.1 CLASSIFICATION

Primary myocardial diseases are generally classified under the general heading of cardiomyopathy. *Primary* indicates the myocardial disease is not secondary to valvular disease, pericardial disease coronary vascular disease, systemic or pulmonary hypertension, congenital abnormalities other than those of the myocardium itself, and myocardial changes due to systemic disease such as hyperthyroidism. The World Health Organization (WHO) has categorized the types of cardiomyopathies and based the categorization scheme primarily on the dominant pathophysiology produced by the myocardial disease.[1] Historically, cardiomyopathy was defined as a myocardial disease of unknown cause, whereas a myocardial disease with a known cause was given a specific name. Over the past 15 years the causes of many of the idiopathic myocardial diseases have been identified in human medicine. Consequently, many of the classic “idiopathic” cardiomyopathies now include groups of patients with a known cause and other groups of patients without a known cause—blurring all lines between idiopathic and specific myocardial diseases. However, the original names of the diseases persist and are useful because they still describe the dominant pathophysiologic process produced by the abnormality in the myocardium.

Cardiomyopathies are the dominant form of cardiac disease in domestic cats. Because there has been only one cause identified for a feline cardiomyopathy (i.e., taurine deficiency in dilated cardiomyopathy [DCM]), no pressure exists to rename the cardiomyopathies from a causative standpoint. Although the WHO classification of cardiomyopathies includes identification of cardiac dysfunction in the definition, this portion of the definition is certainly outdated in human medicine because many patients are now identified as having genetic mutations that produce abnormalities in the myocardium that are not severe enough or are too early to cause cardiac dysfunction.

Therefore feline cardiomyopathy is still defined simply as a primary disease of the myocardium. Cardiomyopathies are classified as (1) DCM, (2) hypertrophic cardiomyopathy (HCM), (3) restrictive cardiomyopathy (RCM), (4) arrhythmogenic right ventricular cardiomyopathy (ARVC) (dysplasia), (5) unclassified cardiomyopathy, and (6) specific cardiomyopathies. Myocarditis is commonly placed in the specific category, although it is also frequently classified separately. In general this classification scheme works reasonably well for cats, and all categories have been identified in cats. However, in individual cats it may be difficult or impossible to comfortably place a cat's myocardial disease into one of these categories. In addition, because cardiomyopathies are so prevalent in cats, it is common for other forms of cardiac disease to be misidentified as one of the forms of cardiomyopathy. For example, mitral valve degeneration is uncommon in cats, and when it is present the cardiac changes are frequently thought to be due to some form of cardiomyopathy.

Is categorization important? In some cases it is extremely important, whereas in other situations the importance is more academic than it is practical. For example, correctly identifying DCM in a cat is essential because DCM may be caused by taurine deficiency, and this form of DCM can be cured using taurine supplementation. HCM is inherited in some cat breeds. Correctly identifying this form of cardiomyopathy is often important to breeding programs.

204.2 DILATED CARDIOMYOPATHY

Myocardial contractility and myocardial contraction are not the same. *Myocardial contractility* is the inherent capability of the myocardium to contract without any forces acting on it. *Myocardial contraction* is how much the myocardium moves and thickens from end-diastole to end-systole (the amount of wall motion and thickening usually observed on an echocardiogram) and is determined by myocardial contractility, preload, afterload, and other variables. It is commonly calculated as the shortening fraction. *Myocardial failure* is defined as a decrease in myocardial contractility and is most commonly manifested as an increase in end-systolic diameter on an echocardiogram. DCM is the name given to diseases in which myocardial failure is present due to primary myocardial disease. Myocardial failure can occur secondary to nonprimary myocardial disease processes.

DCM is characterized on echocardiography by a primary increase in left ventricular (LV) end-systolic diameter and volume (and usually by a compensatory increase in LV end-diastolic diameter and volume). Because end-diastolic diameter and volume do not need to increase as much as end-systolic diameter and volume to maintain a normal stroke volume, shortening fraction (one measure of the amount of wall motion) decreases.

Although most of the cats that are diagnosed with DCM have clinical signs, the diagnosis of DCM may be made in the absence of heart failure, arrhythmia, or sudden death. DCM has a long subclinical phase during which myocardial function, along with cardiac compensatory mechanisms, are adequate to maintain normal hemodynamics.[2] This phase of the disease, during which echocardiographic or electrocardiographic evidence (or both) of the disease is present but clinical signs of the disease are not present, is often termed *occult* in the literature. A patient with DCM may spend most of its life in a subclinical phase and only a short time during which it has clinical signs.

204.2.1 Incidence

Because of the discovery of taurine deficiency as the major cause of feline DCM and the subsequent increase in taurine content in all cat foods, the current incidence of DCM is rare.[3,4] From 1993 to 2003, only 24 cases of feline DCM were diagnosed at the University of California, Davis Veterinary Medical Teaching Hospital (UCD-VMTH). Eight had DCM due to taurine deficiency, whereas 13 were idiopathic. The other three died before a plasma sample could be obtained.

204.2.2 Cause

Taurine deficiency was identified as the primary cause of DCM in cats in 1986 to 1987.[3] Taurine is a sulfur-containing amino acid. One of its functions is to conjugate bile acids.[5] Although some species can also conjugate bile acids with glycine, cats lack this ability and therefore have an obligate loss of taurine through the bile. In addition, they have very limited ability to synthesize taurine in the liver because of the lack of key enzymes. Taurine's definitive role in cellular function is not known, but it is concentrated in the cytoplasm of excitable cells up to 250 times that in plasma.[6] In the heart, taurine has been postulated to help modulate intracellular osmolality, calcium concentration, and transmembrane ion fluxes.[7]

The cause of taurine deficiency in cats is primarily nutritional, although a genetic factor may also be involved.[8] Prior to 1987, dry cat foods contained too little taurine, whereas the taurine in canned foods was not biologically available in adequate amounts, probably because of bacterial overgrowth in the intestinal tract.[9]

Feline DCM due to taurine deficiency has not totally disappeared. It can still occur with the exclusive feeding of one canned food diet. More frequently, taurine deficiency is caused by feeding the cat a home-cooked diet, most commonly one including chicken. One study has documented that cooking meat reduces the taurine content, especially when the meat is constantly surrounded by water during the cooking process.[10] The classic method of producing taurine deficiency is to feed dog food to a cat. Because no taurine is found in vegetables, vegetarian diets also produce taurine deficiency.

Idiopathic feline DCM is now the predominant form of DCM seen in cats. In humans, it is estimated that 30% to 40% of DCM is hereditary, and numerous mutations in a relatively large number of genes have now been identified as causing DCM in people (these include mutations in the genes that encode for cardiac dystrophin, δ-sarcoglycan, actin, α-tropomyosin, β-myosin heavy chain, troponin T, titin, adhalin, lamin A/C, tafazzin, and emerin).[11] It is likely that some cats with idiopathic DCM have a mutational cause for their disease, either because they inherited a mutation from a parent or because they developed a de novo mutation in utero. The latter may be more likely because no cat breeds are known to have feline DCM as a problem.

204.2.3 Pathophysiology

DCM is caused by a myocardial disease that results in a progressive decrease in myocardial contractility, either because of global myocyte dysfunction or because of myocyte death (necrosis or apoptosis). Contractility is mildly decreased initially, which may progress over months to years to a severe decrease in contractility.[12] The decrease in contractility results in an increase in end-systolic diameter and end-systolic volume, which results in a decrease in stroke volume. Chronically the heart compensates for this decreased function by growing larger ventricular chambers through eccentric (volume overload) hypertrophy. This growth is also commonly referred to as *ventricular remodeling* and occurs primarily due to renal sodium and water retention leading to an increase in blood volume that leads to an increase in venous return to the heart. This places stretch on the myocardium that stimulates the myocytes to grow longer and the chambers to grow larger (increased end-diastolic diameter and end-diastolic volume). The increased chamber size allows stroke volume to return to normal when the disease is mild to moderate. At some stage the myocardial failure becomes so severe that the ability of the cardiovascular system to compensate for the disease is overwhelmed. At this stage, LV end-diastolic pressure increases as renal sodium and water retention continues to increase blood volume, resulting in congestive heart failure (CHF).

Myocardial diseases that cause DCM may also cause concurrent diastolic dysfunction, primarily reduced ventricular compliance. A stiffer or less compliant LV results in a higher diastolic pressure for any given diastolic volume, causing pulmonary edema, pleural effusion, or both. Decreased LV compliance has not been documented in cats with DCM but has been in dogs.[13]

Secondary mitral regurgitation is commonly present in DCM. In DCM the atrioventricular (AV) annulus dilates as the LV enlarges, and the papillary muscles are displaced laterally and apically as the ventricular chamber enlarges.[14–16] Both result in the leaflets failing to close completely during systole (incomplete valve closure). The regurgitation is usually mild, however, and so its contribution to the production of heart failure is probably minimal.

204.2.4 Pathology

In cats with severe DCM, the most striking gross pathologic finding is moderate to marked enlargement of all four cardiac chambers. Often the left heart appears more affected. The walls of the LV may appear thin but when measured may be normal or thin. The papillary muscles often appear flattened. Heart weight is greater than normal, indicating the presence of hypertrophy.[17] On cut-section, the LV myocardium often appears remarkably normal, especially in cats with DCM due to taurine deficiency. In other cases, pale regions may be noted. In DCM due to taurine deficiency, histologic findings primarily reveal hypertrophy. In cats with idiopathic DCM, histologically there may be evidence of myocytolysis, myofibril fragmentation, abnormal mitochondria, vacuolization, and fibrosis.

204.2.5 Natural History and Prognosis

Only about 30% of cats that are taurine deficient develop echocardiographic evidence of myocardial failure.[18] 1083
Of the cats with myocardial failure, about 30% develop severe myocardial failure (shortening fraction < 20%). 1084
Some cats have severe myocardial failure for months to years prior to heart failure, yet many cats appear to develop heart failure suddenly.

The short-term prognosis for survival in cats with DCM due to taurine deficiency is guarded. They usually have severe CHF (often with low-output heart failure) and require intensive therapy. Taurine supplementation does not help clinically during this phase. Almost all cats that live longer than 2 to 3 weeks survive. Within 2 to 4 weeks they appear to improve clinically, although no apparent change occurs echocardiographically. Their myocardial function then normalizes over the ensuing 3 to 5 months. Consequently, their long-term prognosis is excellent. In cats with DCM that is not due to taurine deficiency, the long-term prognosis is usually grave (the median survival time [MST] is 2 weeks).[19]

204.2.6 Clinical Manifestations

204.2.6.1 History

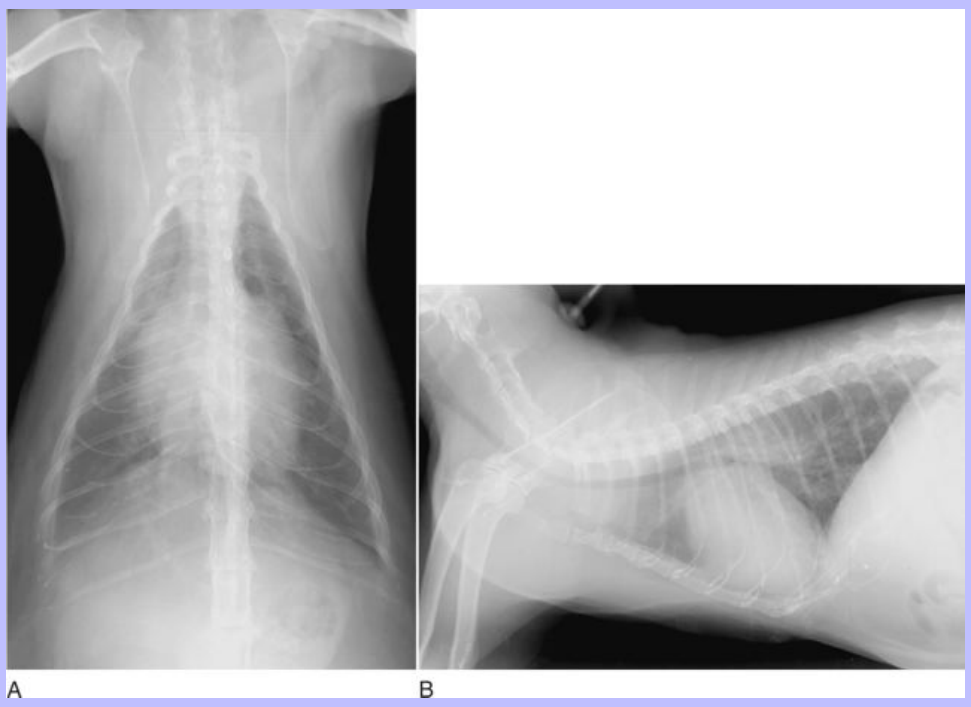
Because cats are relatively sedentary, they often hide the signs of their disease until they are in severe distress. Cats most commonly present in acute respiratory distress from pulmonary edema, pleural effusion, or both. Some cats will cough. This is frequently thought to be vomiting by the owner because vomiting and coughing in cats appear very similar. Distinguishing the two may be possible in the exam room by palpating the trachea vigorously enough to produce a cough while the owners witness the event. A thorough diet history should be obtained on any cat with DCM.

204.2.6.2 Physical Examination

Many cats are tachypneic and dyspneic upon presentation. They may also be lethargic, dehydrated, or hypothermic (or a combination of these symptoms). Auscultation often reveals a soft to moderately loud systolic heart murmur (usually heard best over the sternum, just medial to the left apex beat). A gallop sound may also be heard if the disease is severe. Most cats with DCM have an elevated heart rate so that atrial systole occurs immediately after rapid ventricular filling, making it impossible to distinguish a third from a fourth heart sound. Auscultation of the lungs is often normal except for increased airway sounds due

to hyperpnea. If pleural effusion is present, lung sounds may be absent ventrally when the cat is upright. The ears and feet are commonly cold because of intense peripheral vasoconstriction.

Figure 204-1 **A,** Dorsoventral (DV) radiograph from a cat with dilated cardiomyopathy (DCM) due to taurine deficiency. The cardiac silhouette is grossly enlarged. **B,** Lateral radiograph from the same cat. The cardiac silhouette again is grossly enlarged and pulmonary edema is present.



The retinas should be examined in all cats suspected of having feline DCM for the presence of feline central retinal degeneration (FCRD). If it is present the cat is most likely taurine deficient. However, many cats with taurine deficiency do not have FCRD.[20]

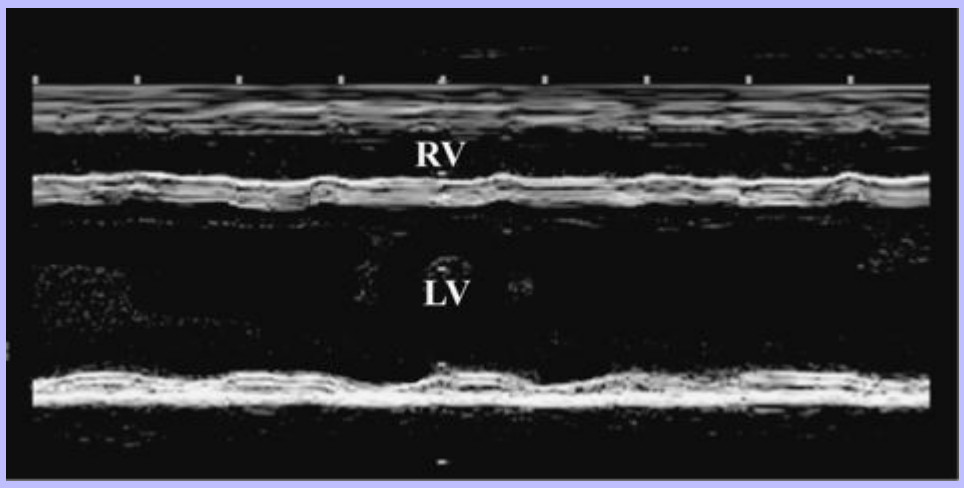
If the cat is severely dyspneic, pleurocentesis using a butterfly catheter should be part of the examination process to determine if pleural effusion is the cause of the dyspnea. If pleural effusion is the cause, one should be able to remove 150 to 250 mL of fluid from the pleural space.

204.2.6.3 Radiography

Radiographs cannot be used to distinguish feline DCM from other forms of feline cardiomyopathy. They should primarily be used initially to determine if a dyspneic cat is in heart failure (cardiomegaly plus pleural effusion, pulmonary edema, or both). Radiographs should not be attempted in a severely dyspneic cat if the process is stressful to the cat because this will often result in death. In cases of severe feline DCM, the cardiac silhouette is markedly enlarged, often especially in the area of the left auricle on the

dorsoventral (DV) or ventrodorsal (VD) view (Figure 204-1). Left atrial enlargement generally cannot be appreciated on the lateral view. If pleural effusion is present, it often becomes impossible to identify pulmonary edema. Pulmonary edema in cats can be caudodorsal in distribution (as in the dog) but is more commonly patchy, is often more ventrally distributed, and may involve the accessory lung lobe.

Figure 204-2 M-mode echocardiogram from a cat with severe dilated cardiomyopathy (DCM). The motion of the interventricular septum (IVS) (between the right ventricle [*RV*] and left ventricle [*LV*]) and the left ventricular free wall (below the LV chamber) are markedly reduced.



204.2.6.4 Echocardiography

Echocardiography is the diagnostic test of choice for identifying DCM. The striking feature of severe DCM is the remarkable lack of LV wall motion (Figure 204-2). The end-systolic diameter is increased to a value over 10 mm (usually over 12 mm and often in the 15 to 20 mm range when severe), whereas the end-diastolic diameter is also increased but to a lesser degree (usually in the 18 to 23 mm range). In cats with severe DCM, the shortening fraction is commonly less than 20%. Both the left ventricular free wall and the interventricular septal motion are reduced, although one may be more reduced than the other. Neither wall is hyperdynamic. Cats that have severely reduced free wall motion and a hyperdynamic interventricular septum (IVS) most commonly have primary mitral valve degeneration or dysplasia rather than DCM. Rarely a cat will have one region of the LV myocardium that is hypokinetic, akinetic, or even dyskinetic and may also be thinner than the rest of the myocardium. Although this may be due to a primary regional myocardial disease, it may also be due to a thrombus or a thromboembolus that has produced an infarct in that region. This pattern of motion may or may not be categorized as DCM, depending on one's viewpoint.

Color flow Doppler echocardiography often reveals the presence of mild mitral regurgitation. Spontaneous echo contrast due to red cell aggregation may be present, especially in the left atrium.

204.2.6.5 Electrocardiography

Electrocardiography Electrocardiography rarely reveals clinically significant information unless an arrhythmia is ausculted. Abnormalities in QRS morphology and an axis deviation may be noted but are nonspecific findings.

204.2.6.6 Clinical Pathology

Any cat with DCM should have a plasma and whole blood taurine concentration measured. The sample must be anticoagulated with heparin, placed on ice, and a portion centrifuged within 15 minutes. Platelets contain a large concentration of taurine, which is released upon platelet activation during the clotting process, so any thrombotic activity in the tube will result in a falsely high plasma taurine concentration. Taurine will also leach out of platelets and white cells into plasma if the sample is left standing, especially at room temperature. Taurine is a very stable compound, but plasma and whole blood samples should generally be frozen to prevent bacterial growth because bacteria will destroy taurine. Normal cats have a plasma taurine concentration greater than 60 nmol and mL and a whole blood taurine concentration greater than 250 nmol/mL. Most, but not all, cats with DCM due to taurine deficiency have a plasma taurine concentration less than 20 nmol/mL and a whole blood taurine concentration less than 100 nmol/mL. Fasting can lower the plasma taurine concentration in cats. Fasting does not alter whole blood taurine concentration.[21] Thromboembolism of skeletal muscle will cause skeletal muscle necrosis and the release of taurine into the circulation, causing a false elevation in a cat that is taurine deficient.

Prerenal azotemia due to low cardiac output is common in cats with severe DCM, cats with dehydration, cats that are not eating or drinking, or cats receiving a high dose of a diuretic. If the azotemia is mild to moderate and the cat feels good enough to eat and drink, the azotemia can safely be ignored. If the azotemia is severe, diuretic therapy must be discontinued and judicious fluid therapy administered. Electrolyte abnormalities occur more frequently in cats on diuretic therapy than in dogs, probably because cats tend to become anorexic more easily when they are dehydrated. Electrolyte levels below the reference range for a laboratory do not mean that this decrease is clinically significant.

204.2.7 Differential Diagnoses

Rarely HCM will progress to severe myocardial failure. Some cases of regional myocardial failure appear to be due to myocardial infarction.[22] Myocardial failure can occur secondary to chronic, severe volume overload, such as primary mitral regurgitation. Sustained tachycardia can also produce myocardial failure, although the rate to produce this phenomenon is not known in cats.

Cats with DCM commonly have pleural effusion. This effusion may be a modified transudate, pseudochylous, or chylous and may change from a modified transudate to a chylous effusion over time. Heart failure is the most common cause of chylous pleural effusion in cats.

204.2.8 Acute Therapy

204.2.8.1 Treatment Goals

The treatment goals depend on the type and severity of the clinical signs. If severely dyspneic the initial goal is to make it easier for the cat to breathe by removing pleural effusion, by reducing pulmonary edema pharmacologically, or by administering oxygen. If the primary problem is a marked reduction in perfusion leading to hypothermia, the goal is to increase cardiac output, if possible, via the administration of an intravenous positive inotropic agent, such as dobutamine, and possibly the judicious use of intravenous fluid administration, especially if the cat is severely dehydrated.

1085

1086

204.2.8.2 Pleurocentesis

Pleurocentesis is often life saving in the severely dyspneic cat that has a large amount of pleural effusion. Thoracocentesis is described in Chapter 103.

204.2.8.3 Diuretic Therapy

Diuretic administration is the only reliable way to reduce pulmonary edema formation in a cat with severe DCM. Furosemide is used almost exclusively. The dose depends on the severity of the pulmonary edema, on whether the cat is currently on furosemide for heart failure, and whether the situation is acute or chronic. Cats in severe respiratory distress may need an initial dose as high as 2 mg/lb parenterally. Intravenous administration is preferred, but the drug should be administered intramuscularly if restraint for intravenous administration produces stress. Absorption half-life after intramuscular administration is around 5 minutes, so the entire dose is fully absorbed within 20 to 25 minutes. The duration of effect of furosemide after parenteral administration is probably 1 to 2 hours in a cat in heart failure. Consequently, another dose should be administered within that period if the cat is still in respiratory distress and is not severely dehydrated. A cat with a lesser amount of pulmonary edema and less respiratory distress needs a smaller dose of furosemide parenterally in the acute setting. Respiratory rate and character should be monitored carefully after diuretic administration with the cat in an oxygen-enriched environment.

204.2.8.4 Oxygen

Increasing the percent concentration of oxygen delivered to the alveoli is critical in cats in respiratory distress. This can be accomplished using a face mask, standard oxygen cage, a pediatric incubator, or nasal insufflation. Generally the goal is to increase fraction of inspired oxygen (FIO_2) to at least 40% (normal is 21%). If the cat resists a face mask, it should not be used. When placed in a confined space, especially a small space like an incubator, it is mandatory to keep the environmental temperature and the carbon dioxide concentration within reasonable levels. Failure to do so can cause death. A canister containing sodium lime or barium hydroxide lime controls carbon dioxide level in an oxygen cage, and a refrigeration unit controls temperature. Carbon dioxide concentration is usually controlled in an incubator by maximizing the flow rate of oxygen (and therefore flushing out the carbon dioxide).

204.2.8.5 Inotropic Support

Beta-adrenergic agonists, usually dobutamine or dopamine, can be used for acute inotropic support in a cat with severe DCM and severe heart failure. However, conscious cats have more side effects with these drugs than do dogs. They often appear agitated and may even seizure. The half-life of these drugs is around 1 minute, so stopping the drug infusion results in rapid cessation of adverse effects. The infusion rate for dobutamine and dopamine in a cat is less than that used in a dog and is generally in the range of 1 to 2.5 µg/lb/min.

204.2.8.6 Nitroprusside

Nitroprusside is a potent dilator (i.e., smooth muscle relaxant) of systemic arterioles and systemic veins. It can only be used in cats with DCM that are not in cardiogenic shock (systolic systemic arterial blood pressure over 100 mm Hg). If systemic pressure is adequate, the drug can be used in one of two ways: (1) empirically at a dose of 2 µg/lb/min or (2) titrated using blood pressure starting at a dose of 1 µg/lb/min and increased until the systolic pressure has decreased by at least 10 to 15 mm Hg. (See Systolic Blood Pressure Monitoring and Techniques in Chapter 128.)[23]

204.2.8.7 General Supportive Measures

Although dogs commonly start to drink water and eat once they are no longer in respiratory distress, cats may not. Dehydration is a common side effect of aggressive diuretic therapy, and some cats are dehydrated at presentation. Generally cats do better if they are sent home as soon as possible. However, if hospitalization is required after the edema and effusion are controlled, judicious use of fluid therapy may be needed. Electrolyte disturbances, most commonly hyponatremia, hypokalemia, and hypochloremia, are also more frequent in cats than in dogs in this acute setting. Consequently, serum electrolyte concentrations should be monitored.

204.2.9 Chronic Therapy

204.2.9.1 Diuretic Therapy

Diuretics are the only drugs that can routinely control the clinical signs referable to congestion and edema due to heart failure. Consequently, it is mandatory for cats with CHF to be on a diuretic, usually furosemide. The chronic orally administered dose for furosemide in cats is wide and ranges from 0.5 mg/lb a day to 2 mg/lb every 8 hours. The most common doses are 6.25 to 12.5 mg per cat every 8 to 12 hours, orally. In general, cats need a lower dose of furosemide when compared with dogs, although the upper end of the dose range can be similar. The goal of diuretic therapy is to keep pulmonary edema and pleural effusion controlled. This should be done with the lowest possible furosemide dose, although in the author's experience, underdosing appears to be a more frequent problem than does overdosing. Every owner should be instructed to count his or her cat's respiratory rate at home when the cat is sleeping or resting quietly in a cool environment and to keep a written log. The normal respiratory rate for a cat is in the 20 to 40 breaths per minute range. If the rate is greater than 40 breaths per minute or the owner notes that the character of breathing is more labored, these are signals that an increased dose of furosemide, pleurocentesis, or both are needed. Changes in furosemide dose should be done in consultation with a veterinarian during the initial stages of management. Some owners will require continued contact with a veterinarian to manage dose

changes, whereas others will reach a point where they feel comfortable doing this on their own. Cats with severe disease that require a maximum dose of furosemide are often mildly to moderately dehydrated and mildly to moderately azotemic. As long as they continue to eat, drink, and appear comfortable, the dose of furosemide should not be decreased. If the dehydration or azotemia becomes severe enough to cause anorexia, the furosemide administration must be discontinued as long as the cat is not taking in fluid. Owners must be warned that continued use of high-dose furosemide administration in a cat that is not drinking or eating can result in severe, life-threatening dehydration. Judicious use of parenteral fluid administration may be required. These, of course, are poor prognostic signs. Cats that are refractory to the maximum dose of furosemide may need to have another diuretic administered along with the same maximum dose of furosemide. Choices include a thiazide diuretic and possibly spironolactone. (See Therapy in Chapter 199.) Parenteral administration of furosemide may also be beneficial because the oral bioavailability of the drug is only around 50%.

204.2.9.2 Pleurocentesis

Repeated pleurocentesis is often required in cats with pleural effusion. Pleurocentesis may need to be done as infrequently as once a month or as frequently as every 4 or 5 days. As much fluid as possible should be removed at each visit. Ultrasound guidance often helps identify regions where fluid has pocketed. Chylothorax secondary to heart failure can result in chylofibrosis, making it very difficult to remove as much fluid as one would like. Risks of repeated pleurocentesis include infection, pneumothorax, and bleeding, but all are rare.

204.2.9.3 Angiotensin-Converting Enzyme Inhibitors

1086

1087

Any cat with idiopathic DCM should be on an angiotensin-converting enzyme (ACE) inhibitor for long-term management unless they have an adverse reaction to the drug. Enalapril is most commonly used at a dose of 1.25 to 2.5 mg per cat orally every 24 hours. ACE inhibitors can almost never be used on their own to control signs of heart failure and are not effective for controlling heart failure in the acute care setting. Rather they must be administered in concert with a diuretic and help in the long-term control of the disease. Generally, ACE inhibitor therapy should be started when the cat is reasonably stable and not dehydrated.

204.2.9.4 Digoxin

Digoxin, in theory, may be administered to cats with DCM. However, in the initial trial that identified taurine deficiency as a cause of feline DCM, digoxin was not administered and most of those cats survived; therefore clearly in cats with DCM due to taurine deficiency, no clear mandate exists to administer digoxin.[3]

204.2.9.5 Dietary Modifications

Any cat with DCM should be supplemented with 250 mg taurine orally every 12 hours until the results of the plasma and whole blood taurine concentration analysis are evaluated. Taurine is inexpensive and can be purchased from health food stores or chemical supply houses. Cats that are taurine deficient should be continued on taurine supplementation, whereas those that are not may be taken off or left on at the discretion of the owner. Sodium-restricted diets may be useful, particularly in cats that are refractory to drug therapy. However, it is more important to keep the cat eating than it is to force sodium restriction.

204.3 HYPERTROPHIC CARDIOMYOPATHY

HCM is a disease of the ventricular (primarily LV) myocardium characterized by mild to severe thickening of the papillary muscles and wall (Figure 204-3). The word *primary* means the hypertrophy is due to an inherent myocardial problem, not secondary to a pressure overload or to hormonal stimulation. Concentric hypertrophy (a thickened wall with a normal to small chamber size) of the LV has several possible secondary causes, including aortic stenosis, systemic arterial hypertension, and hyperthyroidism. When any of these diseases are present, the diagnosis of HCM is in doubt and the cardiac abnormality should not be called *HCM* if one is convinced the primary cause of the hypertrophy is the other disease process. Instead it should be called *concentric hypertrophy secondary to the primary abnormality* (e.g., concentric hypertrophy secondary to hyperthyroidism). Besides concentric hypertrophy, the myocardium can also thicken due to infiltration (e.g., with lymphoma).[24]

Figure 204-3 A cross-sectional view of a two-dimensional echocardiogram from a cat with severe hypertrophic cardiomyopathy (HCM). The interventricular septum *(IVS)* is markedly thickened and thicker than the left ventricular free wall *(LVFW)*. The two papillary muscles in the left ventricular chamber *(LV)* are also markedly enlarged.

204.3.1 Incidence

HCM is the most commonly diagnosed cardiac disease in cats, and its prevalence appears to be increasing. However, echocardiographic screening for the disease has also become more prevalent over the past 10 years, so increased awareness and ease of diagnosis may also be major contributing factors to this increase. During a recent 10-year period, the author's cardiology service diagnosed moderate to severe HCM in 447 cats. This is almost twice as many cases as during a previous 10-year period when the incidence was similar to another report in which 46 cats were diagnosed with HCM during a 2-year period at the Animal Medical Center in New York City.[25]

A male predisposition for HCM is commonly reported in clinical studies, although in a study of Maine coon cats the incidence was the same in males and females. However, males often develop the disease at an earlier age and often develop more severe disease. Consequently, it is likely that the male predominance seen clinically is purely because males develop worse disease, not because they are more predisposed to the disease.

204.3.2 Cause

204.3.2.1 Sarcomeric Gene Mutations in Humans with Hypertrophic Cardiomyopathy

The exact cause of feline HCM is unknown, although the disease is known to be heritable in some breeds. In humans the familial nature of the disease was first reported in 1958.[26] It has been demonstrated that approximately 50% of the human cases of HCM are inherited in an autosomal dominant pattern, with the other cases being sporadic (although often still genetic in origin). Since 1989 over 150 mutations in 10 genes that encode for sarcomeric proteins have been identified in human families with HCM.[27–31] They include the β-myosin heavy chain; α-tropomyosin; cardiac troponins I, C, and T; myosin-binding protein C; essential and regulatory light chains; titin; and actin genes.[27,32–36] Several families with HCM have also been shown to have mutations in the gene that codes for LIM protein.[37] Another set of families has been identified with mutations in the gene coding for AMP-activated kinase that produces glycogen accumulation in the myocardium, mimicking HCM.[38] Interestingly, mutations in β-myosin heavy chain, α-tropomyosin, titin, and troponin T genes also cause DCM in humans (although the mutations are at different sites than those that cause HCM) and mutations in the LIM protein gene cause DCM in mice.[39] It is now known that sarcomeric gene mutations actually cause HCM because several mutations that have been identified in human families with HCM have been placed in transgenic mice, and the disease has been reproduced—thus fulfilling Koch's postulates.[40–42]

The pathophysiology of HCM production by sarcomeric mutations is controversial.[43] One theory is that the abnormal protein produced by a mutated gene results in dysfunctional sarcomeres that forces the functional sarcomeres to bear a larger load. The myocardium compensates by replacing the dysfunctional sarcomeres with additional functional and dysfunctional sarcomeres.[33,44–46] The net result is that the heart has twice as many sarcomeres as it should have. Because sarcomeres make up a large part of the heart muscle, the heart muscle ultimately almost doubles in thickness in severe cases.

204.3.2.2 Familial Feline Hypertrophic Cardiomyopathy

The first “family” of cats with an inherited form of HCM was identified in Maine coon cats in 1992 and reported in 1999.[47] The disease is inherited as a simple autosomal dominant trait in this breed and is 100% expressed in experimental cats. However, in nonexperimental Maine coon cats, it appears that the disease is not 100% expressed because both parents of an affected cat may have no echocardiographic evidence of the disease. This phenomenon is common in human families with HCM with a variety of gene mutations.[27] The disease has been reproduced in Maine coon cats by mating affected to unaffected and affected to affected cats, as well as by breeding affected Maine coon male cats to domestic shorthair female cats. The course of the disease is accelerated in affected cats produced by mating affected to affected cats. The disease is progressive. In most affected Maine coon cats, HCM is not apparent during the first year of life but becomes apparent by 2 years of age in males.[48] Females tend to get the disease later, with most manifesting

the disease by 3 years of age but some not showing evidence of the disease until 6 or 7 years of age. When both parents have HCM, an affected Maine coon kitten may have echocardiographic evidence of the disease as early as 6 months of age and have severe disease by 1 year of age, whether male or female.

The most consistent feature of the disease in Maine coon cats and in most cats with HCM is papillary muscle hypertrophy. It is often present before wall thickening is evident. Systolic anterior motion (SAM) of the mitral valve is common. Studies are currently in progress to determine if a specific sarcomeric gene abnormality exists in this family of Maine coon cats.

A family of American shorthair cats, primarily with SAM of the mitral valve but with other evidence of HCM as well, has also been identified.[49] The disease in this breed also appears to be inherited as an autosomal dominant trait. In addition to these breeds, anecdotal evidence exists of HCM being inherited in numerous other breeds, including Persian, British shorthair, Norwegian forest cats, ragdoll, Turkish van, and Scottish fold cats, along with others. HCM is most likely inherited when it is identified in a specific breed. However, HCM is most commonly identified in domestic (mixed breed) cats. Whether the disease is inherited in these cats, is due to a de novo mutation, or is associated with a different disease process is unknown, although suspicion of inheritance has been reported in mixed breed cats.[50–52] Because the disease is inherited as an autosomal dominant trait in some purebred cats, it is not hard to imagine how these mutations could disseminate into the mixed breed population.

Some mutations in humans produce malignant disease in which survival time is short, whereas other mutations produce benign disease with little change in survival.[53,54] Although the Maine coon breed has a malignant disease, the American shorthair usually has a more benign disease. Ragdoll cats, on the other hand, have a particularly malignant form of the disease and often die before reaching 1 year of age.

204.3.2.3 Other Causes of Concentric Left Ventricular Hypertrophy

Congenital valvular or subvalvular aortic stenosis is a rare cause of concentric LV hypertrophy in cats. Certain systemic diseases, especially hyperthyroidism and systemic hypertension, can induce the LV myocardium to thicken.[55] Acromegaly is rare and usually does not produce concentric LV hypertrophy in the author's experience. At least in theory, each of these diseases should be ruled out before making a definitive diagnosis of HCM. However, in general, none of these diseases causes severe LV wall thickening on their own; therefore if severe hypertrophy is present, it is very unlikely that one of these diseases is the sole cause. Rather it is more likely the cat has severe HCM or the cat has had mild to moderate HCM most of its life and then developed one of these complicating diseases at an older age. This event then stimulates further hypertrophy, leading to severe HCM. The primary reasons for this belief are the documentation of this occurrence in a limited number of cases and the logic that HCM and these other diseases are prevalent in the domestic cat population (making it likely that some cats will have HCM in combination with a potentially exacerbating disease, especially when these cats are older). Consequently, cats with significant LV concentric hypertrophy, especially ones that are geriatric or have a disease that causes systemic hypertension, must be screened for hyperthyroidism and systemic hypertension.

204.4 PATHOPHYSIOLOGY

204.4.1 Hypertrophy, Diastolic Dysfunction, and Congestive Heart Failure

Enlarged papillary muscles and a thick LV myocardium with a normal to small LV chamber characterize HCM (see Figure 204-3). HCM may be mild, moderate, or severe. Severe concentric hypertrophy by itself increases chamber stiffness. In addition, blood flow and especially blood flow reserve to severely thickened myocardium is compromised, which causes myocardial ischemia, cell death, and replacement fibrosis.[56] This has been documented in cats by showing that cardiac troponin I concentration, a protein released into the systemic circulation after cell necrosis, is increased in cats with severe HCM.[57] Increased concentrations of circulating neurohormones may also stimulate interstitial fibrosis.[58] Fibrosis increases chamber stiffness (increased pressure for any given volume) further and is probably the primary reason for the marked diastolic dysfunction seen in this disease. The stiff ventricular chamber causes a greater increase in pressure for any given increase in volume when the ventricle fills in diastole. This produces CHF (i.e., pulmonary edema and pleural effusion). The myocardium from cats with HCM also takes a longer time to relax in early diastole, although the clinical significance of this is unknown.[59]

When LV hypertrophy is severe, it is common for the LV wall thickness to be twice the normal thickness. Consequently, LV wall thickness is commonly in the 7 to 10 mm range when HCM is severe in cats. This severe concentric hypertrophy may encroach on the LV cavity in diastole, decreasing its size, although LV diastolic diameter is commonly within the normal range. The end-systolic volume and diameter are almost always reduced, often to zero (end-systolic cavity obliteration; Figure 204-4). Global myocardial contractility is normal in humans with HCM, and the reduction in end-systolic volume is due to a decrease in afterload (wall stress) brought on by the increase in wall thickness.[60]

204.4.1.1 Systolic Anterior Motion of the Mitral Valve

A phenomenon called systolic anterior motion (SAM) of the mitral valve is common in cats with HCM (Figures 204-5 and 204-6). Cats with HCM and SAM are commonly said to have the obstructive type of HCM or hypertrophic obstructive cardiomyopathy (HOCM). In one survey of 46 cats, SAM was present in 67%.[25] SAM of the mitral valve is the process of the septal (anterior) mitral valve leaflet or the chordal structures inserting on this leaflet being pulled into the LV outflow tract during systole. Here it is caught in the blood flow and pushed toward (and often ultimately against) the IVS. The initial pulling of the mitral valve leaflet toward the LV outflow tract in systole can clearly be seen on many echocardiograms from cats with HCM. The grossly enlarged papillary muscles encroach on the LV outflow tract (the region of the LV between the anterior leaflet of the mitral valve and the IVS in diastole) and pull the mitral apparatus structures into the basilar region of the outflow tract. This situation has been reproduced experimentally in dogs by surgically displacing the papillary muscles cranially.[61] SAM of the mitral valve produces a dynamic subaortic stenosis that increases systolic intraventricular pressure in mid-to late systole. The dynamic subaortic stenosis increases the velocity of blood flow through the subaortic region and often produces turbulence (Figure 204-7). Simultaneously, when the septal leaflet is pulled toward the IVS, this produces a gap in the mitral valve, creating mitral regurgitation. These abnormalities are by far the most common cause of the heart murmur heard in cats with HCM. The process of SAM is dynamic—worsening when contractility increases and lessening when contractility decreases. This also makes the murmur dynamic—increasing in intensity with increasing excitement and softening when the cat becomes calmer.

Figure 204-4 The same view as in Figure 204-3 but at the end of systole. End-systolic cavity obliteration occurs.

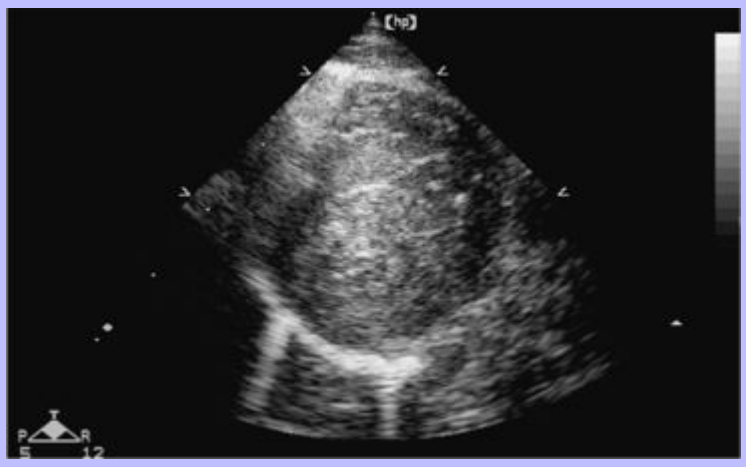


Figure 204-5 A long-axis view of a two-dimensional echocardiogram taken in late systole (same cat as in Figure 204-3). Systolic anterior motion (SAM) of the mitral valve *(arrowhead)*. The enlarged papillary muscle *(P)* is pulling the chordal structures and a portion of the tip of the anterior mitral valve leaflet into the left ventricular (LV) outflow tract, where it is contacting the interventricular septum *(IVS)* and creating an obstruction between the outflow tract and the aorta *(Ao)*. End-systolic cavity obliteration is again present. *LVFW,* Left ventricular free wall; *LA,* left atrium.

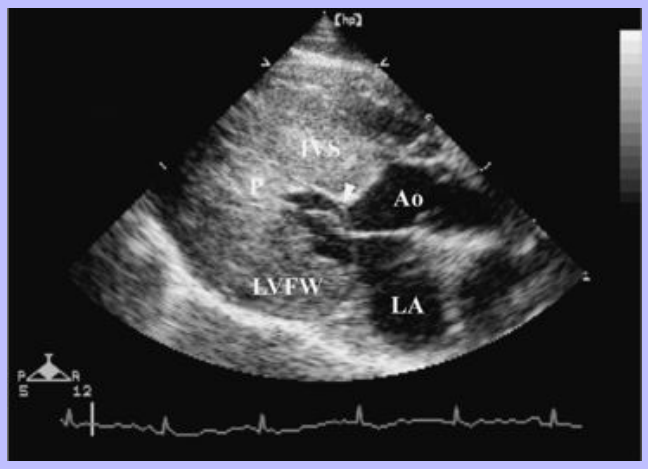

Figure 204-6 A left apical four-chamber view from the cat in Figure 204-4 showing systolic anterior motion (SAM) of the mitral valve. The portion of the mitral valve apparatus causing the dynamic obstruction is aligned with the caudal papillary muscle *(P)*. *LA,* Left atrium; *Ao,* aorta.

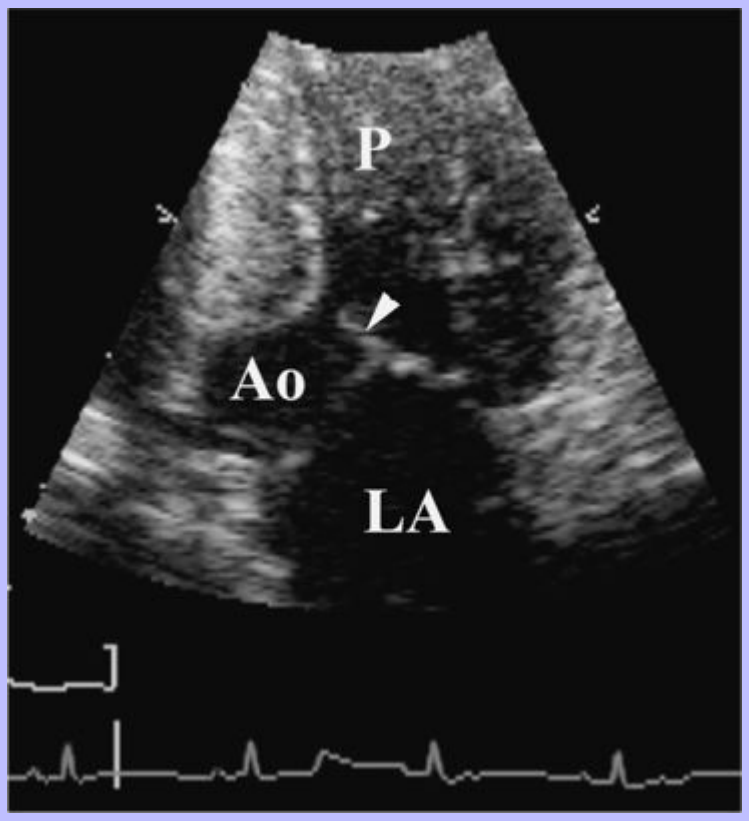

Figure 204-7 A black-and-white rendition of the color flow Doppler signal seen with systolic anterior motion (SAM) of the mitral valve. A bilobed jet—both originating from the left ventricular outflow tract region of the left ventricle *(LV)*. The top jet is created by the dynamic subaortic stenosis (SAS). The lower jet that extends into the left atrium *(LA)* is due to mitral regurgitation, created when the anterior mitral valve leaflet is displaced.

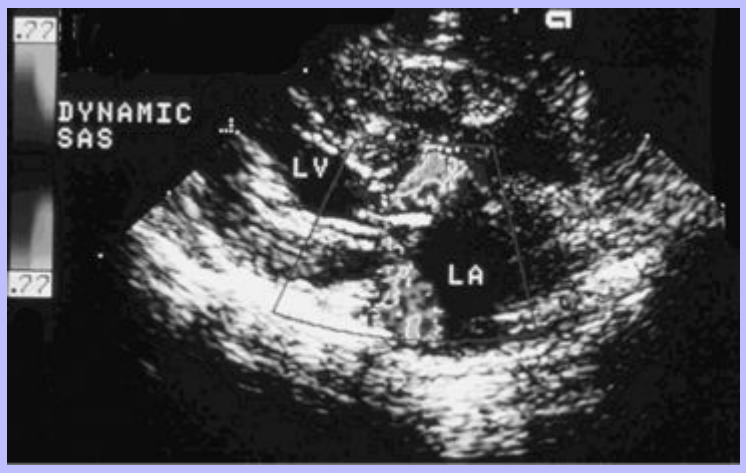

204.4.1.2 Pleural Effusion

Along with pulmonary edema, pleural effusion is common in cats with heart failure. It can be a modified transudate, pseudochylous or true chylous in nature. The most common cause of chylothorax in cats is heart failure.[62] It is unknown exactly why pleural effusion develops in these cats. Two possibilities exist: The first is that left heart failure results in pulmonary hypertension severe enough to cause right heart failure. This does not appear to occur very frequently in cats because it is unusual to identify echocardiographic right heart enlargement, jugular and hepatic vein distension, or ascites in these cases. The second possibility is that feline visceral pleural veins drain into the pulmonary veins such that elevated pulmonary vein pressure (congestive left heart failure) causes the formation of pleural effusion. In the dog the visceral pleura is supplied by pulmonary arteries and drained by pulmonary veins.[63] The dog, the cat, and the monkey have type II lungs.[64] One characteristic of type II lungs is that the visceral pleura is supplied not by bronchial arteries but by pulmonary arteries. Presumably this means that the cat visceral pleura is also drained by pulmonary veins. This means that pulmonary venous hypertension secondary to left heart failure could cause pleural effusion in cats as it does in humans.[65]

1089 1090

204.4.2 Pathology

204.4.2.1 Gross Pathology

Cats with severe HCM have severe thickening of the LV myocardium (the IVS and free wall), with the LV wall commonly being 7 to 10 mm thick (Figures 204-8 and 204-9). The hypertrophy may be symmetrical, involving the entire circumference of the LV, but it may also be asymmetrical. In some cats the IVS is significantly thicker than the free wall, whereas in others the free wall is thicker (asymmetrical hypertrophy).[25,66,67] In those cats with primarily septal hypertrophy, the hypertrophy may be confined to the basilar region of the septum, and in others may be apical. Isolated free wall hypertrophy most commonly occurs in the region between the papillary muscles. As in many pathologic specimens, hearts from cats with HCM may undergo contraction (rigor) after death, resulting in a wall thickness that is closer to the end-systolic wall thickness in life rather than the end-diastolic thickness. Consequently, heart weight must be combined with subjective or objective evidence of LV wall thickening to make the diagnosis of HCM postmortem. To weigh a cat heart the pericardium should be removed and the aorta and pulmonary artery transected so that no more than 2 to 4 cm are left. Normal heart weight–to–body weight ratio has been reported to be 10.6 +/– 4 g/lb, with cats with HCM having a ratio of 13.2 +/– 3.1 g/lb.[25] This results in a large overlap between the two groups. In the author's experience, most normal-sized cats (6 to 12 lb) have a heart that weighs less than 20 g and most cats in this size range with HCM have a heart that weighs more than 20 g. Cats with severe HCM almost always have a heart that weighs more than 25 g, usually over 30 g, and can be as heavy as 38 g.

The left atrium is often enlarged in cats with severe HCM, often markedly so (Figure 204-10). However, with early, severe disease, the author has identified normal left atrial size in some Maine coon cats. Occasionally a thrombus is present in the body of the left atrium or within the left auricle.

Cats with milder forms of the disease (mild to moderate HCM) have lesser wall thickening and a more normal-sized LV chamber. The left atrium may be normal in size or may be enlarged. Papillary muscle hypertrophy may be the predominant lesion.

Figure 204-8 Gross pathologic cardiac specimen from a cat with severe hypertrophic cardiomyopathy (HCM). The heart has undergone rigor postmortem, causing end-systolic cavity obliteration. Heart weight must be obtained to confirm that the HCM is present (see text).

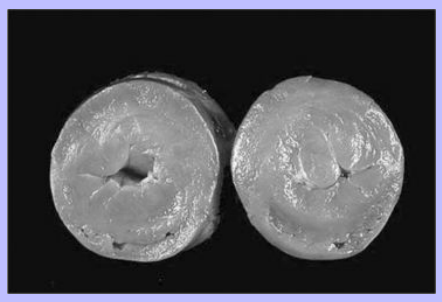

Figure 204-9 Gross pathologic cardiac specimen from a cat with severe hypertrophic cardiomyopathy (HCM). The left ventricular (LV) outflow tract *(arrow)* is narrowed as one papillary is pulling the anterior leaflet of the mitral valve into the outflow tract. *IVS,* Interventricular septum; *LA,* left atrium; *Ao,* aorta.

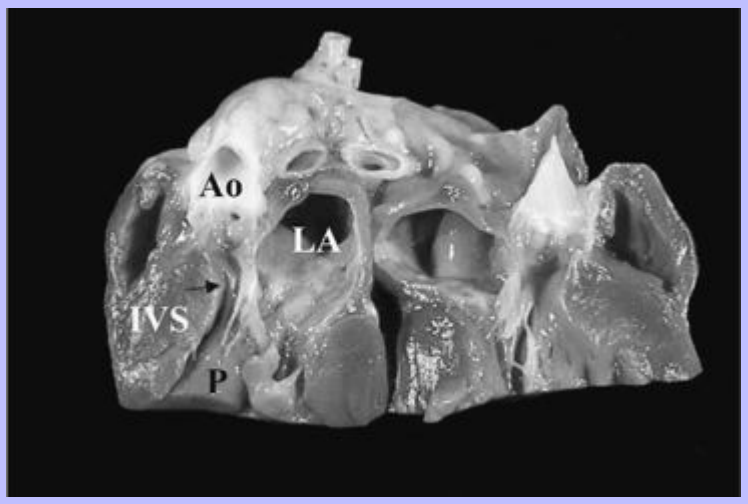

204.4.2.2 Histopathology

Histopathologically, a wide range of abnormalities exist. In some hearts, only myocyte hypertrophy is evident. On the other end of the spectrum, some cats have moderate to severe interstitial and replacement fibrosis and dystrophic mineralization (20% to 40% of cases).[66,68] Intramural coronary arteriosclerosis is present in approximately 75% of cats with HCM.[25,66] Intramyocardial small artery disease is not specific for HCM because it is also identified in cats and dogs with many cardiac diseases.[69]

In humans, myocardial fiber disarray that involves at least 5% of the myocardium in the IVS is found in 90% of patients with familial HCM.[70,71] Other diseases that produce concentric hypertrophy can also cause myocardial fiber disarray, but this almost always involves less than 1% of the myocardium. In cats with HCM, myocardial fiber disarray in the IVS of the same magnitude observed in humans is only identified in 30% to 60% of cases.[66,68,72] However, myocardial fiber disarray is a consistent feature of HCM in Maine coon cats (Figure 204-11).[47] Sarcomeres also have disarray in human patients with HCM. Interestingly, infecting isolated feline cardiocytes with an adenoviral vector containing a full-length mutated human β-myosin heavy chain gene causes sarcomere disruption.[73]

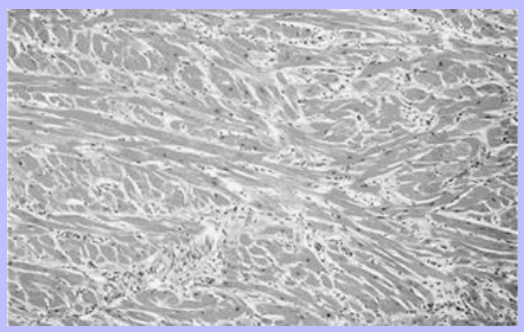
Figure 204-11 Histopathology from a Maine coon cat with severe hypertrophic cardiomyopathy (HCM) showing myocardial fiber disarray.



204.4.3 Natural History and Prognosis

The prognosis, as with most cardiac diseases, is highly variable for HCM. Some of it is determined by clinical presentation and echocardiographic severity of the disease. Adult cats that are asymptomatic and have mild to moderate disease and no to mild left atrial enlargement have a good short-term (and possibly a good long-term) prognosis. Some, however, may progress to more severe disease and some may die suddenly. Asymptomatic cats with severe wall thickening and mild to moderate left atrial enlargement have a guarded prognosis for developing heart failure in the future. They probably have some risk for developing thromboembolism and may be at risk for sudden death.[74] Cats with no clinical signs but with severe wall thickening and moderate to severe left atrial enlargement are at risk for developing heart failure or often already have mild to moderate heart failure that has gone undetected. These cats are at risk for developing systemic thromboembolic disease and sudden death, although both of these risks appear to be relatively small.[74] Cats presented in heart failure usually have a poor prognosis, but survival time is highly variable. Most die of intractable heart failure. Some develop thromboembolism, and some die suddenly. In one study a MST of 3 months was reported yet some cats (about 20% in one study) in this class stabilize and do well for prolonged periods. The author and colleagues have seen some cats with severe HCM live as long as 2.5 years after the diagnosis of heart failure (see www.vmth.ucdavis.edu/cardio/cases/case5/case5.htm).[75] Some of these cats may develop heart failure when they are stressed and become severely tachycardic and then stabilize after that time. Cats with severe HCM and aortic thromboembolism in the aforementioned study had a very poor prognosis with a MST of 2 months.

204.4.4 Clinical Manifestations

204.4.4.1 Development

In humans, familial HCM develops in most individuals over the first 2 decades of life.[76] HCM is a progressive disease in Maine coon cats and likely in other purebred and mixed breed cats. When a veterinarian examines an older cat with HCM, the disease may have been present for most of the cat's life.

204.4.4.2 History

Cats with HCM may have no clinical signs. Many have a heart murmur; some are brought to a veterinarian with subtle, moderate, or severe heart failure; and some are presented because of thromboembolic disease. Cats with no clinical signs can have mild to severe LV thickening; however, those with severe thickening usually go on to develop heart failure. Cats with severe disease that appear to have no clinical signs may show subtle signs of heart failure (e.g., tachypnea) that may be detected by an observant owner but more often goes undetected. The respiratory rate is often increased in these cats at rest, and they may become more tachypneic or even dyspneic if stressed. Stressed cats with severe HCM may recover quickly after stress or may go on to develop fulminant heart failure. Cats with mild to moderate thickening may never develop clinical signs referable to their disease and may live normal lives. In others, the LV wall may thicken further, and complications may develop when they are older and develop a complicating disease such as systemic hypertension or hyperthyroidism.

Cats with severe HCM and moderate to severe heart failure are usually presented to a veterinarian because of respiratory abnormalities (tachypnea, dyspnea, or both) due to pulmonary edema, pleural effusion, or

both. Because household cats are generally sedentary, owners usually do not notice that they are having respiratory difficulty until the dyspnea is advanced. At that time the onset of the disease commonly appears to be acute or peracute to the owner; however, in reality the disease has been present for years, and the heart failure probably has been gradually worsening over weeks to months.

Cats with HCM may develop systemic thromboembolism (see the last section of this chapter). This markedly worsens their prognosis.

Cats with HCM may die suddenly, often with no prior clinical signs referable to heart disease or failure.[74] The cause of the sudden death in these cats is unknown. In humans, sudden death appears to be either due to arrhythmic or hemodynamic causes.[77] The hemodynamic cause is usually an acutely worsening outflow tract obstruction associated with strenuous exercise (which probably ultimately leads to a terminal arrhythmia). This can, in theory, occur with extreme excitement (e.g., being chased by a dog) in a cat with HCM. A large thrombus occluding flow in the left heart is another possible cause of sudden death. However, in the family of Maine coon cats studied by the author and colleagues, sudden death is usually not associated with physical stress or with thromboembolic disease. These cats likely die of an acute ventricular tachyarrhythmia that degenerates into ventricular fibrillation or of a bradyarrhythmia. The incidence of sudden death in feline HCM is probably under-represented in the veterinary literature because cats that die suddenly are usually not presented or reported to veterinarians.

204.4.4.3 Physical Examination

Cats with severe HCM commonly have auscultatory abnormalities. A systolic murmur, heard best over the midsternum or left apex beat is common and is usually due to SAM of the mitral valve. The murmur is often dynamic, increasing in intensity when the cat becomes excited and heart rate and myocardial contractility, especially contractility of the papillary muscles, increase and decreasing in intensity or disappearing when the cat is calm. A gallop sound may be present in cats with severe HCM. It should be noted that not all three heart sound rhythms are due to gallop sounds. In the author's experience, using an electronic stethoscope, systolic clicks also occur with some frequency in cats. Systolic clicks tend to wax and wane in intensity more than do gallop sounds and are more frequently present in cats with mild or no apparent cardiac disease.

1091 1092

204.4.4.4 Radiography

HCM cannot be distinguished from the other forms of cardiomyopathy using plain radiography. In a cat in CHF the left atrium is almost always enlarged and usually severely enlarged. Pulmonary edema is commonly present, but its pattern is often different from dogs, being patchy or more ventrally distributed. Pleural effusion is also common. Angiography to diagnose HCM has been supplanted by echocardiography.

204.4.4.5 Echocardiography

The diagnosis of HCM is almost always made using echocardiography. Cats with severe HCM have severe papillary muscle hypertrophy, markedly thickened LV walls (7 to 10 mm), and usually an enlarged left atrium (see Figure 204-3). The hypertrophy can be global, affecting all areas of the LV wall, or it can be regional or segmental.[25] Segmental forms can primarily affect the entire (or one region of) IVS or the free wall, the apex, or the papillary muscles (and often the adjacent free wall). Because of these forms, HCM is a diagnosis that should be made by examining several different two-dimensional echocardiographic views

and measuring wall thickness in diastole from the thickest region or regions on the two-dimensional images. M-mode echocardiography may miss regional thickening unless it is guided by the two-dimensional view. End-systolic cavity obliteration is commonly present in cats with severe HCM, although this phenomenon can occasionally occur in cats without HCM (see Figure 204-4).

204.4.4.5.1 Systolic anterior motion of the mitral valve

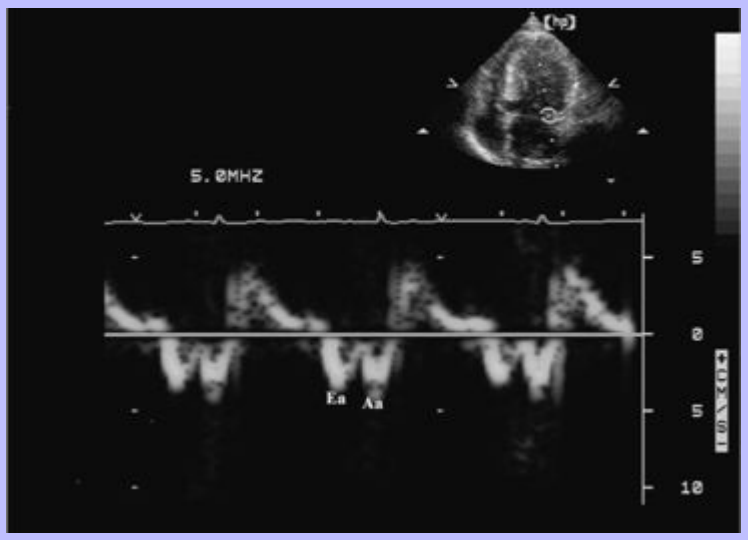
Mitral valve SAM can often be most easily identified using two-dimensional echocardiography, either in real time or in slow motion of a cine loop (see www.vmth.ucdavis.edu/cardio/cases/case5/echodopp.htm and Figures 204-5 and 204-6). Color flow Doppler echocardiography can be used to demonstrate the hemodynamic abnormalities associated with SAM (see Figure 204-7). With this modality, one observes two turbulent jets originating from the LV outflow tract: one regurgitating back into the left atrium and the other projecting into the aorta. Spectral Doppler can be used to determine the pressure gradient across the region of dynamic subaortic stenosis produced by the SAM. The pressure gradient roughly correlates with the severity of the SAM, although it can be quite labile, changing with the cat's level of excitement. Care must be taken not to record the high-velocity mitral regurgitation jet that is positioned close to the dynamic subaortic stenosis jet. Usually, the dynamic subaortic stenosis jet is narrower (shorter period of systole) on spectral Doppler than the mitral regurgitation jet, often becoming even narrower in mid-to late systole. SAM can also be seen with M-mode echocardiography but is usually more difficult to perform because cats' hearts are small.

SAM is not present in all cats with HCM. Although most cats with SAM have severe HCM, some cats develop SAM before they have any evidence of wall thickening, when their papillary muscles are thickened or long. Although the basilar region of the IVS is often thickened during diastole in cats with HCM, the basilar LV outflow tract does not need to be narrowed for SAM to occur.

204.4.4.5.2 Diastolic dysfunction

Diastolic dysfunction in cats with severe HCM has been documented using Doppler tissue imaging (DTI) and measures of transmitral flow and relaxation time. Cats with severe HCM routinely have a decrease in early diastolic wall motion of the left ventricular free wall and mitral valve annulus using DTI (Figure 204-12).[78] In addition, on pulsed wave Doppler echocardiography, peak E wave velocity may be reduced, peak A wave velocity increased, isovolumic relaxation time prolonged, and rate of deceleration of early inflow reduced in cats with severe HCM when the heart rate is slow enough that E and A wave velocities can be identified (Figure 204-13).[79]

Figure 204-12 A Doppler tissue image (DTI) tracing taken from a cat with severe hypertrophic cardiomyopathy (HCM). The DTI is taken from the lateral mitral valve annulus. The early diastolic wave velocity *(Ea)* is markedly reduced to approximately 4 cm/sec. *Aa,* Annular velocity during atrial systole.



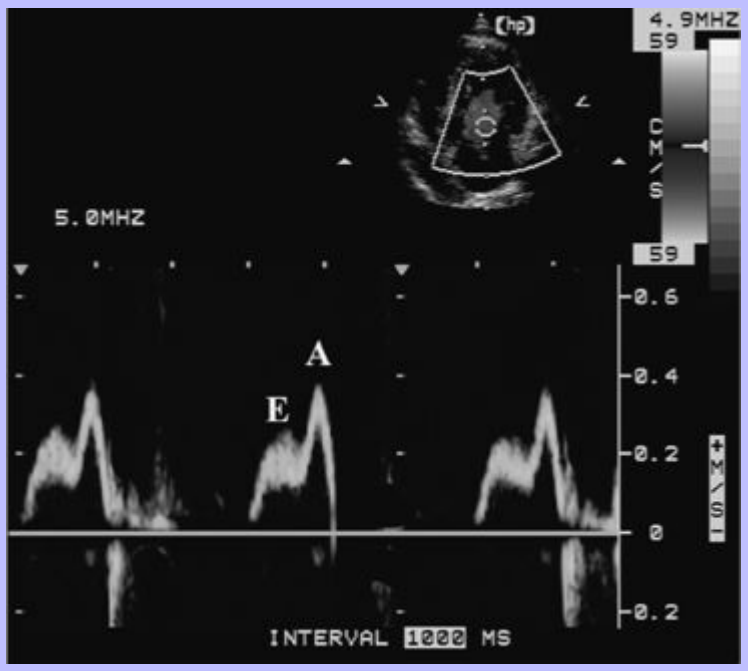
204.4.4.5.3 Mild to moderate hypertrophic cardiomyopathy

The diagnosis of HCM is much more difficult and controversial in cats that do not have severe HCM or that only have regional wall thickening on an echocardiogram. In human families with HCM associated with specific gene abnormalities, varying degrees of severity have been noted within the affected family members.[80] Echocardiographic findings in family members with the same mutation range from no abnormalities to severe HCM. This may also be true in cats. Distinguishing mild disease from normal or distinguishing mild to moderate HCM from hypertrophy secondary to other abnormalities is not easy in individual cases. In a clinical situation where one is examining an older cat with what appears to be mild to moderate concentric hypertrophy, one must first decide whether hypertrophy is present or not. Then one must determine if another disease is present and may be causing the hypertrophy before one can really make the diagnosis of feline HCM.

1092

1093

Figure 204-13 A pulsed wave blood flow Doppler tracing taken from just below the mitral valve leaflets during diastole from a cat with severe hypertrophic cardiomyopathy (HCM). Normally the early ventricular diastolic filling velocity *(E)* is faster than the ventricular filling velocity in late diastole, during atrial systole *(A)*. In this cat the relative waveform velocities are reversed.



The upper limit for normal LV wall thickness is generally considered to be 5.0 to 5.5 mm in the cat, although normal ranges that have been generated in cats may be contaminated by cats with mild HCM because of the disease's prevalence. In most normal Maine coon cats the LV wall thickness is in the 3 to 4 mm range. Certainly any cat with a LV wall thickness greater than or equal to 6 mm is abnormal.

204.4.4.6 Magnetic Resonance Imaging

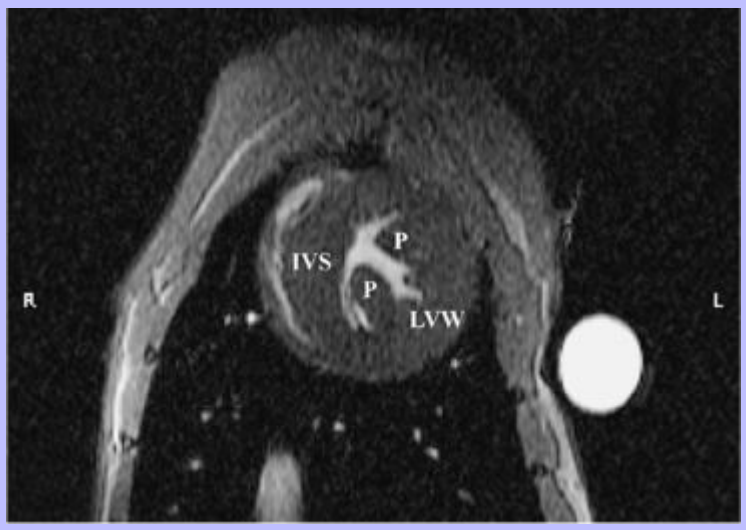
Magnetic resonance imaging (MRI) is a new modality that has been used primarily in humans to assess cardiac anatomy and function. It is more accurate than echocardiography in quantitating LV mass in patients with HCM.[81] It can also be used to quantitate diastolic function.[82] The technique is feasible in cats and may become a useful tool for identifying mild disease and assessing response to therapy (Figure 204-14).

204.4.5 Differential Diagnoses

Hyperthyroidism and systemic hypertension need to be ruled out as either primary or complicating factors. Hyperthyroidism is usually easy to rule out. Devices to measure blood pressure in the cat, however, are not always readily available, and the technique requires some practice to acquire accurate values. In addition, systolic systemic arterial blood pressure may be increased in a normal cat that is stressed, so repeat measurements of increased blood pressure are preferred before a diagnosis of systemic hypertension is made. If systemic arterial blood pressure cannot be measured, one should at least rule out the common causes of systemic hypertension in a cat with LV concentric hypertrophy (i.e., hyperthyroidism, renal failure).

Rarely, infiltrative disease such as lymphoma will produce hypertrophy that is indistinguishable from HCM on an echocardiogram. One such case has been reported.[24] Cats that are homozygous for the dystrophin deficiency seen in hypertrophic feline muscular dystrophy also have thickened but hypoechoic myocardium with hyperechoic foci in the LV myocardium and papillary muscles.[83] The myocardium contains foci of mineralization and no dystrophin.

Figure 204-14 Cross-sectional view of the heart taken using magnetic resonance imaging (MRI) from a cat with severe HCM. The papillary muscles *(P)*, left ventricular free wall *(LVW)*, and interventricular septum *(IVS)* are all markedly thickened. (Picture courtesy of Dr. Kristin MacDonald.)



204.4.6 Precipitating Factors

Certain factors may precipitate heart failure or sudden death in a cat with HCM. Stress (cat fight), anesthesia (especially with ketamine), and surgery appear to be factors.[74] The administration of a long-acting

corticosteroid also appears to be a factor that either produces or worsens heart failure in cats, presumably through the mineralocorticoid effects of these drugs.

204.4.6.1 Therapy of Cats with No Clinical Signs

No evidence exists to show that any drug alters the natural history of HCM in domestic cats until they are in heart failure. Diltiazem, atenolol, or enalapril are commonly administered to cats with mild to severe HCM that are not in heart failure on an empiric basis. Whenever HCM is diagnosed in a cat, the veterinarian should explain the situation to owners and try to let them make informed decisions based on their wishes and life styles. Because no intervention is known to change the course of the disease, treatment at this stage is not mandated.

204.4.6.2 Treatment Goals and General Therapy of Cats in Heart Failure

Cats that present in heart failure have clinical signs referable to pulmonary edema, pleural effusion, or both. Consequently, therapy is generally aimed at decreasing left atrial and pulmonary venous pressures in these cats and physically removing the effusion. In some cats with severe heart failure, clinical evidence of hypoperfusion (low-output heart failure) may be apparent in addition to the signs of CHF. The signs may be manifested primarily as cold extremities.

Pulmonary edema is primarily treated with diuretics (almost exclusively with furosemide) acutely and chronically and an ACE enzyme inhibitor chronically, although recent evidence suggests that ACE inhibition may not be that helpful in prolonging survival in cats with HCM.[84] Diltiazem and beta-adrenergic blockers, usually atenolol, have been commonly used as adjunctive agents. Recent evidence suggests that diltiazem is not helpful in prolonging survival in cats with heart failure due to severe HCM and that atenolol may actually shorten survival time.[84] Pleurocentesis is most effective for treating cats with severe pleural effusion. Furosemide is helpful for preventing or slowing recurrent effusion.

204.4.7 Acute Therapy

Just as with DCM, cats that have respiratory distress suspected of having heart failure secondary to HCM may need to be placed in an oxygen-enriched environment as soon as possible. If possible the cat should be initially evaluated by doing a cursory physical examination, taking care not to stress the patient during this or any other procedure, because stress exacerbates dyspnea and arrhythmias and often leads to death. Most, but not all, cats with severe HCM that are in heart failure will have a heart murmur and gallop rhythm. A butterfly catheter should be used to perform thoracentesis on both sides of the chest to look for pleural effusion as soon as possible. Generally this should be done with the cat in a sternal position so that it does not become stressed during the procedure. Clipping of the hair is not needed. If fluid is identified, it should be removed. Most cats that are dyspneic due to pleural effusion have 150 to 250 mL of fluid in their pleural space. If none is identified, a lateral thoracic radiograph to identify pulmonary edema may be taken with the veterinarian present to ensure that the cat is not stressed (e.g., the clinician should make sure no one stretches the cat out or in any way interferes with its ability to breathe). If the patient struggles or appears to be stressed or fractious during or before radiographic examination, the procedure should be canceled and the patient placed into an oxygen-enriched environment. A preferable alternative to blind tapping is to perform a superficial ultrasonographic examination to identify and locate fluid accumulation.

1093

1094

204.4.7.1 Furosemide

Furosemide should initially be administered intravenously or intramuscularly to the cat in severe respiratory distress. The route of administration depends on the stress level of the patient. Furosemide should be administered intramuscularly to cats that are very distressed and cannot tolerate restraint for an intravenous injection. Cats that can tolerate an intravenous injection may benefit from the more rapid onset of action (within 5 minutes of an intravenous injection versus 30 minutes for an intramuscular injection). The initial furosemide dose to a cat in distress should generally be in the 1 to 2 mg/lb range, intramuscularly or intravenously. This dose may be repeated within 1 hour to 2 hours (see Chapter 199).

High-dose parenteral furosemide therapy commonly produces electrolyte disturbances and dehydration in cats. Cats with severe heart failure that require intensive therapy are often precarious. They may be presented dehydrated and electrolyte-depleted because of anorexia. They may remain anorexic and consequently dehydrated and depleted of electrolytes once the edema, the effusion, or both are lessened. Judicious intravenous or subcutaneous fluid administration may be required to improve these cats clinically. Overzealous fluid administration will result in the return of CHF. If fluid administration is required, the furosemide administration must be discontinued for that time.

204.4.7.2 Nitroprusside

Anecdotally, nitroprusside may be beneficial in cats with severe pulmonary edema due to HCM. As with DCM, it may be administered empirically at 2 μg/lb/min or titrated, using blood pressure measurement to document efficacy, starting at a dose of 1 to 2 μg/lb/min. Nitroprusside has a very short half-life. Consequently, if clinically significant systemic hypotension is produced (e.g., weakness, collapse, poor capillary refill time) cessation of the infusion will result in the systemic blood pressure returning to normal within several minutes.

204.4.7.3 Nitroglycerin

Nitroglycerin cream may be beneficial in cats with severe edema formation secondary to feline cardiomyopathy. However, no studies have examined effects or efficacy. Nitroglycerin is safe and some benefit may occur with its administration in some cats. Consequently, one-eighth inch to one-fourth inch of a 2% cream may be administered to the inside of an ear every 4 to 6 hours for the first 24 hours as long as furosemide is being administered concomitantly. Nitroglycerin is not a primary drug. Tolerance develops rapidly in other species, and prolonged administration is probably of even lesser benefit.

Once drug administration is complete, the cat should be left to rest quietly in an oxygen-enriched environment. Care should be taken not to distress the cat. A baseline measurement of the respiratory rate and assessment of respiratory character should be taken when the cat is resting. This should be followed at 30-minute intervals and furosemide administration continued until the respiratory rate starts to decrease (a consistent decrease of the respiratory rate from 70 to 90 breaths per minute into the 50 to 60 breaths per minute range is a general guide), the character of the cat's respiratory effort improves, or both occur. When this happens, the furosemide dose and dose frequency should be curtailed sharply.

204.4.7.4 Sedation or Anesthesia

In some cats, sedation with acepromazine (0.02 to 0.5 mg/lb intramuscularly or intravenously) may help by producing anxiolysis. Oxymorphone (0.02 to 0.04 mg/lb every 6 hours intramuscularly, intravenously, or subcutaneously) or butorphanol tartrate (0.04 mg/lb intravenously or 0.18 mg/lb every 4 hours subcutaneously) may also be used but are secondary choices because they can produce respiratory depression. Oxymorphone may produce excitement in some cats.

In some cats with fulminant heart failure, anesthesia, intubation, and ventilation are required to control the respiratory failure. Although this method is not preferred for most severely dyspneic cats, it can be life saving in some. This procedure has the advantage of being able to administer 100% oxygen and to be able to drain or suction fluid from the large airways in a controlled environment. The disadvantage is the administration of anesthetic agents to a cat that has cardiovascular compromise.

204.4.8 Chronic Therapy

Many aspects of chronic therapy of HCM are controversial. All therapy is palliative. Furosemide is the only drug that has a clearly beneficial effect chronically on survival in cats with HCM.[84]

204.4.8.1 Pleurocentesis

Many cats with HCM are dyspneic because of pleural effusion that reaccumulates despite appropriate medical therapy. These cats need periodic pleurocentesis (see Chapter 103).

204.4.8.2 Furosemide

In cats with CHF due to HCM, furosemide administration, once initiated, should usually be maintained for the rest of the cat's life. In a few cases, furosemide can be discontinued gradually once the cat has been stabilized. This usually only occurs in a cat that has had a precipitating stressful event.

As for DCM, the maintenance dose of furosemide in cats usually ranges from 6.25 (one half of a 12.5 mg tablet) once a day to 12.5 mg orally every 8 hours, although the dose may be increased further if the cat is not responding to a conventional dose. The author and colleagues have administered higher doses (up to 37.5 mg every 12 hours) than commonly recommended to a few cats with severe heart failure without identifying severe consequences as long as the cats were eating and drinking. Cats on high-dose furosemide therapy are commonly mildly dehydrated and mildly to moderately azotemic. However, they often continue to maintain a reasonable quality of life.

The furosemide dose needs to be titrated carefully in each patient. The owner should be taught how to count the resting respiratory rate at home and instructed to keep a daily written log of the respiratory rate as outlined previously under DCM. This is highly beneficial for making decisions regarding dose adjustment in individual patients.

204.4.8.3 Angiotensin-Converting Enzyme Inhibitors

Although furosemide has been used to treat heart failure secondary to feline HCM for decades, the use of ACE inhibitors in cats with HCM is relatively recent, because veterinarians, like their colleagues who treat humans, feared that the use of ACE inhibitors would worsen SAM in their patients. Over the past 10 years it has become obvious to most veterinary cardiologists that ACE inhibitors do not worsen the clinical signs referable to HCM, and a recent study has documented that SAM is not worsened by enalapril administration in cats.[85] Many have believed and one study has suggested that ACE inhibitors improve the quality and quantity of life of cats with HCM.[86] Preliminary evidence from a recent placebo-controlled and blinded clinical trial suggests that enalapril produces little to no benefit when compared with furosemide alone in cats with heart failure due to HCM.[84] However, this study also included cats with unclassified (restrictive) cardiomyopathy and both cats with and without SAM. Subgroup analysis failed to change the conclusions of the study but the subgroups were small. Consequently, it is the recommendation of this author to continue to use an ACE inhibitor in cats in heart failure due to HCM at a dose of 1.25 to 2.5 mg orally every 24 hours.

1094
1095

204.4.8.4 Diltiazem

In cats with severe HCM that have or have had evidence of CHF, diltiazem or a beta-adrenergic blocking agent are often administered. Both provide symptomatic benefit in human patients. Their use in cats with HCM is controversial; however, little doubt exists that neither drugs produces dramatic benefits. Diltiazem, however, appears to produce no harm.[84]

Diltiazem is a calcium channel blocker previously reported to produce beneficial effects in cats with HCM when dosed at 7.5 mg every 8 hours.[87,88] Beneficial effects that have been reported include lessened edema formation and decreased wall thickness in some cats. In the author's experience only a few cats appear to experience a clinically significant decrease in wall thickness, and it is impossible to tell if this is due to drug effect or time. Rarely does it appear clinically that diltiazem controls CHF on its own or helps control pulmonary edema or pleural effusion when added on to furosemide therapy. Diltiazem does improve the early diastolic relaxation abnormalities seen in feline HCM.[59,88] Whether this helps decrease diastolic intraventricular pressure and so decrease edema formation is unknown. Theoretically it should have little benefit in the resting cat with a slow heart rate. Slower myocardial relaxation during rapid heart rates may not allow the myocardium enough time to relax, resulting in increased diastolic intraventricular pressure. Diltiazem may help protect a cat that undergoes a stressful event. Incomplete relaxation and decreased compliance, however, are more plausible explanations for increased diastolic pressure due to diastolic dysfunction in feline HCM. In humans, diltiazem does not change LV chamber stiffness and so does not alter passive diastolic function.[89] In cats it also appears not to alter late diastolic filling properties.[90] Diltiazem decreases SAM, which may decrease the amount of mitral regurgitation, but beta blockers generally produce a greater decrease in the amount of SAM.[91] Recent evidence suggests that diltiazem has no effect on survival time in cats with severe HCM and heart failure.[84]

Dilacor XR is dosed at 30 mg per cat orally every 12 hours and produces a significant decrease in heart rate and blood pressure in cats with HCM for 12 to 14 hours.[92]

204.4.8.5 Beta-Adrenergic Receptor Blockers

Beta blockers are primarily used to reduce SAM and heart rate in cats with HCM. At this stage, beta blockers should probably be reserved for cats with severe SAM at rest or with tachyarrhythmias and not routinely administered to the affected population as a whole, because a recent study has suggested that atenolol shortens the survival of cats with diastolic dysfunction, including cats with HCM.[84] Beta blockade is questionable for SAM and tachycardia observed in a clinical situation. Cats spend 85% of their life asleep, and sleep probably reduces sympathetic activity better than a beta-adrenergic blocking drug. Consequently, many cats with mild to moderate SAM in a veterinary clinic probably have no or milder SAM at home, and the same can be said for tachycardia. Beta blockers are effective for reducing SAM. Two studies have examined the effects of esmolol, a short-acting β_1-adrenergic blocking drug, in cats with HCM and obstruction to LV outflow due to SAM; both showed a reduction in the pressure gradient across the outflow tract.[91,93] In both studies the degree of outflow tract obstruction decreased and the heart rate slowed, and in one esmolol was more effective than diltiazem.[91] If the data on esmolol can be translated to atenolol's effects in cats (which seems reasonable), one would predict that atenolol would decrease SAM.

Atenolol is a specific β_1-adrenergic blocking drug that needs to be administered twice a day, usually at a total dose of 6.25 to 12.5 mg orally every 12 hours.[92,94] In the cat, atenolol has a half-life of 3.5 hours. When administered to cats at a dose of 1.4 mg/lb, atenolol attenuates the increase in heart rate produced by isoproterenol for 12 but not for 24 hours.

204.4.9 Refractory Heart Failure

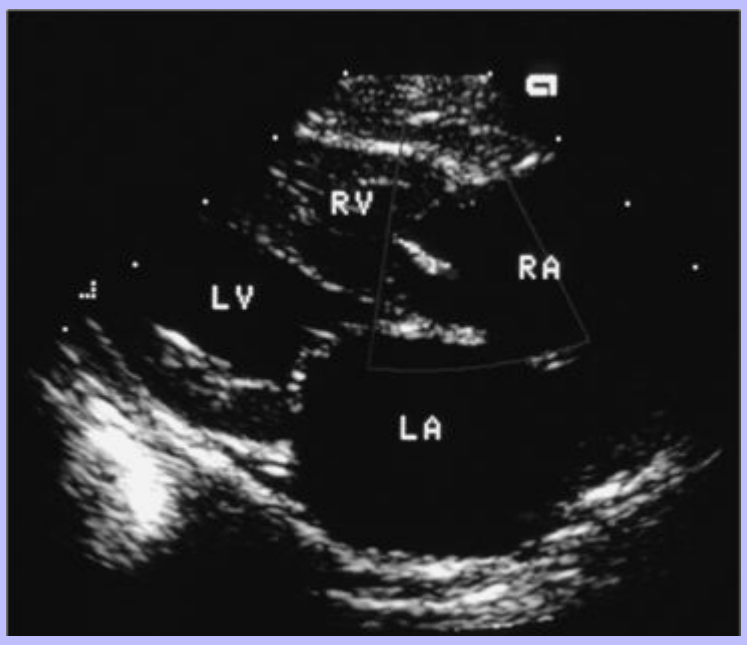
Heart failure that is refractory to furosemide and an ACE inhibitor portends a poor prognosis. Another diuretic may be added to the therapeutic regimen. A thiazide diuretic is generally the most rewarding but is also more likely to cause complications, such as dehydration and electrolyte (sodium, potassium, chloride, magnesium) depletion. Spironolactone, in theory, may have some beneficial effects related to blocking aldosterone's actions; however, clinically it rarely results in noticeable improvement, and its efficacy is unproven. A low sodium diet may be helpful, if palatable. This diet can be a commercial one or one that is devised by a nutritional service. Home-cooked diets formulated by the owner are discouraged unless the owner is counseled. If severe SAM is present and atenolol is not already part of the therapeutic regimen, it may be added at this stage.

204.5 FELINE UNCLASSIFIED CARDIOMYOPATHY

A relatively common echocardiographic finding in cats with heart disease and heart failure is normal to mildly abnormal ventricular chamber size, wall thickness, and wall motion with atrial enlargement (Figure 204-15). The left heart is most commonly affected, but there may also be concurrent right heart changes. It is commonly believed that because no evidence of systolic dysfunction, left-to-right shunting, or obvious valvular regurgitation exists, these cats must have diastolic dysfunction. Consequently, these cats are often assumed to have RCM. One study has suggested that this is not the case.[78] In this study, diastolic function was examined in nine cats with the aforementioned findings using DTI. DTI is a pulsed Doppler technique that measures the velocity of ventricular or annular wall motion and is an accurate means of detecting RCM in humans.[95] Six of the cats in the study had clear evidence of diastolic dysfunction (i.e., lower than normal early diastolic wall velocity). Three cats clearly had normal diastolic function on DTI and therefore did not have RCM. Consequently, not all cats with the

echocardiographic findings described previously have RCM. Therefore the author feels that the more appropriate term for this disease is *unclassified cardiomyopathy* unless it can be documented that diastolic dysfunction exists. In this scheme, RCM then is often a subclassification of unclassified cardiomyopathy, whereas the other subclass is unknown or idiopathic.

Figure 204-15 Two-dimensional echocardiogram from a cat with unclassified cardiomyopathy. The left ventricle *(LV)* appears normal and the left atrium *(LA)* is enlarged. A small color flow Doppler jet of tricuspid regurgitation in the right atrium *(RA)*, which is also enlarged but not to the same degree as the LA. *RV,* Right ventricular chamber.



What could cause this echocardiographic pattern other than RCM? Some form of atrial myopathy is one possibility, and atrial standstill is occasionally identified in these cats (see www.vmth.ucdavis.edu/cardio/cases/case18/case18.htm). Misdiagnosis is another possibility. In the author's clinic, many cats arriving with a diagnosis of primary mitral regurgitation, mitral and tricuspid valve dysplasia, and hyperthyroidism have been placed into this category (called either *unclassified* or *RCM*), probably because it was convenient and gave the clinician a false sense of security of making a “definitive” diagnosis. Significant mitral regurgitation is most often missed when only a high-frequency ultrasound probe is used. A lower-frequency transducer and several views are recommended. Some ultrasound machines do not have a frame rate high enough to adequately detect apparent severe mitral regurgitation in cats.

In some cats, evidence of endocardial scarring can be seen on the echocardiogram, either as a discrete lesion most commonly at the level of the mid-LV or as diffuse scarring of the endocardium. In these cases the diagnosis of RCM may be made echocardiographically.

The terms *intermediate* and *intergrade cardiomyopathy* have been used previously to describe this class of cardiac disease in cats. They are probably inappropriate because they suggest that the characteristic changes seen in these cats share clinical and echocardiographic features of both dilated and HCM.

204.6 FELINE RESTRICTIVE CARDIOMYOPATHY

Although listed as a separate entity in this chapter, in most situations RCM is a subclassification of unclassified cardiomyopathy. Feline RCM is a diverse group of myocardial conditions characterized by abnormal diastolic function, normal to mildly increased LV wall thickness, and normal to mildly reduced systolic function. RCM occurs when ventricular diastolic compliance is impaired (i.e., stiffness is increased) by infiltration of the endocardium, subendocardium, or myocardium by fibrous tissue or another component. In contrast to human medicine where specific causes, such as amyloidosis and eosinophilic infiltration are causes of RCM, specific causes for RCM have not been clearly defined in the cat. Without the use of invasive diagnostic procedures to directly measure LV diastolic function, DTI, other indirect measures of diastolic function, or necropsy examination, it is often impossible to distinguish this disorder from the form or forms of unclassified cardiomyopathy that are idiopathic.

204.6.1 Incidence

The exact incidence of RCM is unknown. Unclassified cardiomyopathy is the second most common feline cardiomyopathy, of which RCM is a component.

204.6.2 Cause

The precise cause of feline RCM is unknown. Some evidence indicates that it may be inflammatory in nature. Endomyocarditis has been recognized in cats at postmortem examination for over 25 years.[96] Endomyocarditis in cats is characterized by focal or diffuse infiltration of the endocardium by lymphocytes, plasma cells, histiocytes, and a lesser number of neutrophils. The inflammatory component of endomyocarditis may be infectious, immune-mediated, or toxic. An interstitial pneumonia may also be common in this group. Within the past 10 years a study documented endomyocarditis in 37 cats at necropsy over a 7-year period.[97] Over this same 7-year span, 25 cats with endocardial fibrosis were identified at the same institution. Four of these 62 cats had features of both diseases. This study and previous findings from Dr. Sam Liu have lead to the speculation that chronic endomyocarditis leads to endocardial fibrosis, a pathologic disease that leads to the physiologic entity termed *RCM*. However, unless an agent that causes endomyocarditis in cats is identified, the theory that endomyocarditis leads to endocardial fibrosis will remain unproven.

In addition to the previous findings and speculation, one study has identified a transmissible myocarditis-diaphragmitis in young cats.[98] The disease is generally self-limiting and causes a transient fever and depression. The investigators were unable to isolate a causative agent in these cats.

Eosinophilic endocardial inflammation is common in humans, more commonly in tropical climates. RCM has been reported in several cats with hypereosinophilic syndrome, although it is impossible to determine if the hypereosinophilia in this small number of cats caused RCM or the two diseases happened to occur together.[99,100]

204.6.3 Pathophysiology

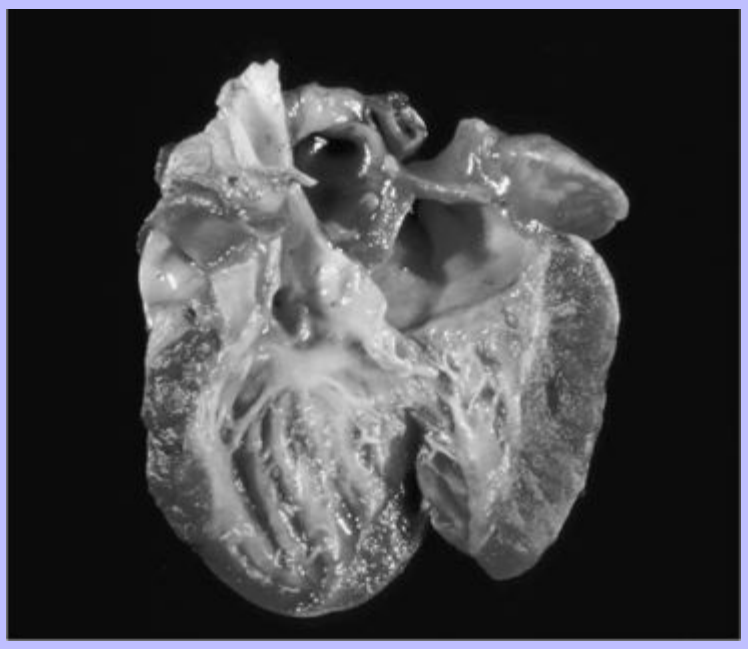
In its classic form, endocardial, subendocardial, or myocardial fibrosis impede ventricular diastolic filling and so impair diastolic function. These disorders are generally and primarily characterized by decreased compliance leading to an elevated LV diastolic pressure with a normal LV filling volume. The elevation in diastolic ventricular pressure results in atrial enlargement and the formation of pulmonary edema and pleural effusion. The lesions are generally confined to the LV in humans and left CHF predominates the clinical presentation.[101] In cats, right atrial enlargement is also common. In some cats the LV is perfectly normal in appearance, whereas in others the LV may be misshapen and may have additional false tendons traversing the ventricle.

204.6.4 Pathology

The postmortem changes are unique to this form of cardiomyopathy and may be used to differentiate it from other disorders. Patchy or diffuse endocardial, subendocardial, or myocardial depositions of fibrous tissue are characteristic necropsy findings. The endocardium may appear whitish-gray, opaque, and thickened when endocardial or endomyocardial fibrosis is present (Figure 204-16). Fibrous adhesions between papillary muscles and the myocardium with distortion and fusion of the chordae tendineae and mitral valve leaflets may also be noted in RCM.[96] In extreme cases a portion of the LV cavity, most commonly the mid-LV, may be obliterated. As with most cardiomyopathies, the LV appears to be most severely affected, although other cardiac chambers may exhibit similar pathologic findings. Extreme left atrial and auricular enlargement is common. Other cats demonstrate apparently earlier stages of the disease in which microscopic evidence of myocarditis is evident without gross pathologic abnormalities. The lesions suggest an inflammatory response; however causative factors have not been identified. Systemic thromboembolism is prevalent.[102]

Histologic features of endocardial fibrosis include extreme endocardial thickening by hyaline, fibrous, and granulation tissue.[96] Chondroid metaplasia is occasionally exhibited by the surface layer of hyaline tissue. A layer of loose fibrous tissue lies beneath this layer with a layer of granulation tissue adjacent to the myocardium. These changes are similar but not identical to those seen in humans with RCM.

Figure 204-16 Postmortem specimen showing the left ventricle *(LV)* and left atrium from a cat with endomyocardial fibrosis producing restrictive cardiomyopathy (RCM). The endocardium of the LV is white and thickened by fibrotic tissue.



204.6.5 Natural History and Prognosis

As with other forms of cardiomyopathy, prognosis is difficult to predict for individual cases, especially prior to observing the initial response to therapy. A high incidence of serious arrhythmias, systemic thromboembolism, and refractory CHF is often present. In the author's experience, cats with RCM, on average, have a poor long-term prognosis. Although an initial response to standard therapy is often possible, progressive and refractory heart failure develops in the majority of cases.

204.6.6 Clinical Manifestations

204.6.6.1 History

Signalment is difficult to accurately report, because little agreement exist among veterinary cardiologists as to which cases fall within this classification. From a series of pathologic studies in cats, Liu reported an age range of 8 months to 19 years.[103] No breed predisposition has been reported. There may be a male predominance, or it may be that males develop more severe disease, as in HCM. Most cats are middle-aged or older. Presenting complaints and clinical signs are similar to other forms of myocardial disease and

include dyspnea and tachypnea, poor general condition, weakness, lethargy or rarely exercise intolerance, and anorexia. In one report, 45% had evidence of systemic thromboembolism at necropsy.[102]

204.6.6.2 Physical Examination

A heart murmur heard best on the sternum, just medial to the left apex beat, is common. An arrhythmia may be ausculted. Many cats are dyspneic.

204.6.6.3 Radiographs

No specific findings exist for unclassified or RCM. Pulmonary edema and pleural effusion are common.

204.6.6.4 Echocardiography

The echocardiographic findings in RCM are variable. Left atrial dilation is the common feature, and the LV internal dimensions are typically normal but may be mildly to moderately reduced or mildly increased. Most commonly the LV looks normal. However, two-dimensional echocardiography may demonstrate loss of normal LV symmetry, distorted or fused papillary muscles, mild LV concentric hypertrophy, mild wall thickening, a mild reduction in shortening fraction, and a mild increase in chamber diameter. Some cats may have evidence of more pronounced endocardial scarring. In these cases the endocardium may be notably thickened and irregular with an increased echogenicity. Others have evidence of cavity obliteration. Mild mitral regurgitation may be detectable with color flow Doppler. A large color flow Doppler jet suggests that the primary problem is primary mitral valve disease rather than unclassified cardiomyopathy. A left atrial thrombus may be identified.

Doppler echocardiography may be abnormal in cats with RCM. However, this remains to be proven. As noted previously, the early diastolic waveform on DTI is reduced in cats with RCM, whereas it is normal in cats with the idiopathic form of unclassified cardiomyopathy.

204.6.6.5 Electrocardiography

No specific findings appear on electrocardiogram (ECG). Supraventricular and ventricular arrhythmias may be present, but sinus tachycardia is most commonly present in the clinic. Shifts in the mean electrical axis and evidence of chamber enlargement may occur.

204.6.6.6 Clinical Pathology

No specific clinical pathologic findings exist. Azotemia due to reduced cardiac output, either from CHF or dehydration caused by diuretic therapy, is the most common abnormality. Elevated liver enzymes may be encountered.

204.6.6.7 Differential Diagnosis

The primary differential diagnoses for RCM are unclassified cardiomyopathy not due to RCM, mitral regurgitation due to primary mitral valve disease, and myocardial infarction. Chronic myocardial infarction usually results in a region of akinetic or hypokinetic myocardium. Often the region of affected myocardium is thinner than normal. With severe mitral regurgitation due to primary mitral valve disease, a large jet is

seen with color flow Doppler (although it may take a lower-frequency transducer and various views, including the left apical four-chamber view, to identify it). The IVS is commonly hyperdynamic, whereas the left ventricular free wall commonly moves less than normal. The LV chamber is usually larger than normal in diastole.

204.6.7 Therapy

Therapy of restrictive and unclassified cardiomyopathy is the same. It is palliative and consists primarily of the administration of furosemide and an ACE inhibitor as outlined in the two previous sections of this chapter. Diltiazem is not indicated because a calcium channel blocker is not able to help to relax scar (i.e., fibrous) tissue. A recent study suggests that atenolol may decrease the survival time in patients with diastolic dysfunction.[84] However, if the cat is persistently tachycardic at home, diltiazem or atenolol may be indicated in an attempt to slow the heart rate.

204.7 ARRHYTHMOGENIC RIGHT VENTRICULAR CARDIOMYOPATHY

ARVC is a recently reported and rare form of feline cardiomyopathy.[104] It has been identified in humans, dogs (boxer dogs), and cats. It is characterized by fibrofatty or fatty infiltration of primarily the right ventricular free wall. The right ventricular wall is commonly thinned in humans and cats with the disease. Ventricular tachyarrhythmias are common in all three species, and sudden death is a common feature of the disease in humans and boxer dogs.[105] The disease is also commonly known as arrhythmogenic right ventricular dysplasia (ARVD).

204.7.1 Cause

The cause of ARVC is unknown in cats. In humans at least six forms of the disease (ARVD 1 to 6) are inherited as an autosomal dominant trait, and one (Naxos syndrome) is inherited as an autosomal recessive trait.[105] The cause of ARVD 2 has been recently identified as several mutations in the gene that encodes for the calcium release channel (also known as the *ryanodine receptor*) on the myocardial sarcoplasmic reticulum.[106] Ryanodine receptor dysfunction has been identified in boxer dogs with ARVC.[107]

1097
1098

204.7.2 Pathophysiology

In cats, ARVC most commonly (8 of 12 cats in the one study reported to date) produces right heart failure, presumably through the destruction of right ventricular myocardium resulting in right ventricular systolic and, possibly, diastolic dysfunction along with secondary tricuspid regurgitation.[104] The changes in the right ventricular free wall also commonly produce ventricular tachyarrhythmias (9 of 12 cats) and supraventricular tachyarrhythmias (5 of 12 cats). Tumor necrosis factor (TNF) is commonly increased in cats with right heart failure, which may contribute to the systemic effects of the disease.[108]

204.7.3 Pathology

The right ventricular and atrial chambers are markedly enlarged in cats that die of the disease.[104] Thinning of the right ventricular free wall is a consistent feature of the disease and may be focal or diffuse. Aneurysms of the wall may occur, especially at the apex of the right ventricle (RV). The wall is often so thin that light can be

seen through it. Histopathologically either fibrofatty or fatty replacement of myocardium exists. Inflammatory cells are commonly present, especially in regions of fibrofatty replacement. Although most prominent in the right ventricular free wall, these changes are also commonly present in the LV and occasionally identified in the left atrium. Apoptosis is common.

204.7.4 Clinical Manifestations

Evidence of right heart failure, including ascites, pleural and pericardial effusions, and jugular vein distension, is common. The pleural effusion may be severe enough to cause tachypnea and dyspnea. A heart murmur secondary to tricuspid regurgitation is common. Arrhythmias are also commonly heard on auscultation, and ECG evidence of a ventricular arrhythmia may be one clue that one is dealing with ARVC and not tricuspid valve dysplasia. Supraventricular tachyarrhythmias, including atrial fibrillation, may also occur. In the severe stage, echocardiography reveals marked enlargement of the right ventricular and right atrial chambers. The right ventricular chamber enlargement may be segmental. Tricuspid regurgitation is usually present on color flow Doppler. Careful echocardiographic interrogation may reveal localized regions of right ventricular wall thinning or regions of aneurysmal dilation. The right ventricular trabeculae may appear abnormal, especially at the apex. The disease may not be confined to the right heart, which means the left atrial and ventricular chambers may also be enlarged. Syncope due to ventricular tachycardia may be present.

204.7.5 Differential Diagnosis

Cats with severe ARVC are commonly misdiagnosed as having tricuspid valve dysplasia because tricuspid regurgitation is a common sequel to the disease. Cats from 1 to 20 years of age have been diagnosed with the disease.

204.7.6 Therapy

Right heart failure is treated with furosemide and an ACE inhibitor. Digoxin combined with either diltiazem or atenolol may be used to control supraventricular tachycardia or the ventricular rate in cats with atrial fibrillation. Malignant ventricular tachycardia or ventricular tachycardia that causes clinical signs (e.g., syncope) can be managed acutely with lidocaine (5 to 20 μg/lb/min) and chronically with sotalol (1 to 2 mg/lb every 12 hours orally).[109]

204.8 SECONDARY MYOCARDIAL DISEASES

204.8.1 Hyperthyroidism

Hyperthyroidism commonly produces echocardiographic changes, although the changes are usually relatively mild. Changes can include an increase in LV wall thickness, left atrial size, and LV diastolic diameter. Shortening fraction may also be increased.[110,111] Often these changes regress over months once the hyperthyroidism is successfully controlled. These changes are physiologic in response to the direct effects of the excess thyroid hormone on the cardiac myocytes, the increase in metabolic rate, and systemic hypertension. Consequently hyperthyroidism is not a form of cardiomyopathy (i.e., primary myocardial disease). However, some cats with hyperthyroidism will have the classic features of severe HCM, including SAM in some, and a few may experience heart failure. Although unproven, the author theorizes that some of

these cats may have had mild to moderate HCM all their lives and that the hyperthyroidism has exacerbated the hypertrophy.

204.8.2 Systemic Hypertension

Systemic arterial hypertension causes a pressure overload of the LV and leads to concentric hypertrophy. This hypertrophy is generally mild, however, with the average increase in wall thickness being approximately 1 mm.[112] As with hyperthyroidism, the author theorizes that some cats with mild to moderate HCM have an exacerbation of their concentric hypertrophy when they develop systemic arterial hypertension. In addition to the LV wall becoming thicker, the proximal aorta also increases in size with systemic arterial hypertension.

204.8.3 Acromegaly

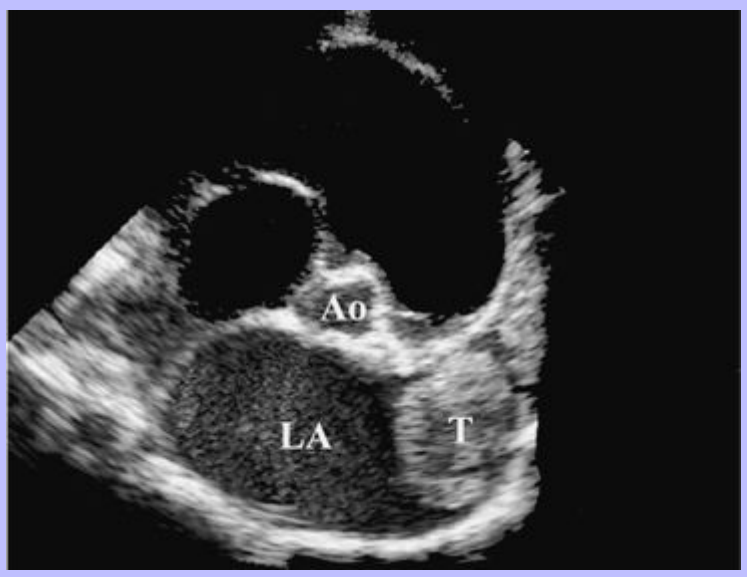
Acromegaly has been reported to increase LV wall thickness severe enough to produce heart failure in cats. In one study, significant wall thickening was identified in seven of 14 cats with acromegaly and six developed heart failure.[55] However, in six cats examined echocardiographically by the author, no evidence of cardiac change was found.

204.9 SYSTEMIC ARTERIAL THROMBOEMBOLISM

A thrombus is a blood clot. Thrombi are usually formed (to prevent hemorrhage) when a blood vessel is traumatized. They can also form spontaneously within the cardiovascular system. A systemic thrombus becomes a systemic thromboembolus when it dislodges from the primary site where it forms in the cardiovascular system and is pushed by blood flow to a distal site where it lodges, partially or completely occluding blood flow distal to the thromboembolus. Most clots that occlude systemic arterial blood vessels are thromboemboli. Spontaneous formation of a clot in a systemic arterial vessel causing occlusion of a systemic artery is an unusual event and requires a predisposing factor (e.g., trauma) to allow it to occur. Most systemic thrombi that form and cause thromboemboli in cats appear to form in the left atrium, most commonly in the left auricle, as they do in humans (Figure 204-17).[113]

Systemic arterial thromboembolism (STE) is most commonly observed in cats with any form of cardiomyopathy, most frequently in those with severe left atrial enlargement, although they also have been reported to occur in cats with hyperthyroidism.[114–116] However, it is unknown if cases of hyperthyroidism have confounding HCM or not. Left atrial chamber enlargement in the absence of mitral regurgitation causes blood flow stasis, especially in the left auricle, allowing red cells to aggregate and thrombus formation to occur. Although STE can occur in cats that do not have cardiac disease, more than 70% of cases seen in veterinary small animal practice are in cats with cardiomyopathy.[115,116]

Figure 204-17 A two-dimensional echocardiogram from a cat with hypertrophic cardiomyopathy (HCM), showing a large thrombus *(T)* in the left atrium *(LA)*, specifically the left auricle, and spontaneous echocardiographic contrast in the left atrium. *Ao,* Aorta.



Most cats (approximately 90%) with STE have the thromboembolus lodge at the terminal abdominal aorta (the aortic trifurcation). The thromboembolus commonly extends down the external iliac arteries, giving it the appearance of a saddle. Consequently, it is commonly called a *saddle thromboembolus*. Thromboembolism of the terminal aorta causes acute cessation of blood flow to the caudal limbs, producing acute caudal limb paresis and paralysis and pain with a loss of the femoral pulses, cold extremities, and pale or cyanotic pads (pain, poikilothermia, paralysis, pulselessness, and pallor). Some cats have a smaller thromboembolus lodge in one femoral artery, a brachial artery, or another smaller artery. Occasionally, a large thromboembolus lodges more proximally in the aorta, above the renal arteries, resulting in acute renal failure. In other cats, a very large thromboembolus lodges in the mitral valve orifice, the LV, or the proximal aorta at the region of the brachiocephalic trunk, causing sudden death.[117]

204.9.1 Pathophysiology

In fast-flowing blood, as occurs with injury to a systemic blood vessel, the principal elements forming a thrombus are platelets, which form a white clot.[118] As blood flow slows due to the clot formation, red cells are incorporated in the clot to form a red thrombus. On the other hand, in slow-flowing blood, coagulation enzymes play the major role in thrombus formation. Here red cells entrapped in a fibrin network result in the formation of a red thrombus. Although no one has examined the composition of left atrial thrombi in cats, in humans they are composed of red cell aggregates within a fibrin meshwork.[118]

The most plausible explanation for thrombus formation in the left atrium of cats with STE is sluggish blood flow. At a postmortem examination, atria from cats with cardiac disease and thromboembolism are often very large and may be fibrotic. In one study the left atrium was severely enlarged in 57%, moderately enlarged in 14%, and mildly enlarged in 22% of cats with STE.[115] Only 5% had a normal left atrial size. The amount of blood that flows through an enlarged left atrium of a cat with cardiomyopathy is normal to low unless significant mitral regurgitation is present, resulting in a lower than normal blood flow velocity within the chamber. When blood flow slows to a certain velocity, red cells and other blood factors clump together (see www.vmth.ucdavis.edu/cardio/cases/case18/echo.htm).[119] In vitro this occurs when blood flow velocity decreases below 10 cm/sec, whereas in humans with atrial fibrillation it occurs when the velocity from the left auricle to the left atrium slows to less than 35 cm/sec.[119,120] Increasing plasma fibrinogen concentration also increases red cell aggregation, whereas red cell aggregation is not altered by the absence of platelets, stimulation of platelet aggregation with ADP, or inhibition of platelet aggregation with aspirin.[119]

Red cell aggregation can be observed with ultrasound and is termed *spontaneous echocardiographic contrast* (SEC), also known euphemistically as “smoke.” SEC is often observed swirling in the enlarged left atrium of a cat with severe cardiomyopathy. In humans, SEC is associated with increased left atrial size and with reduced left atrial blood flow velocity.[120] It is the factor most strongly associated with left auricular thrombus formation and with systemic embolic events. No studies on this subject have been performed in veterinary medicine. However, it is common to see spontaneous contrast in the left atrium of a cat with severe cardiomyopathy and an STE. If low blood flow velocity is such an important factor, one might also expect dogs with DCM to be prone to left atrial thrombus formation. Systemic thromboembolism is rare in dogs with DCM. The reason for this discrepancy may be due to species differences in erythrocyte aggregability. One study has documented that normal cat red cells are more aggregable than those of dogs, rats, rabbits, humans, and gerbils.[121] Although platelets are not necessary for thrombus formation in the left atrium and auricle, cat's platelets are also more reactive than other species. Feline platelets undergo spontaneous aggregation in vitro and are more responsive to serotonin-induced aggregation than are platelets from other species.[122,123] Cats also have a greater volume of platelets per body weight than other species.[122] One study has documented increased platelet aggregability in some cats with cardiomyopathy.[124]

In humans, hyperhomocysteinemia has been associated with venous thrombosis, atherosclerosis, and arterial occlusive disease.[125] Consequently, hyperhomocysteinemia is thought to be associated with atherogenesis and thrombogenesis. Homocysteine is an amino acid metabolically converted from methionine. This conversion is dependent on folic acid and vitamins B_6 and B_{12}, acting as cofactors. The resting plasma concentrations of vitamins B_6 and B_{12} are lower in cats with cardiomyopathy and in cats with STE than control cats, but resting plasma homocysteine concentration is not lower.[126] However, when challenged with methionine, some normal cats show a clear abnormality in their ability to produce homocysteine, showing a marked elevation in plasma homocysteine concentration after oral methionine administration.[127] This may suggest that some cats have an abnormality in their homocysteine metabolic pathway that could make them more susceptible to thrombosis.

204.9.1.1 Thromboembolism

Once a left atrial thrombus has formed, it can do one of four things: (1) it can remain static, especially if it is lodged in the left auricle; (2) it can dislodge and become an STE; (3) it can grow very large and occlude intracardiac blood flow; or (4) it can be dissolved by the body's thrombolytic system. The incidence of the

first and fourth outcomes is unknown, because if a thrombus causes no clinical abnormalities, the thrombus usually goes undetected. If it occludes intracardiac flow, it causes death, and if a postmortem examination is not done, the cause of death is never known. Only the second scenario results in clinical signs for which owners commonly seek medical attention for their pets.

The clinical signs produced depend primarily on the site occluded by the thromboembolus, whether the occlusion is total or partial, and the amount of collateral circulation. Before they dislodge, most left atrial thrombi apparently become larger than any artery exiting off the aorta. Consequently, blood flow pushes them the length of the aorta to lodge at the aortic trifurcation, where the aorta divides into the two external iliac arteries and the common origin of the internal iliac arteries. Here they obstruct blood flow to the caudal limbs.

1099 1100

Physical obstruction is only a part of the pathophysiology. Experimentally, the terminal aorta has been ligated in an attempt to reproduce the disease.[128,129] Surprisingly, cats with aortic ligation exhibit no pain and walk after surgery, although the femoral pulses are absent and caudal limb blood flow is only 30% of baseline.[130] Slight weakness and hyporeflexia are present, but even these resolve within 72 hours when caudal limb blood flow returns to 90% of baseline. Aortograms in these cats confirm the presence of collateral blood flow through the lumbar vertebral arteries and the cranial and caudal epigastric arteries. The disease can be reproduced, however, if a thrombus is created within the terminal aorta.[129,130] Aortograms from these experimental cats are identical to those from spontaneous clinical cases; both demonstrate very poor collateral flow beyond the region of the thromboembolus. Pretreatment with an antiserotoninergic agent or with indomethacin prevents the loss of collateral circulation, and serotonin or thromboxane A_2 injection reproduces the clinical situation when injected into a caudal aortic segment.[128,131–133] It is hypothesized that thromboemboli release serotonin and thromboxane A_2, agents present in platelets and known to produce intense vasoconstriction, and disrupt collateral flow.[134] Administering antiserotonin agents (e.g., cyproheptadine) and indomethacin after a thromboembolus is present apparently has no effect.

204.9.2 Clinical Manifestations

204.9.2.1 History

The majority of cats seen with STE are mixed breed cats.[115,135] Because more severe HCM is seen in males and HCM is the most common feline cardiomyopathy, more male cats are seen with STE. Most cats with STE have heart disease, but up to 90% have no evidence of heart disease prior to developing STE.[115] Consequently, owners often think that their cat has experienced an acute traumatic event. At the onset of STE, the cat may fall off a structure on which it was lying. Often the cat is found unable to walk and vocalizing because of pain.

204.9.2.2 Physical Examination

Auscultation often reveals a heart murmur or a gallop sound (or both) at presentation.[115] Many cats are in heart failure and so are tachypneic and dyspneic. The rectal temperature is usually reduced.

In cats with a large thromboembolus at the aortic trifurcation, the femoral artery pulses are absent to very weak. Once a thromboembolus lodges in the terminal aorta, ischemic damage to the skeletal muscles and

peripheral nerves occurs. The cranial tibial and gastrocnemius muscles are most severely affected and are commonly swollen, turgid, and painful, especially when palpated and the animal has loss of neural reflexes and motor function to the hind limbs (paresis and paralysis). Initially, the ischemic damage to the muscles of the caudal legs results in intense pain. The pain usually subsides as sensory nervous input is lost. The distal portions of the legs are cool and the nail beds are pale or very dark (purple to black). Femoral artery pulses in most cats with STE (78% in one study) are absent upon presentation.[115] In some cats a smaller thromboembolus may lodge in one external iliac artery, resulting in cessation of blood flow to only one leg. In other cats the femoral artery pulses may be weakly present because of recanalization of the aorta. In some cats it is difficult to determine if a pulse is present or not and a false diagnosis of thromboembolism in a cat with neurologic disease is common.[136] A Doppler blood flow detection device is helpful to identify the presence or absence of blood flow. In cats that have no sensation in their distal limbs, a nail can be cut back to the "quick" to determine if active bleeding occurs.

Most aortic thromboemboli lodge terminally in the aorta where they disrupt blood flow to the spinal canal beyond L_5, meaning blood supply to the spinal cord is not disrupted. Instead, perfusion is lost to the cauda equina and the peripheral nerves that originate from this area. Consequently, loss of motor function is due to lower motor neuron disease. Motor function loss to the caudal body is variable. Many cats retain the ability to move their tails. Some cats lose the ability to move their caudal legs starting at the hip, whereas others only lose the ability to move the limbs distal to the stifles or distal to the hock. These latter cats can extend and flex their hips and so "walk" on their stifles. Loss of cutaneous sensation occurs relatively early and follows the pattern of motor loss. The patellar reflex is lost in many cats but remains intact in others. Anal tone and the anal reflex are usually normal. Bladder function is often normal. Some cats may have urine retention, but the bladder can usually be easily emptied by external manual compression. In cats with experimental thrombosis of the terminal aorta, neurologic function (patellar reflex, withdrawal reflex, thigh adduction, digit extension, caudal limb weight bearing, locomotive ability, and cutaneous sensation) to the caudal limbs is completely lost in 80% of cases.[130] The remaining cats have very little residual neurologic function. Presumably the cats seen clinically with some remaining neurologic function must have some collateral flow to explain their neurologic findings. Acute ligation of the aorta in experimental cats, prior to collateral circulation becoming fully developed, produces cessation of blood flow to the distal portion of the caudal limbs, although proximal flow remains apparently normal.[130] This mimics the situation observed in some feline patients that have function remaining in the proximal portion of their caudal limbs.

After the acute embolic event, thrombolysis starts as plasmin is activated. In some cats with a small thromboembolus, thrombolysis is rapid and complete, allowing function to return within hours. In other cats the thromboembolus is large and the thrombolytic activity of the cat is low, resulting in permanent loss of perfusion to the caudal limbs and permanent paralysis. Regions of necrotic skin and muscle (most commonly dry gangrene) often develop, and muscle contracture takes place over time. Between these two extremes are cats that recover function over time with no untoward events and cats that partially recover function but have skin and muscle necrosis develop. The latter cats may require surgery to débride open wounds or amputate toes or parts of limbs. Cats that have complete and lasting occlusion of blood supply to only one limb do very well after limb amputation.

Coagulopathies can occur in cats with STE, although they are usually not severe enough to produce clinical signs.[137] The platelet count is generally within the normal range, and no evidence of fibrin degradation products is seen. Individual clotting factors, however, may be low in certain cases.

Cats with thromboemboli commonly have severe underlying cardiac disease. Acute terminal aortic blockade by the thromboembolus increases afterload to the LV. This can increase left heart filling pressures

and resultant pulmonary edema and respiratory distress.[116] The heart failure must be treated appropriately. If pulmonary edema is severe, it worsens the short-term prognosis.

204.9.3 Diagnosis

The diagnosis of STE in cats is usually based on the presence of typical clinical signs described previously in this chapter. However 20% to 30% of cases referred for STE have primary neurologic disease, so it does not appear that a diagnosis based only on clinical signs is accurate. Consequently, some effort should be placed into doing more definitive diagnostic tests in these cats. In most cases, simply cutting a nail back to the "quick" is adequate. Cats without blood flow to the caudal limbs will not have any bleeding from a cut nail, or very dark blood will ooze from the site. A Doppler device can also be used to determine if blood flow to affected limbs is present and if flow is returning to a limb. Imaging of the affected regional vessels by intravenous or intraarterial angiography or nuclear tracers is the definitive diagnostic procedure for thromboembolic disease. Risks to the patient must be considered when contemplating angiography. Stabilizing the patient is the primary consideration before attempting invasive diagnostic procedures. Color flow Doppler imaging of the area may demonstrate lack of or severely compromised flow.

1100
1101

Radiographs reveal cardiomegaly in almost 90% of cats with STE and evidence of heart failure in approximately 50% to 70%.[115,116,135] Most cats (85% in one study) have ECG abnormalities[115] (LV enlargement, conduction system abnormalities, and sinus tachycardia).

Echocardiography is used to identify the underlying cardiac disease. In one study, about 60% of cats had HCM and 25% had unclassified cardiomyopathy, whereas in another study unclassified cardiomyopathy predominated.[115,116]

204.9.3.1 Clinical Pathology

Laboratory abnormalities are common in cats with STE.[115] Most have increases in serum aspartate aminotransferase and alanine aminotransferase concentrations due to muscle necrosis, and serum glucose concentration (stress). Severe increases in serum urea nitrogen and creatinine concentrations may suggest the thromboembolus has lodged in the region of the renal arteries.

204.9.4 Treatment

204.9.4.1 Euthanasia

In cats that are in acute pain that have a poor prognosis due to severe cardiomyopathy, euthanasia is a humane means of dealing with the problem. Systemic thromboembolism is often a horrible complication of cardiomyopathy, the treatment options are all relatively poor, and rethrombosis is common. Consequently, although one should not automatically give up on a patient, one should not give false hope either.

204.9.4.2 Pain Control

Cats that present in pain must be treated appropriately for their pain. Appropriate drugs include a fentanyl patch, oxymorphone (intramuscularly, intravenously, or subcutaneously) and butorphanol tartrate (subcutaneously). Aspirin does not produce adequate pain control. Oxymorphone may produce excitement

in some cats. The analgesic properties of butorphanol are five times that of morphine, and it remains a nonscheduled drug by the Food and Drug Administration. Its respiratory depressant effects equal that of morphine. Consequently, one must be careful when administering this drug to a patient with dyspnea. Acepromazine may be administered intravenously in addition as an anxiolytic agent to cats that still appear distressed after the administration of the analgesic or to cats that become agitated after oxymorphone administration. The pain abates with time (usually hours) as sensory nerves undergo necrosis.

204.9.4.3 Palliative Therapy

Beyond pain control, many cats with STE receive only supportive care or the administration of drugs with no proven benefit. The primary outcome of arterial occlusion depends upon the extent of occlusion and the time to spontaneous reperfusion. Poor prognostic factors for short-term survival include worsening azotemia, moderate to severe pulmonary edema or pleural effusion, malignant arrhythmias, severe hypothermia, disseminated intravascular coagulation, and evidence of multiorgan embolization. Long-term, cats may lose an affected leg because of ischemic necrosis, die of toxemia, remain paralyzed from peripheral nerve damage, or regain full or partial function of their legs. About 50% of cats that are not treated definitively will regain all or most caudal limb motor function within 1 to 6 weeks.[116,138] Return of function presumably is due to the cat's own thrombolytic system (e.g., plasmin) disrupting the thromboembolus. The degree and rapidity of the dissolution depend on the activity of a particular cat's thrombolytic system and the size and quality of the thromboembolus. Usually, cats that have some evidence of caudal limb flow recover more rapidly than do cats with no evidence of flow. Presumably this is because the size of the thromboembolus in cats with some flow is smaller. With total occlusion, some cats recanalize within days (others never recanalize). This extreme variability makes it very difficult to render a prognosis for a particular patient at presentation.

Palliative therapy may be only cage rest and pain control or can include administering drugs such as heparin, aspirin, or arteriolar dilators along with the cage rest. No drugs administered for palliation have any proven benefit over cage rest alone.

Heparin is commonly administered in the hopes of preventing new thrombus formation on top of the existing thromboembolus or in the hope of preventing a new thrombus from forming in the left atrium. However, no evidence indicates that heparin is of benefit in cats with STE. Heparin does not aid in thrombolysis. Heparin can be administered at an initial dose of 100 U/lb intravenously followed by a maintenance dose of 30 to 100 U/lb subcutaneously every 6 hours. The dose should be tailored to each individual cat to increase the activated partial thromboplastin time (aPTT) to at least 1.5 times baseline.

Indomethacin is effective at preventing vasoconstriction distal to the thromboembolus when administered to experimental cats prior to creating an aortic thrombus.[139] Theoretically aspirin could do the same thing. However, no evidence indicates that it improves collateral blood flow.

The administration of drugs that dilate systemic arterioles (e.g., hydralazine, acepromazine) has been advocated. These drugs act by relaxing the smooth muscle in systemic arterioles. The exact anatomy of collateral vessels is not well described, but they are probably larger vessels than arterioles. They contain smooth muscle, because they can open and close. The ability of arteriolar dilators to counteract serotonin and thromboxane A_2-induced vasoconstriction is unknown.

204.9.4.4 Definitive Therapy

Definitive treatments for STE in cats include administration of exogenous fibrinolytic agents, balloon embolectomy, rheolytic thrombectomy, and surgery. All definitive procedures are associated with high mortality and common recurrence of the thromboembolus days to months after the initial removal.

204.9.4.4.1 Surgery

Surgical removal of systemic thromboemboli is generally thought to be associated with high mortality and is not frequently performed. Cats with STE commonly have underlying cardiac disease, and many are in heart failure. They are poor anesthetic risks, and reperfusion syndrome may be produced. In reperfusion syndrome the muscles of the legs prior to removal of the STE undergo necrosis, cellular breakdown, and the release of potassium and hydrogen ions from the cells into the interstitial spaces. Sudden reperfusion carries these ions into the systemic circulation, causing acute and often severe hyperkalemia and metabolic acidosis. Surgical intervention may be a viable option if careful monitoring and treatment for reperfusion syndrome with insulin and glucose, sodium bicarbonate, or calcium (or a combination of these therapies) can be initiated immediately if it occurs.

204.9.4.4.2 Balloon embolectomy

The procedure of choice in human medicine is balloon embolectomy.[140] The author has had limited experience with balloon embolectomy. In this procedure the femoral arteries are isolated and a small balloon embolectomy catheter is passed from one femoral artery into the aorta. The femoral arteries are not extremely difficult to isolate. The catheter is pushed past the thromboembolus, and the balloon is then inflated and the catheter withdrawn, along with thromboembolic material. The catheter is passed sequentially, first in one artery and then in the other. Usually this sequence must be repeated several times. Reperfusion syndrome may occur with balloon embolectomy.

1101

1102

204.9.4.4.3 Thrombolytic therapy

Thrombolytic therapy is a possible means of dealing with cats with STE using fibrinolytic agents. Thromboemboli in cats are composed of red cells, strands of fibrin, and possibly platelets. Fibrinolytic agents cleave plasminogen to plasmin. Plasmin hydrolyzes fibrin, resulting in thrombolysis. Different agents vary in their ability to bind specifically to fibrin-bound plasminogen and in their half-lives. Efficacy and complication rates appear to be very similar in humans.[141] Complications consist primarily of hemorrhage due to fibrinolysis and rethrombosis. Fibrinolytic agents can be very effective at lysing systemic thromboemboli. However, the author and colleagues currently treat few cats with STE with these agents because reperfusion syndrome and rethrombosis are common.

Tissue plasminogen activator (t-PA) and streptokinase have been used in cats. Tissue plasminogen activator is an intrinsic protein present in all mammals. Numerous reports exist of the use of t-PA for the lysis of thrombi as therapy for acute myocardial infarction, pulmonary thromboembolism, and peripheral vascular obstruction in humans and experimental animals.[141] The activity of genetically engineered t-PA in feline plasma is 90% to 100% of that seen in human plasma. The half-life of t-PA is quite short. Heparin must be administered concomitantly to prevent acute rethrombosis but does not need to be administered with streptokinase because it has a longer half-life. A clinical trial with t-PA in cats with

aortic thromboemboli has shown acute thrombolytic efficacy (shortened time to reperfusion and ambulation) associated with the administration of t-PA at a rate of 0.1 mg to 0.4 mg/lb/hr for a total dose of 0.4 to 4 mg/lb intravenously.[142] Forty three percent of cats treated survived therapy and were walking within 48 hours of presentation. Post-t-PA angiograms demonstrated resolution of the primary vascular occlusion. Thus acutely, t-PA effectively decreases the time to reperfusion and return to function in cats with aortic thromboemboli. However, 50% of the cats died during therapy in this clinical trial, which raises extreme concerns regarding acute thrombolysis. Fatalities resulted from reperfusion syndrome (70%), CHF (15%), and sudden arrhythmic death, presumably the result of embolization of a small thrombus to a coronary artery (15%). Severe hemorrhage into the region distal to the STE causing anemia was also a common complication. The cats that successfully completed t-PA therapy exhibited signs of increasing neuromuscular function and ambulatory ability within 2 days of presentation. This contrasts with 1 to 6 weeks before seeing similar signs of improvement in most cats exhibiting spontaneous resolution.

Mortality due to reperfusion syndrome can be reduced if the patient can be observed continuously by an individual trained to identify clinical and electrocardiographic evidence of hyperkalemia, if intensive monitoring of electrolytes and blood pH can be performed, and if aggressive medical therapy for hyperkalemia and metabolic acidosis can be initiated very quickly. This means dedicated care 24 hours a day until the thromboembolus is lysed. Thrombolysis may occur within 3 hours or take as long as 48 hours.

If reperfusion syndrome was the only major complicating factor in cats treated with thrombolytic agents, continued use in selected patients might be warranted. However, 90% of the cats that were successfully treated in the aforementioned clinical trial had another STE within 1 to 3 months. Rethromboembolism occurred despite aspirin, warfarin, or heparin administration. In addition, t-PA is expensive. Consequently, the author does not currently use t-PA for STE in cats.

Streptokinase has clinical efficacy very similar to t-PA in human patients with coronary artery thrombosis.[143] Streptokinase is less expensive. No controlled clinical trials of streptokinase use for STE in cats are available, and the author's clinical experience with the drug has been generally negative. There has been one small experimental study in which thrombin was injected between two ligatures placed at the terminal aorta to create a soft thrombus, followed by removal of the ligatures.[144] Streptokinase was administered as a loading dose at 90,000 IU followed by 45,000 IU/hr for 3 hours. This dose produced evidence of systemic fibrinolysis in a separate group of normal cats but without evidence of severe fibrinolysis or bleeding. In most cats there was no angiographic change and no improvement in limb temperature. There was a tendency for the thrombus weight to be lower in the treated cats when compared with control cats at postmortem examination. However, lysis of a fresh thrombus created with thrombin is probably much different from trying to lyse an established thromboembolus. Streptokinase is usually unsuccessful, may hasten the death of some cats through bleeding complications, and should not be routinely used.

204.9.4.4.4 Rheolytic thrombectomy

Rheolytic thrombectomy is an experimental catheter-based system used for the dissolution of the thromboembolus using a high-velocity water jet at the end of the catheter that breaks up the thromboembolus and sucks it back into the system using the Venturi effect. Anesthesia is required and blood transfusion is almost always needed. The catheter is passed from the carotid artery to the region of the thromboembolus. The author and colleagues have used it in six cats. The procedure successfully

removed the thromboembolus in five cats but only three left the hospital (Figure 204-18). Time from onset of clinical signs to thrombectomy was several hours to 8 days. The cat that had the procedure 8 days after the event had residual neurologic deficits but was the longest survivor. Interestingly, reperfusion syndrome has not been a common complication.

204.9.4.4.5 Adjunctive therapy

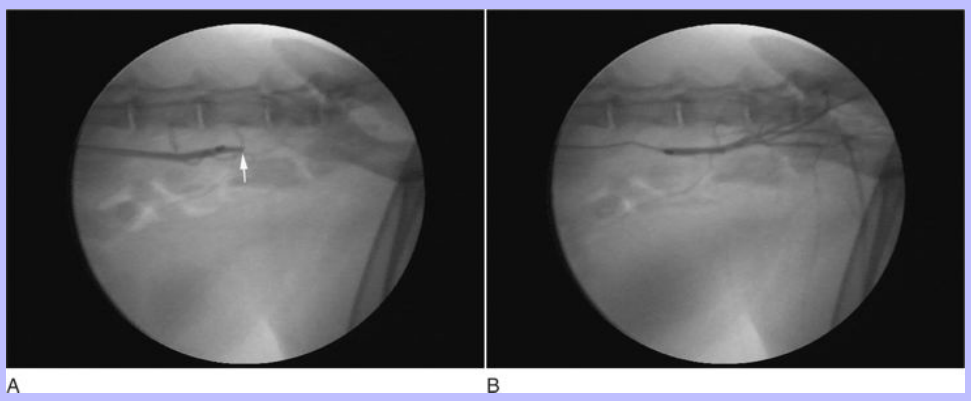
Cats with STE are commonly in heart failure at the time of presentation.[116] Medical therapy with furosemide and an ACE inhibitor is often indicated. Cats that are in pain usually do not eat or drink. Fluid therapy is warranted but must not aggravate or produce heart failure.

Cats that take a long time to recover caudal limb function or that only attain partial function may develop regions of skin and muscle necrosis, especially on the distal limbs. These regions may need to be débrided surgically. Cats that lose the function of only one leg or that do not regain function of one leg benefit from amputating that leg. Cats that have permanently lost muscle function distal to the hock may benefit from arthrodesis.

204.9.4.5 Prognosis

The short-term prognosis for life is guarded in cats without heart failure. Cats with a rectal temperature lower than 98.9° F had a worse prognosis in one study.[116] The long-term prognosis is highly variable and depends on the ability to control the heart failure and the events surrounding the STE. One of the most common causes of death within the first 24 hours is euthanasia.[135] In one study, cats lived between 3 and 30 months after the initial episode.[115] The average survival time was about 10 to 12 months. In another study, MST for cats that recovered and were discharged from the hospital was approximately 4 months but was only about 2.5 months in cats that were also being treated for heart failure.[116] The long-term prognosis for limb function depends on the ability of the cat to lyse its own clot or on the success of intervention. Many biologic variables determine whether or not reperfusion will spontaneously occur. A significant percentage of cats will develop a new thromboembolus, days to months after recovery.

Figure 204-18 **A,** Angiogram of the aorta from a cat with a thromboembolus lodged in its terminal aorta. Contrast can be visualized in the aorta to the level of middle of the sixth lumbar vertebra where it abruptly terminates *(arrow)*. No blood flow is demonstrated past that point. **B,** An angiogram from the same cat after rheolytic thrombectomy. The thromboembolus has been removed. The tip of a catheter can be seen at the junction of the fifth and sixth lumbar vertebrae. Beyond that point the contrast agent outlines the normal blood flow pattern to the caudal limbs.



204.9.4.6 Prophylaxis

Feline patients with myocardial disease, especially those with an enlarged left atrium, should be considered at risk for developing intracardiac thrombi and signs of peripheral arterial thromboembolism, although the incidence appears to be low. Preventing peripheral thrombosis is, in theory, one of the most important therapeutic objectives for the veterinarian managing cats with severe myocardial disease. The ideal means of preventing thrombosis is resolution of the underlying myocardial disease. This is usually only possible in a cat with DCM secondary to taurine deficiency.

At present, the only option available is to manipulate the patient's coagulation system in an attempt to alter the delicate balance between the pathways that promote clotting and those that inhibit thrombus formation to reduce the patient's thrombogenic potential. At this time, antiplatelet and anticoagulant therapies are the only means of preventing thrombus formation in cats with myocardial disease. Unfortunately, they are often ineffective and, in the case of warfarin, can produce serious side effects.[145] Experience is similar in human medicine.[146]

204.9.4.6.1 Antiplatelet therapy

Prostaglandins enhance platelet aggregation via activation of cyclic adenosine monophosphate (cAMP). Aspirin (acetylsalicylic acid) acetylates platelet cyclooxygenase, preventing the formation of thromboxane A_2, a potent prostaglandin-like platelet aggregating substance.[147] The inhibition of platelet cyclooxygenase is irreversible, and bleeding time is restored to normal only after the production of new platelets. The inhibition of endothelial cyclooxygenase is reversible. The dose of aspirin recommended in cats is 10 mg/lb every third day. Whether or not this dose allows endothelial cyclooxygenase to recover or not in cats is undetermined. At this dose, aspirin has a half-life of 45 hours in the cat. In humans, doses as low as 20 to 100 mg/day inhibit platelet cyclooxygenase; however, no evidence suggests that this low dose has any more benefit than conventional daily doses of 625 to 1250 mg. In one study in cats, no difference was seen in thromboembolus recurrence between cats on low dose (5 mg/cat every 72 hours) and high dose (greater than or equal to 40 mg/cat every 72 hours).[116] No evidence indicates that any dose of aspirin is effective at preventing the formation of an intracardiac thrombus in cats with myocardial disease. Clinical impression of aspirin's efficacy varies between clinicians. Cats that have already experienced one STE are the only appropriate population in which to study the efficacy of an agent meant to prevent STE. Aspirin does not prevent recurrence of peripheral thromboembolism in this population.

Glycoprotein IIb and IIIa, an integrin present on platelet surfaces, is a receptor for fibrinogen, fibronectin, and von Willebrand factor. It mediates aggregation, adhesion, and spreading of platelets. The binding of prothrombin to glycoprotein IIb and IIIa also enhances the conversion of prothrombin to thrombin. Glycoprotein IIb and IIIa antagonists have been developed, and one (abciximab) increased mucosal bleeding time and reduced thrombus area when combined with aspirin (when compared with aspirin and placebo).[148]

204.9.4.6.2 Anticoagulant therapy

Available anticoagulants include heparin, the low molecular weight heparins, and warfarin. Heparin binds to a lysine site on AT, producing a conformational change at the arginine-reactive site that converts AT from a slow, progressive thrombin inhibitor to a very rapid inhibitor of thrombin and factor Xa. AT binds covalently to the active serine centers of coagulation enzymes.[150] Factor Xa bound to platelets and thrombin bound to fibrin are protected from activation by the heparin-antithrombin III complex.[147] Heparin may be administered intravenously or subcutaneously. Repeated intramuscular injection is discouraged because local hemorrhage may result. Some owners can administer heparin subcutaneously at home but the method is not ideal. The author and colleagues have noted rethrombosis with heparin therapy in some cats with cardiac disease. The dose of heparin for preventing thrombosis in cats is unknown.

Low molecular weight heparins include nadroparin calcium, enoxaparin sodium, dalteparin, ardeparin, tinzaparin, reviparin, and danaparoid sodium. The low molecular weight heparins have fewer bleeding complications in experimental animals, improved pharmacokinetics over heparin, are administered subcutaneously, and do not require monitoring in most situations.[150] Although heparin does not reduce red cell aggregation in slow-moving blood, heparin and low molecular weight heparins are effective at preventing deep vein thrombosis in humans. Consequently, they may be beneficial in preventing

intracardiac thrombus formation in cats with cardiomyopathy. No controlled studies are available. The author empirically uses enoxaparin sodium at a dose of 2.2 mg/lb every 12 hours subcutaneously in cats that have recovered from an STE or that have a severely enlarged left atrium and SEC.

Warfarin sodium is an oral anticoagulant (see Chapter 199).[147] Warfarin exerts no anticoagulant effect in vitro. In vivo, inhibitory effects on synthesis of clotting factors begin immediately. However, clotting is unaffected until already existing clotting factors decline. Therefore a delay occurs between initial administration and effect on the prothrombin time (PT). Historically, oral warfarin therapy has been monitored with the PT. This test measures the activity of factors II, VII, and X. The factor depressed most quickly and profoundly (usually factor VII) determines the PT during the initial days of therapy. The PT is performed by measuring the clotting time of platelet-poor plasma after the addition of thromboplastin and calcium, a combination of tissue factor and phospholipid.[151] Intra-and interlaboratory variation in the PT was a significant problem for laboratories in the past, when crude extracts of human placenta or rabbit brain were the only source of thromboplastin. The international normalized ratio (INR), developed by the WHO in the early 1980s, is designed to eliminate problems in oral anticoagulant therapy caused by variability in the sensitivity of different commercial sources and different lots of thromboplastin. The INR is used worldwide by most laboratories performing oral anticoagulation monitoring and is routinely incorporated into dose planning for human patients receiving warfarin. When the anticoagulant effect is excessive, it can be counteracted by administering vitamin K_1. However, once synthesis of factors II, VII, IX, and X is reinstituted, time must elapse before factors achieve concentrations in the plasma that will adequately reverse the bleeding tendency. If serious bleeding occurs during therapy with warfarin, it may be stopped immediately by administering fresh blood or plasma that contains the missing clotting factors. Other drugs can modify the anticoagulant actions of warfarin by altering the bioavailability of vitamin K by altering the absorption, distribution, or elimination of the coumarins; by affecting synthesis or degradation of clotting factors; or by altering protein binding of the warfarin.[152] The maintenance dose should be evaluated daily during the initial titration (3 days), then every other day (twice), and then weekly until a safe and stable dose regimen is determined. The therapeutic effect should be reevaluated periodically (at least once per month). The recommended initial dose is 0.1 to 0.2 mg per cat every 24 hours orally to a 6 to 10 lb/cat. The dose may then be increased to maintain an INR of 2.0 to 3.0. It can take up to 1 week for new steady state conditions to be achieved.

The efficacy of warfarin at preventing recurrent thrombosis in cats with cardiac disease has been reported.[114,115] In one report, out of 23 cats examined retrospectively, 10 experienced a new thromboembolic episode while being administered warfarin. Two of these cats had at least two new episodes. In the other report, eight of 18 cats on warfarin experienced a new thromboembolic episode. This may be some improvement over the 75% recurrence rate reported for aspirin alone after t-PA therapy, but these results are still disappointing.[136] In the first report, four cases also died suddenly (which could have been caused by thromboembolism). Three of these cats did not have postmortem examinations. The one cat that did have a postmortem examination had a thrombus present in its left atrium. One cat also died of a renal infarct that produced renal failure. Four cats appeared to have bleeding complications. In the second report, one cat died of a hemoabdomen and one was suspected to have an acute intracranial hemorrhage resulting in death. Consequently, it appears that warfarin therapy can produce fatal complications. However, it should be noted that these studies were performed without using the INR for monitoring.

205 CHAPTER • 205 Pericardial Disorders

Anthony H. Tobias

Pericardial disorders have previously been reported to account for approximately 1% of cardiac disease in small animals.[1] More recent reports estimate that pericardial disorders comprise approximately 8% of the canine cardiology caseload at referral institutions. Pericardial disorders occur slightly less frequently in cats, but the prevalence remains fairly high at 6% of the feline cardiology caseload. In contrast to dogs, pericardial disorders in cats are usually found as incidental manifestations of underlying disease, rather than as the primary cause for the presenting signs.[2]

Pericardial disorders are emerging as increasingly common and important in small animal practice. The presenting signs associated with pericardial disorders are diverse, and the clinical findings are often subtle. Consequently the prevalence of pericardial disorders may previously have been underestimated, especially before the widespread use of echocardiography. Alternately or coincidentally the increased prevalence may reflect a change in the epidemiology of pericardial disorders over time, possibly associated with increased popularity of breeds that are predisposed to pericardial disorders, such as the golden retriever.

205.1 STRUCTURE AND FUNCTION

The pericardium is the fibroserous envelope of the heart. It is divided into an outer fibrous and inner serous part. The serous pericardium consists of a parietal and visceral layer.[3] The fibrous pericardium is a thin tough sac that contains the heart, serous pericardium, and a small amount of fluid. The base of the fibrous pericardium is continued on the great arteries and veins that leave and enter the heart and blends with the adventitia of these vessels. The apex of the fibrous pericardium is continued to the ventral part of the diaphragm as the phrenico-or sternopericardical ligament.[3]

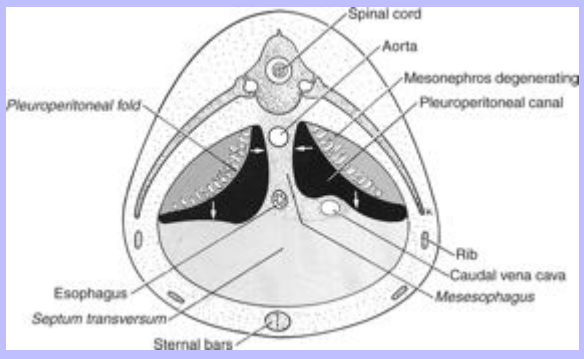
The serous pericardium is a closed sac, approximately half of which is invaginated by the heart. The invaginated portion forms the visceral layer of the serous pericardium or the epicardium. It is firmly attached to the heart muscle, except along the grooves that contain fat and the coronary vessels. The epicardium has a smooth mesothelial surface that is underlaid by a stroma containing elastic fibers. The noninvaginated part or parietal layer of the serous pericardium forms the inner surface of the fibrous pericardium. It is composed of interlacing collagen fibers that blend with the tissue of the fibrous pericardium on one side and a layer of mesothelium on the other. The pericardial space that occurs between the two layers of the serous pericardium contains a small amount of clear light-yellow fluid. The normal amount of pericardial fluid in the dog has been reported as 0.3 to 1.0 mL, and 0.25 ± 0.15 mL per kg.[3,4]

The vagus, recurrent laryngeal, and phrenic nerves pass over the outer surface of the pericardium. The pericardium is innervated by fibers from the vagus, recurrent laryngeal nerve, and various intrathoracic ganglia and plexi. Blood supply is derived from the pericardial branches of the aorta and internal thoracic and musculophrenic arteries.[5] Lymphatic drainage of the pericardial space occurs via the coronary lymphatic ducts to the cardiac and mediastinal lymph nodes and via the left and right parasternal lymphatic ducts to the cranial sternal lymph node.[6]

The physiologic significance of the pericardium remains speculative. Functions attributed to the pericardium include preventing overdilation of the heart, protecting the heart from infection and forming adhesions to

surrounding tissue, maintaining the heart in a fixed position within the chest, regulating the interrelationship between stroke volumes of the two ventricles, and preventing tricuspid regurgitation when ventricular diastolic pressures are increased. In addition, the lubricant effect of pericardial fluid allows the heart to move easily within the pericardial sac during systole and diastole.[5] However, it is clear that the pericardium serves no vital function because it can be removed surgically when diseased without untoward effect.

Figure 205-1 Diagram of the caudal surface of the developing diaphragm. Major structures involved in the formation of the diaphragm are in italics. *Septum transversum* forms the ventral half of the diaphragm and fuses dorsomedially with the *mesesophagus*. *Pleuroperitoneal folds* or membranes extend ventrally and medially *(arrows)* to close pleuroperitoneal canals by fusing with septum transversum and mesesophagus. A pericardioperitoneal diaphragmatic hernia develops as a result of a defect in the ventral portion of the septum transversum. (From King AS: The Cardiorespiratory System. Integration of Normal and Pathological Structure and Function. Oxford, Blackwell Science, 1999, pp 178–217. With permission.)



205.2 CONGENITAL PERICARDIAL DISORDERS

Congenital pericardial disorders include pericardioperitoneal diaphragmatic hernia (PPDH), benign intrapericardial cysts, and pericardial defects. Congenital pericardial disorders are much less common than those that are acquired. However, they represent an important group because they are frequently amendable to surgical correction and, consequently, generally confer an excellent prognosis.

205.2.1 Pericardioperitoneal Diaphragmatic Hernia

A PPDH exists when a defect in the ventral diaphragm and pericardium allows abdominal contents to enter the pericardial space. Herniated structures include liver, gall bladder, spleen, stomach, small intestine, omentum, and falciform ligament. In the dog and cat the defect is congenital, whereas in humans, the diaphragm forms one wall of the pericardial sac and PPDH can be traumatic. The diaphragm does not form part of the pericardium in small animals, and traumatic PPDH has not been reported in either the dog or cat.[7,8]

205.2.1.1 Pathophysiology

In the developing embryo, the diaphragm forms from four structures: (1) the septum transversum, (2) the mesesophagus (or caudal mediastinum), (3) a pair of pleuroperitoneal folds or membranes, and (4) tissue from the body wall (Figure 205-1). The septum transversum, a thick plate of ventrally located mesodermal tissue, partially separates the thoracic and abdominal cavities. It fuses with the mesesophagus, which is located dorsomedially. The aorta, esophagus, and the caudal vena cava pass through the mesesophagus. The pleural and peritoneal cavities communicate on either side of the mesesophagus via the right and left pleuroperitoneal canals. Closure of the pleuroperitoneal canals occurs via formation of the pleuroperitoneal folds or membranes, which expand and fuse with the septum transversum ventrally and with the mesesophagus medially. Finally, as the thoracic cage enlarges during fetal growth, tissue from the body wall becomes incorporated circumferentially into the diaphragm.[9–11]

Several theories for the formation of PPDH have been proposed, including failure of complete fusion of the pleuroperitoneal membranes with the septum transversum or mesesophagus.[12] However, defects in that location result in congenital diaphragmatic hernias or communications between the pleural and peritoneal spaces. Congenital diaphragmatic hernias are among the most common congenital malformations in humans,[11] but they are rare in small animals.[9,10] In small animals with PPDH, communication between the peritoneal and pericardial space occurs via the ventral portion of the diaphragm, and the following pathogenesis has been proposed: the liver arises as a large ventral outgrowth from the foregut ectoderm, and it grows cranioventrally and penetrates the septum transversum.[9–11] Hematopoietic cells, Kupffer cells, and connective tissue of the liver are all derived from the septum transversum.[13] As the liver develops, it distracts from the septum transversum, forming the ventral mesentery that eventually becomes the falciform ligament. If separation between the developing liver and septum transversum is defective, an opening in the ventral part of the diaphragm may occur or the tissue may be so thin that it ruptures, allowing the peritoneal and pericardial cavities to communicate. Abdominal organs may then pass through the defect directly into the pericardial, space resulting in a PPDH.[9,10]

1105 1106

205.2.1.2 Epidemiology

Whereas PPDH is the most common congenital pericardial anomaly in small animals, it is an uncommon diagnosis. The veterinary medical data base (VMDB) at Purdue University from January 1992 to April 2003 included 62 cats with PPDH among 114,826 new cases, giving a prevalence rate of 0.054%, or one case for every 1852 cats in the data base. Fifty three percent were diagnosed in cats 4 years of age or less, and 16% were first diagnosed in cats 10 years of age or older. The cases in the VMDB disclosed no apparent sex predisposition (35 males:27 females). The majority of affected cases were domestic long-or shorthairs (n = 35). The most commonly affected purebred cats were Himalayans (n = 11). Persians were the second most common purebred cats in the data base (n = 7), and this breed may be predisposed to PPDH.[8] A pattern of inheritance of PPDH in cats has not been established, but congenital agenesis of all or part of the diaphragm in cats is reported to have an autosomal recessive mode of inheritance.[14]

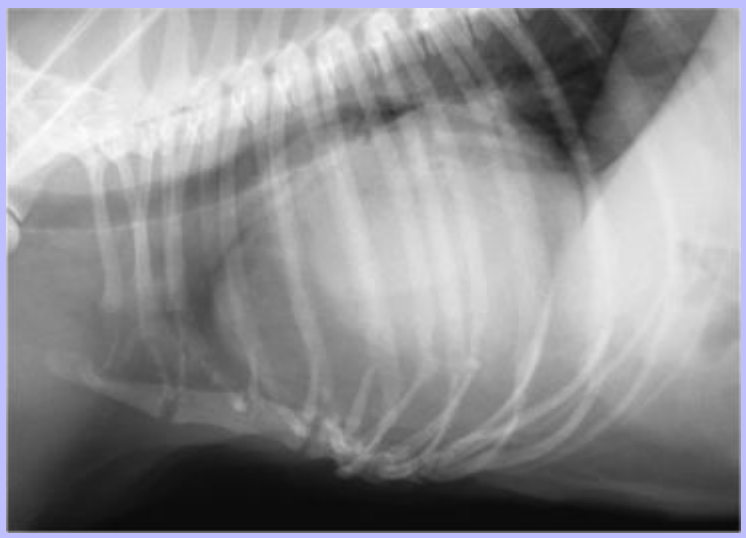
PPDH is less prevalent among dogs than cats. The VMDB from January 1992 to April 2003 included 76 dogs with a PPDH among 399,195 new cases, giving a prevalence rate of 0.019%, or one case for every 5263 dogs in the data base. The diagnosis was most common in younger dogs, with 65% of cases diagnosed in dogs 4 years of age or younger. As in cats, no sex predisposition was apparent (40 males:33 females [the

sex of three dogs was not reported]). Most cases were in mixed breed dogs (n = 12). Among purebred dogs, weimaraners were most commonly affected (n = 7), and this breed appears to be predisposed.[12]

205.2.1.3 Presenting and Clinical Signs

Presenting and clinical signs vary depending on the herniated organ, organs, or tissue. Some affected animals show no clinical signs, and PPDH is an incidental finding. In symptomatic animals, signs referable to the respiratory and gastrointestinal (GI) systems predominate. Tachypnea, respiratory distress, vomiting, and anorexia are common.[8,15] Other presenting complaints include lethargy, weight loss, diarrhea, and coughing. On physical examination, the apex beat may be absent or displaced, and heart sounds are frequently muffled. Some cases have a fever. Additional associated abnormalities in dogs are commonly reported and include sternal malformations (incomplete xiphoid; pectus excavatum; and absent, deformed, and fused sternebrae), ventral abdominal hernias, and other congenital heart defects (pulmonic stenosis, ventricular septal defect).[12,16] Associated abnormalities in cats are less common and are usually limited to sternal malformations and ventral abdominal hernias.[8,12,17] A PPDH should be suspected in any animal with a large umbilical or cranial abdominal hernia, sternal malformation, or history of abdominal hernia repair.[18,19]

Figure 205-2 Lateral thoracic radiograph of a dog with a pericardioperitoneal diaphragmatic hernia showing an enlarged cardiac silhouette that contains differential opacities and missing and deformed sternebrae.



205.2.1.4 Diagnosis

Radiographic findings that support a diagnosis of PPDH include enlargement of the cardiac silhouette with dorsal displacement of trachea, overlapping of the diaphragmatic and caudal cardiac silhouette borders, and

sternal malformations. Signs of left-sided congestive heart failure (CHF) are absent. The cardiac silhouette often contains differential opacities and gas-filled bowel loops (Figure 205-2). A radiographic feature of PPDH that has been described in cats is the presence of a dorsal peritoneopericardial mesothelial remnant. The dorsal peritoneopericardial mesothelial remnant represents the dorsal border of the hernia, and it is recognized in the lateral view as a curvilinear opacity between the cardiac silhouette and the diaphragm ventral to or superimposed over the caudal vena cava. The hepatic silhouette may be smaller than normal or absent in the anterior abdomen (Figure 205-3).[12,17] Positive and negative contrast peritoneography and GI contrast studies are occasionally necessary to confirm the presence of a PPDH.

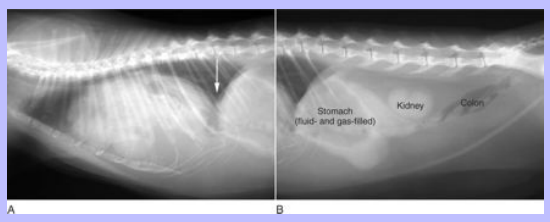
Electrocardiograms in cases with PPDH may be normal or show low-voltage complexes and abnormal orientation of the mean electrical axis.[8] Echocardiography readily discloses the presence of abdominal viscera within the pericardial sac.[7] Pericardial effusion is present in some cases.[7,8] In cats the liver is the most commonly herniated organ, and focal hyperechoic areas are frequently seen within the herniated liver lobe or lobes (Figure 205-4). Myelolipomas, nodules composed of mature adipose tissue and bone marrow elements, have been reported within herniated liver in cats. These nodules originate as metaplastic change resulting from chronic hypoxia caused by incarceration of liver.[7,20,21] The presence of myelolipomas, or nodular myelomatosis, probably accounts for the focal areas of hyperechogenicity seen within herniated liver lobes.[7]

205.2.1.5 Treatment

Surgical repair is necessary for all cases with PPDH that show clinical signs ascribable to the defect. Repair is also recommended in all young animals with PPDH, whether symptomatic or not. Resection of devitalized herniated tissue is frequently necessary. The prognosis with surgery is generally excellent. In older animals, adhesions between herniated organs and the pericardium that complicate or preclude reduction of the hernia may be present.[15] Consequently, in an asymptomatic older animal in which PPDH is detected as an incidental finding, and especially in those cases where the hernia includes only omentum or falciform fat, it may be prudent to recommend observation rather than surgical repair.

1106 1107

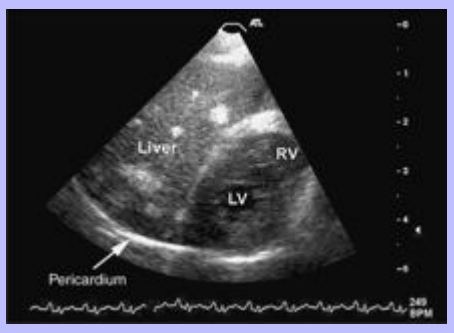
Figure 205-3 Lateral thoracic and abdominal radiographs of a cat with a pericardioperitoneal diaphragmatic hernia. **A,** Markedly enlarged cardiac silhouette that contains differential opacities and gas-filled bowel loops. The curvilinear opacity between the diaphragm and cardiac silhouette *(arrow)* is the dorsal margin of the hernia or the dorsal pericardioperitoneal mesothelial remnant. **B,** Most of the abdominal contents, including the liver and small intestines, are displaced into the pericardial sac.



205.2.2 Benign Intrapericardial Cysts

Large benign intrapericardial cysts occur occasionally in dogs. In virtually all cases, histopathology discloses that the cysts are encapsulated adipose tissue (with extensive hemorrhage and necrosis) or organizing cystic hematomas. True congenital pericardial cysts in humans are endothelium-, epithelium-, or mesothelium-lined, depending on their origin. These are extremely rare in dogs[22,23] and have not been described in cats. Clinical signs in affected dogs include abdominal distention, exercise intolerance, anorexia, and labored breathing. The intrapericardial cysts are demonstrated by echocardiography, and most cases have concomitant pericardial effusion. In some cases, benign intrapericardial cysts are associated with a small PPDH. In others the cyst is attached by a pedicle to the apex of the pericardium. In such cases the cyst is thought to represent prenatal herniation of omentum or falciform fat from the peritoneum into the pericardium and subsequent closure of a PPDH. Cyst formation probably results from vascular obstruction of the herniated tissue or repeated trauma from the beating heart.[19,22] Intrapericardial hepatic cysts have been described in cats with PPDH as a result of incarceration of portions of the liver.[24,25] Benign intrapericardial cysts are treated by surgical removal of the cyst and its associated pedicle, pericardiectomy, and PPDH repair when necessary.

Figure 205-4 Echocardiogram (short axis view from the right parasternal location) from cat with a pericardioperitoneal diaphragmatic hernia. Liver is present within pericardial sac adjacent to caudal aspect and right side of heart. The focal areas of hyperechogenicity within the liver parenchyma are probably due to myelolipomas. *LV,* Left ventricle; *RV,* right ventricle.



205.2.3 Pericardial Defects

Pericardial defects are very rare in dogs and are usually found incidentally on postmortem examination. Some of these defects are thought to be congenital. In a series of eight cases, single defects were present in four dogs, with up to four defects in the remaining dogs. The defects ranged in size from a single 10 × 5 mm hole to total absence of one side of the pericardium. The defects were on the left side in four dogs, on the right side in two, and on both sides in two.[26] Herniation and incarceration of cardiac chambers through pericardial defects has been reported.[26–28]

205.3 ACQUIRED PERICARDIAL DISORDERS

205.3.1 Pericardial Effusion

The most common pericardial disorders in small animals are associated with abnormal accumulations of pericardial fluid or pericardial effusions. At the Veterinary Hospital, University of Pennsylvania from 1990 to 1993, pericardial effusion was present in 7% of dogs with reliable signs of heart disease.[29] At the University of Minnesota Veterinary Medical Center (UMVMC) from January 1999 to December 2001, pericardial effusion was confirmed as the primary cause for clinical signs in 87 of 20,282 new canine cases that were presented to the small animal hospital. This reflects a prevalence rate of 0.43%, or one dog with clinically significant pericardial effusion among every 233 new hospital cases. Thus pericardial effusion is fairly common in the canine patient population at referral hospitals.

1107 1108

205.3.1.1 Pathophysiology of Pericardial Effusion: Cardiac Tamponade

Cardiac tamponade is defined as significant compression of the heart by accumulating pericardial contents. *Significant compression* depends on whether tamponade is approached from a physiologic or clinical standpoint. Tamponade is a pathophysiologic continuum, not an all-or-none phenomenon. Physiologic abnormalities can be detected with very small amounts of pericardial effusion, although affected cases may show only mild clinical signs (mild tamponade). At the opposite end of the spectrum, acute accumulations of even small amounts of effusion can result in life-threatening hemodynamic compromise (florid tamponade).[30] The classic clinical hemodynamic profile of tamponade includes pulsus paradoxus, elevation and equilibration of right and left ventricular diastolic pressure with pericardial pressure, and depressed cardiac output.[31]

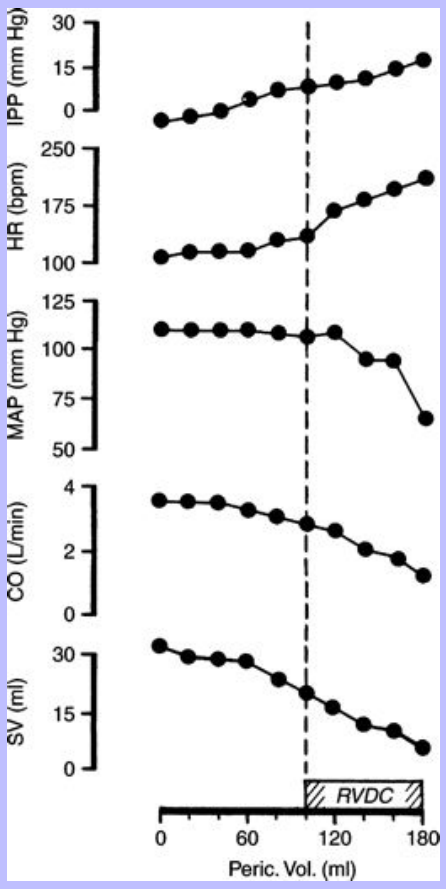
The major pathophysiologic abnormality associated with increased intrapericardial pressure is impaired ventricular filling in diastole, resulting inevitably in diminished stroke volume. For each cardiac chamber, transmural pressure (intracardiac pressure minus intrapericardial pressure) is a principle determinant of its filling. Mean atrial pressure and ventricular diastolic pressure is normally higher than intrapericardial pressure, resulting in positive transmural or filling pressure. In tamponade, rising intrapericardial pressure progressively reduces and can eventually make the transmural pressures of first the right-and then the left-sided cardiac chambers phasically negative. In addition to the deleterious effects on diastolic function, pericardial effusion results in decreased systolic performance because the compressed and underfilled chambers operate at the lower end of their respective Frank-Starling curves.[30]

Figure 205-5 shows the results of an experiment in which intrapericardial volume was increased by infusing 10 mL of warm saline per minute in a dog. Cardiac output and stroke volume steadily decreased with increasing intrapericardial volume and pressure. Mean arterial pressure (MAP) was maintained until intrapericardial volume had increased to approximately 100 mL, and intrapericardial pressure was approximately 10 mm Hg. MAP then dropped sharply as intrapericardial volume was further increased.[32] As illustrated by this experiment, acute accumulations of relatively small amounts of pericardial effusion can result in profound hemodynamic compromise with a clinical picture that is dominated by signs of low cardiac output.

With more chronic accumulations of pericardial effusion, the volume of the pericardial space increases with concomitant expansion of the pericardial sac. The precise mechanisms of pericardial expansion are

uncertain and may include fibroblast proliferation with new connective tissue deposition, remodeling of the pre-existent connective tissue, or both.[33] In addition, a variety of compensatory mechanisms increase preload or filling pressure in an effort to restore cardiac output. The compensatory mechanisms are similar to the various neurohormonal changes that accompany other forms of cardiac disease. Activation of the renin-angiotensin-aldosterone system leads to increased angiotensin II, aldosterone, vasopressin, and sympathetic nervous stimulation, which result in fluid retention and increased heart rate. However, unlike other forms of cardiac disease that result in increased preload, atrial natriuretic peptide does not increase. Despite increased venous pressure, atrial distention, the primary stimulus for secretion of atrial natriuretic peptide, does not occur because of external compression of the heart. Thus tamponade prevents this mechanism for increased renal natriuresis, and this, together with the various other compensatory mechanisms, contributes to increased blood volume and venous pressure.[34,35] Consequently, with chronic pericardial effusion, signs of increased systemic venous pressure predominate and manifest as right-sided CHF.

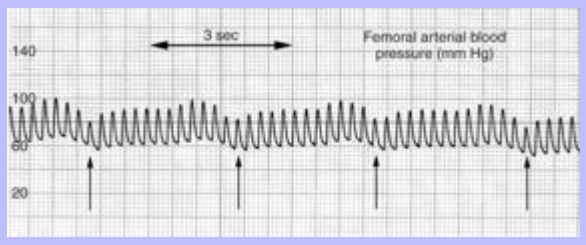
Figure 205-5 Hemodynamic effects of intrapericardial saline infusion in a dog. Cardiac output *(CO)* and stroke volume *(SV)* decrease as soon as intrapericardial volume begins to increase. Mean arterial pressure *(MAP)* is maintained until intrapericardial volume *(Peric. Vol.)* has increased to 100 mL and intrapericardial pressure *(IPP)* is approximately 10 mm Hg. MAP then drops rapidly with any further increases in intrapericardial volume and pressure. Echocardiography performed during experiment showed that right ventricular diastolic collapse *(RVDC)* first develops when intrapericardial pressure reaches approximately 10 mm Hg. *HR*, Heart rate. (From Leimgruber PP et al: The hemodynamic derangement associated with right ventricular diastolic collapse in cardiac tamponade: an experimental echocardiographic study. *Circulation* 68:612, 1983. With permission.)



Pulsus paradoxus was first described by Kussmaul in 1873 as the apparent paradox of a disappearing pulse during inspiration despite persistence of the heartbeat in patients with pericardial disease.[36] It is defined as a decrease (>10 mm Hg) in systolic arterial blood pressure with inspiration during normal breathing (Figure 205-6).[37] Pulsus paradoxus is an accentuation of the normal small decline of left ventricular stroke volume and systemic arterial blood pressure that occurs with inspiration. During inspiration, intrathoracic pressure decreases and blood flows preferentially into the pulmonary veins, right atrium, and ventricle, because these are the most compliant intrathoracic blood vessels and cardiac chambers. Blood pooling in the pulmonary veins reduces preload to the left heart and consequently reduces left ventricular stroke volume. In humans, left ventricular stroke volume normally decreases by an average of 7% during inspiration, and this is associated with a 3% drop in systolic arterial blood pressure. Right ventricular stroke volume, on the other hand, increases during inspiration due to increased right-sided filling. With a normal pericardium, the phasic variations in right ventricular volume have little effect on the left ventricle, and pooling of blood in the pulmonary veins is the most important contributor to decreased left ventricular stroke volume during inspiration.[38]

1108
1109

Figure 205-6 Femoral arterial blood pressure showing pulsus paradoxus in a dog with pericardial effusion. At end-inspiration *(arrows)*, systolic blood pressure decreases by more than 10 mm Hg and pulse pressure narrows.



Reciprocal and phasic changes with respiration in left and right ventricular filling and stroke volume are exaggerated in the presence of pericardial effusion. Outward expansion of the ventricles is limited, and any increase in the volume of one ventricle can only occur at the expense of the other. Thus greater right ventricular filling during inspiration increases the pressure within the pericardial sac. This, in turn, further compresses the left ventricle. In addition, increased right ventricular filling causes the interventricular septum to deviate toward the left ventricle, further compromising left ventricular volume.[36] This interaction between the ventricles is superimposed upon the normal decrease in left ventricular stroke volume that occurs during inspiration and leads to pulsus paradoxus. The inspiratory increase in right ventricular filling is indispensable for pulsus paradoxus. When systemic venous return is held constant, tamponade does not result in pulsus paradoxus.[39]

205.3.1.2 Epidemiology

Pericardial disorders resulting in effusion occur primarily in older, large breed dogs. No apparent sex predisposition exists. At the UMVMC from January 1999 to December 2001, the average age among 87 dogs with pericardial effusion was 9.7 years (±2.2 years), average weight was 31.2 kg (±12.6 kg), and

males and females were nearly equally represented (46 males:41 females). Pericardial effusion occurred most frequently in golden retrievers, and its prevalence in this breed was striking. Of the 87 affected dogs, 23 (26%) were golden retrievers. The breed was significantly over-represented when compared with the general hospital population (odds ratio, 4.4; 95% confidence interval, 2.7 to 7.0). Golden retrievers were also the most common breed among dogs with pericardial effusion at the Veterinary Hospital, University of Pennsylvania from 1990 to 1993.[29]

Information regarding the epidemiology of pericardial effusions in cats is limited. One study reported 66 cases with pericardial disease among 2852 feline necropsies. Pericardial effusion was present in 58 cases, and eight had pericardial pathology but no significant effusion. In virtually all cases the pericardial disorder formed part of a more generalized disease, most commonly CHF and feline infectious peritonitis (FIP). Pericardial pathology appears to attend many feline diseases, but symptomatic pericardial effusion in the cat is uncommon.[40]

205.3.1.3 Presenting and Clinical Signs

The presenting signs among dogs with pericardial effusion are remarkably diverse and include lethargy, respiratory distress, reduced appetite, episodic collapse, vomiting, and abdominal distention. Polydipsia, weakness, and coughing are also occasionally reported. Common physical examination findings are muffled heart sounds, weak pulses, pale mucous membranes, and abdominal distention with a fluid wave. Thorough examination reveals jugular distention in most cases. Pulsus paradoxus is usually subtle, but careful pulse palpation may disclose variations in pulse quality associated with phase of respiration.

205.3.1.4 Diagnostic Procedures

205.3.1.4.1 Radiology

Thoracic radiographs in cases with pericardial effusion are frequently described as showing an enlarged and globoid cardiac silhouette, with tracheal elevation and widening of the caudal vena cava. The cardiac silhouette and diaphragm overlap, and in the dorsoventral or ventrodorsal projection, the pericardial sac may touch the costal margins bilaterally. The edge of the distended pericardial sac is often distinct because it undergoes little, if any, motion during systole and diastole. The lung fields are clear of any infiltrate to indicate the presence of left-sided CHF (Figure 205-7).

These radiographic findings, when present, strongly support the presence of a pericardial effusion. *1109*
However, such “typical” findings are only present in more chronic cases with large volume pericardial *1110*
effusions. In cases with accumulations of smaller amounts of pericardial effusion, findings on thoracic radiography are much more subtle. In these cases the cardiac silhouette is enlarged but it is not necessarily globoid, suggesting additional differential diagnoses such as dilated cardiomyopathy. Some pleural effusion is frequently present in dogs with pericardial effusion and may obscure the cardiac silhouette.

Figure 205-7 Lateral thoracic radiograph of a dog with severe, chronic pericardial effusion. Cardiac silhouette is globoid and overlaps diaphragm, and trachea is elevated. A total of 1600 mL of pericardial effusion was removed by pericardiocentesis. Histopathology of the pericardium disclosed pericardial mesothelioma.

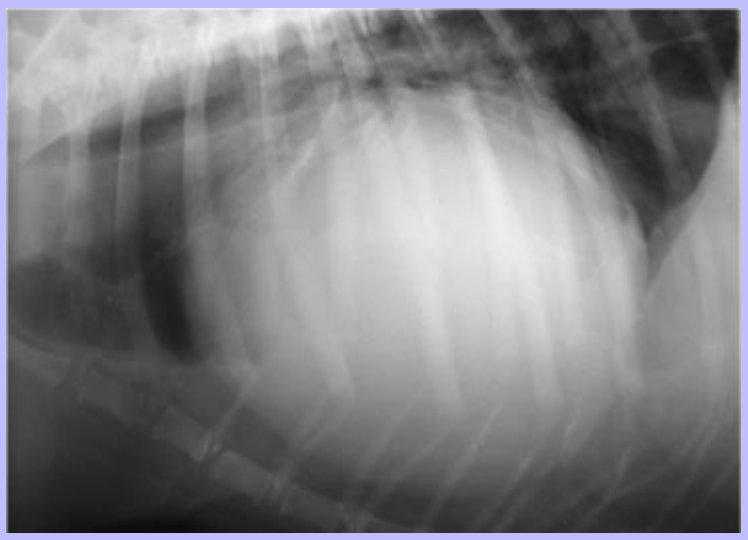


Figure 205-8 Lateral thoracic radiographs of two dogs with pericardial effusions. In both cases, volume of effusion was considerably less than in dog in Figure 205-7, and cardiac silhouettes are consequently much smaller and less globoid. **A,** Focal disseminate pulmonary metastases. The final diagnosis was metastatic cardiac hemangiosarcoma. **B,** A radiopaque foreign body due to an intrapericardial metal pellet.

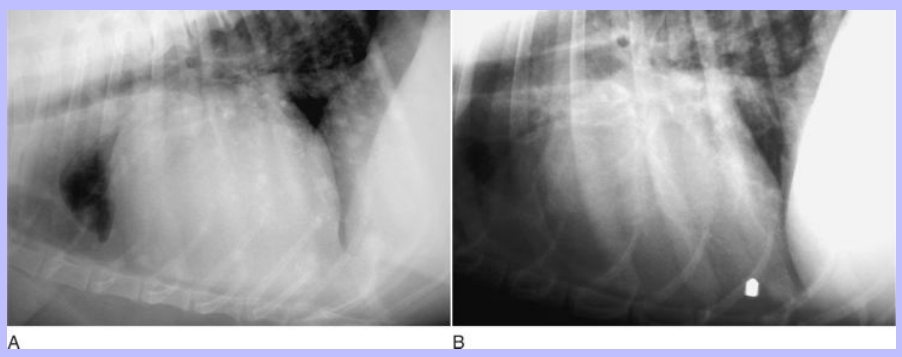


Despite the various limitations, thoracic radiography is an important component of the diagnostic evaluation of cases with suspected pericardial effusion. In addition to facilitating a diagnosis of pericardial effusion in many cases, thoracic radiographs may demonstrate the presence of other abnormalities, such as pulmonary metastases (Figure 205-8, *A*), or radiopaque intrapericardial foreign bodies (Figure 205-8, *B*).

205.3.1.4.2

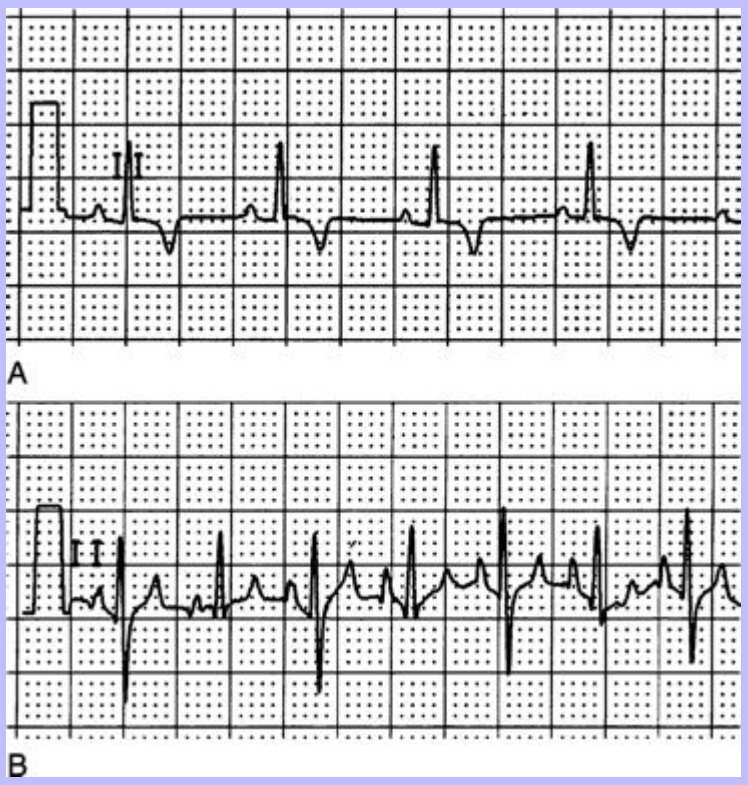
Electrocardiography

In most dogs with pericardial effusion, electrocardiography discloses either a normal sinus rhythm or a sinus tachycardia. Ventricular arrhythmias are fairly common, and supraventricular arrhythmias occasionally occur. Low-voltage QRS complexes (<1 mV in all limb leads) are present in approximately half of the cases with pericardial effusion in which electrocardiography is performed (Figure 205-9, *A*). Other differential diagnoses that result in low-voltage electrocar-diographic complexes include pleural effusion, obesity, and hypothyroidism.

Electrical alternans, a beat-to-beat variation in the contour and amplitude of the QRS and ST-T complexes (Figure 205-9, *B*), is strongly suggestive of a pericardial effusion.[41] Electrical alternans results from 2:1 swinging of the heart, or swinging once every other heartbeat in large pericardial effusions. In humans, clinical data and mathematic modeling show that electrical alternans is a rate-dependant phenomenon that occurs at heart rates of between 90 and 144 beats per minute.[42]

In the original report of electrical alternans in dogs, the electrocardiographic feature was present in seven of 11 dogs (64%) with pericardial effusion, and it was more prone to occur in cases with larger effusions.[41] However, subsequent reports indicate that electrical alternans among dogs with pericardial effusion occurs relatively infrequently. In two studies in dogs with confirmed pericardial effusions, electrical alternans was present in only two of 33 (6.4%) and two of 10 cases (20%).[43,44] Electrical alternans is a similarly insensitive indicator of pericardial effusion in humans, and it occasionally occurs with disorders other than pericardial effusion in both humans and dogs.[41,45,46] Electrical alternans has been reported in cats with pericardial effusion.[40] Electrocardiographic findings are generally too few, subtle, and insensitive to be considered particularly useful as an indicator of the presence of pericardial effusion. However, electrocardiography is indicated in patients with signs of low cardiac output, when arrhythmias are detected on physical examination, and when thoracic radiographs demonstrate enlargement of the cardiac silhouette. Under these circumstances, an electrocardiogram that shows changes consistent with a pericardial effusion will facilitate the diagnosis.

Figure 205-9 Electrocardiograms (lead *II*) from two dogs with pericardial effusions. Calibration square wave is 1 mV in amplitude. **A,** Low-voltage (<1 mV) complexes. **B,** Beat-to-beat variations in amplitude and contour of QRS and ST-T complexes that characterize electrical alternans.



205.3.1.4.3 Pericardial Fluid Analysis

The diagnostic value of pericardial fluid analysis is limited. In dogs, the gross appearance of pericardial effusions is virtually always sanguineous or serosanguineous irrespective of cause, and they are usually classified as hemorrhagic effusions or sterile inflammatory exudates. Total nucleated cell counts, red cell counts, and protein concentrations of pericardial fluid overlap extensively between the various neoplastic and non-neoplastic causes.[47] The pH of pericardial fluid has been reported to distinguish between neoplastic and non-neoplastic effusions.[48] However, considerable overlap in pH values exists between the various causes of pericardial effusion, and pH measurements of pericardial fluid have little clinical use.[49] Hemangiosarcoma and aortic body tumors, the most common tumors associated with pericardial effusions in dogs, are rarely identified on cytologic evaluation of pericardial fluid, presumably because they do not readily exfoliate. Further, pericardial diseases that lead to effusion result in dramatic mesothelial proliferation, and exfoliated mesothelial cells often have characteristics that mimic

malignancy. Consequently, pericardial fluid analysis is associated with a high incidence of false-negative and false-positive cytologic diagnoses of neoplasia.[47,50,51]

Despite these limitations, pericardial effusion cytology does occasionally provide crucial information, and pericardial effusion analysis is especially important for those cases in which no intrapericardial masses suggestive of hemangiosarcoma or aortic body tumor are detected on echocardiography. Some of the less common causes of pericardial effusion, such as infective pericarditis and lymphosarcoma, are diagnosed primarily based on pericardial fluid cytology. Consequently, pericardial fluid analysis is an important component of the evaluation in cases with pericardial effusion, but the results must be interpreted with appropriate care and understanding of the limitations of the test.

205.3.1.4.4

Additional Laboratory Tests

Dogs with hemangiosarcoma are frequently anemic and may have nucleated red blood cells (RBCs), schistocytes, acanthocytes, and thrombocytopenia. Mild to moderate elevations in liver enzymes are frequently present as a result of hepatic congestion. Analysis of ascitic fluid is consistent with a modified transudate. Mild azotemia, which is usually prerenal, may be present. Cats with FIP may have a neutrophilia, lymphocytopenia, and hyperglobulinemia. *Coccidioides immitis* serology should be performed in cases with pericardial disease from endemic areas. Some assessment of coagulation (e.g., activated coagulation time [ACT]) should be performed prior to pericardiocentesis, especially if a coagulopathy is suspected clinically.

205.3.1.4.5

Echocardiography

Echocardiography is the most sensitive and specific noninvasive method to confirm the presence of pericardial effusion, and it has replaced many of the radiographic procedures (fluoroscopy, angiography, and pneumopericardiography) that were previously used to identify the presence and causes of pericardial effusions. With two-dimensional echocardiography, pericardial effusion appears as an anechoic space surrounding the heart. In cases with concurrent pleural effusion, the pericardium is well visualized with anechoic fluid on either side. The heart may show swinging motions within the pericardial fluid. The various heart chambers may appear small, and the walls may show thickening or pseudohypertrophy due to compression.[52]

Pericardial fluid is usually readily distinguishable from pleural effusion, although this is not invariably the case. Pericardial effusion is contained within a circular region around the heart, where it provides contrast for various cardiac chambers, such as the walls of right atrium and auricle and the proximal aorta. Pleural effusion is more diffuse and contains the edges of lung lobes and mediastinum.

The changes in transmural pressure and intracardiac flow with pericardial effusion are reflected in several useful and readily detectable echocardiographic findings. These include inversion or collapse of the right atrial and ventricular free walls resulting from reversal of transmural pressure, as well as exaggerated respiratory variation in blood flow through the right and left heart.

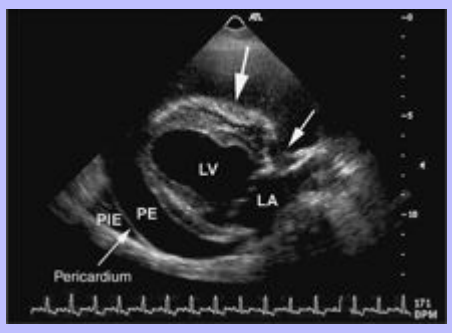
The right atrial free wall is normally rounded throughout the cardiac cycle, reflecting the normal positive right atrial transmural pressure. Any inversion of the right atrial free wall is therefore indirect evidence of elevated intrapericardial pressure and transient reversal of transmural pressure. Right atrial inversion occurs in late diastole and continues into ventricular systole for a variable period before normalizing. Right ventricular diastolic collapse is characterized by inward motion of the right ventricular free wall

during diastole. With mild tamponade, this inward movement produces a localized concavity of the right ventricular free wall. With severe cardiac tamponade, right ventricular diastolic collapse persists throughout diastole, and the right ventricular chamber is almost completely obliterated (Figure 205-10).[53]

Doppler studies of normal hearts demonstrate slightly decreased flow velocity across the mitral valve and slightly increased flow velocity across the tricuspid valve during inspiration. The changes in aortic and pulmonic flow velocity are smaller; however, aortic flow velocity decreases slightly during inspiration, and pulmonic flow velocity increases. In humans, these respiratory changes in flow velocity become markedly accentuated with pericardial effusion, even in the absence of clinical signs of cardiac tamponade.[53] These Doppler indicators are present in dogs with experimentally induced tamponade.[54] 1111

However, the clinical use of Doppler studies in the evaluation of small animals with pericardial effusion has yet to be determined. In addition to confirming the presence of a pericardial effusion and providing evidence of tamponade, echocardiography is the noninvasive procedure of choice to detect intrapericardial masses such as hemangiosarcoma and heart base tumors. Although histopathology is necessary to confirm and definitively identify a tumor, the location and characteristics of an intrapericardial or myocardial mass demonstrated during echocardiography provides important information about the probable tumor type.[55,56] 1112

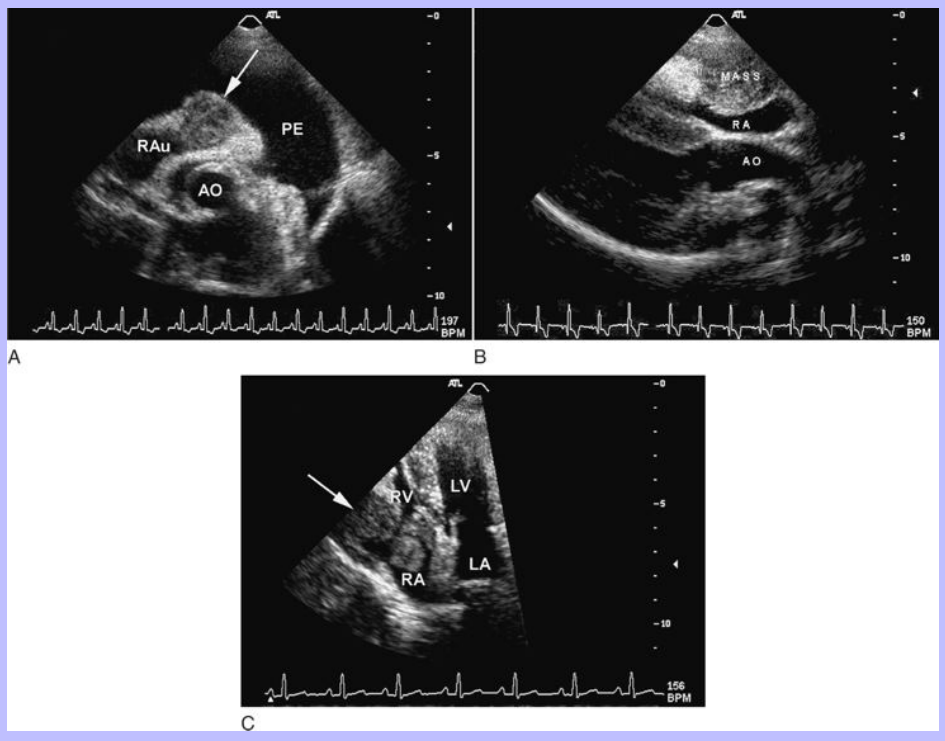
Figure 205-10 Echocardiogram (long axis four-chamber view from the right parasternal location) from dog with pericardial effusion *(PE)* and echocardiographic evidence of tamponade. Right atrial inversion is apparent *(small arrow)*, and right ventricular collapse *(large arrow)* results in virtually complete obliteration of right ventricular chamber. *LA,* Left atrium; *LV,* left ventricle; *PlE,* pleural effusion.



Hemangiosarcoma, a highly malignant neoplasm of vascular endothelium, is the most commonly diagnosed cardiac tumor in dogs. It occurs with an approximately tenfold greater prevalence than the second most common cardiac tumor—aortic body tumors.[57] Primary and metastatic cardiac hemangiosarcoma in the cat has been reported, but it is rare.[58] Hemangiosarcoma most commonly arises from the wall of the right atrium or auricle, protrudes into the pericardial space, and moves with the right auricle or atrium (Figures 205-11, *A* and *B*). These tumors may also protrude into the right atrial chamber, spread to involve other areas of the heart base and pericardium, and involve the right atrioventricular (AV) junction (Figure 205-11, *C*). Hemangiosarcoma involving the wall of the left

ventricle has been described.[59] Hemangiosarcoma typically contains small hypoechoic spaces, giving the tumor a mottled or cavitary appearance, and the tumors are occasionally cystic. Hemangiosarcoma, when present, is usually demonstrated while imaging from the right parasternal long and short axis views. However, these tumors may be small and elusive. Imaging from the left caudal parasternal location to obtain a four-chamber view and from the left cranial parasternal location to provide alternate imaging planes, especially of the right auricle, is necessary to demonstrate the presence of hemangiosarcoma in some cases.

Figure 205-11 Echocardiograms from dogs with cardiac hemangiosarcoma. **A,** Short axis view from right parasternal location, shows a round, cavitary, transmural tumor *(arrow)* near tip of right auricle *(RAu)*. **B,** Long axis left ventricular outflow view from right parasternal location, shows tumor *(MASS)* that involves wall of the right atrium *(RA)*. **C,** Four-chamber (inflow) view from the left caudal parasternal location, shows cavitary tumor *(arrow)* that extensively involves right atrioventricular junction. Part of the tumor protrudes into the right atrium *(RA)* and partially occludes tricuspid valve. *AO,* Aorta; *PE,* pericardial effusion; *RV,* right ventricle; *LA,* left atrium; *LV,* left ventricle.



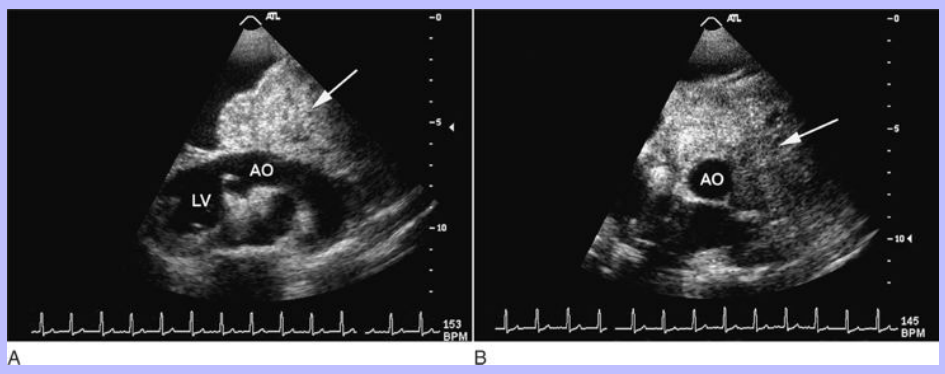
The term *heart base tumor* is used to designate any mass located at the base of the heart in association with the ascending aorta and main pulmonary artery. The most common heart base tumors in dogs are aortic body tumors, which arise from specialized neuroepithelial cells that reside within the adventitia of the aortic arch. The specialized neuroepithelial cells or chemoreceptors serve to detect minute changes in blood oxygen and carbon dioxide tensions, pH, and temperature. Tumors of chemoreceptors are termed *chemodectomas*. They comprise a subgroup of tumors referred to as *paragangliomas*, all of which arise from cells that share a common embryologic origin from the neural crest. Chemoreceptors occur in a variety of locations in the body, including the aortic body, carotid body, nodose ganglion of the vagus nerve, ciliary ganglion in the orbit, pancreas, internal jugular vein below the middle ear, and glomus jugulare along the recurrent branch of the glossopharyngeal nerve.[60,61] Owing to the location of the aortic chemoreceptors, only aortic body chemodectomas are associated with pericardial effusion.[61] In addition to aortic body tumors, between 5% and 10% of heart base tumors in dogs are thyroid tumors (both adenomas and adenocarcinomas) that arise from ectopic thyroid tissue at the base of the heart.[62–66] Aortic body tumors have occasionally been reported in cats.[67–70]

Heart base tumors are usually associated with the ascending aorta. They vary from small ovoid structures attached to the cranial aspect of the ascending aorta to very extensive masses that surround the aorta and main pulmonary artery (Figure 205-12). Tumor indentation or invasion of the atria may be seen. Heart base tumors tend to have a more homogenous appearance than the mottled or cavitary appearance of hemangiosarcoma. They are usually (but not invariably) associated with pericardial effusions.

Echocardiography may also demonstrate other cardiac tumors, the presence of abdominal viscera within the pericardial sac in cases with PPDH, benign intrapericardial cysts, and intrapericardial thrombi associated with left atrial rupture. Left atrial rupture is suspected when signs of acute tamponade develop in smaller breed dogs with significant mitral regurgitation.

Confirming the presence of pericardial effusion with echocardiography is rapid, straightforward, and accurate. However, echocardiography is also crucial for determining the presence or absence of intrapericardial masses, and it provides important information about the size and location of tumors and their accessibility for surgical resection. Identification of intrapericardial tumors is frequently challenging, and transthoracic imaging in multiple planes from both left and right-sided locations may be necessary. The presence of pericardial fluid greatly facilitates the detection of intrapericardial masses, and this is particularly relevant to the diagnosis and delineation of hemangiosarcoma and heart base tumors. Pericardial fluid forms an echolucent zone around the right atrium and auricle and the ascending aorta, the locations at which these tumors most commonly occur. In the absence of pericardial fluid, these locations are obscured by lung interference. Consequently, whenever the clinical condition of the patient permits, pericardiocentesis should be deferred until a thorough echocardiographic examination has been completed.

Figure 205-12 Echocardiogram from dog with a heart base tumor. **A,** Long axis left ventricular outflow view obtained from the right parasternal location, shows a large tumor *(arrow)* attached to cranial aspect of ascending aorta *(AO)*. **B,** Short axis view obtained from right parasternal location, shows that tumor *(arrow)* virtually completely encircles the aorta. Histopathologic diagnosis was ectopic thyroid adenocarcinoma. *LV,* Left ventricle.



205.3.2 Acquired Pericardial Effusions: Specific Causes, Epidemiology, Treatment, and Prognosis

205.3.2.1 Idiopathic Pericardial Effusion

Idiopathic pericardial effusion is a diagnosis of exclusion. It is made in cases with pericardial effusion where no intrapericardial masses are identified after thorough echocardiographic evaluation and the results of ancillary tests, such as pericardial fluid analysis, fail to disclose a cause. Pericardial histopathology and immunohistochemistry from dogs with idiopathic pericardial effusion demonstrate extensive pericardial fibrosis and a mixed inflammatory response of greatest intensity at the cardiac surface of the tissue. Perivascular lymphoplasmacytic aggregates are present at the pleural surface within the fibrosed pericardium. No vascular pathology or deposition of immunoglobulin or complement within the vessel wall exists, suggesting that the pericarditis is not due to a vasculitis. Immunohistochemistry findings are consistent with a predominantly humoral immune response, but they do not support a primary immune-mediated pathogenesis. The factor or factors that initiate idiopathic pericarditis remain unknown.[71]

As with any diagnoses of exclusion, a diagnosis of idiopathic pericardial effusion should be made with appropriate caution. Small intrapericardial tumors may elude detection, especially in cases where echocardiography is performed after pericardiocentesis. In addition, mesothelioma is a diffuse neoplasm of the pericardium and other serosal surfaces, and it does not result in appreciable thickening of the pericardium on echocardiography. Cytology of pericardial effusion cannot distinguish between idiopathic pericardial effusion and mesothelioma.[51] Consequently, mesothelioma should always be considered as an

important differential diagnosis for idiopathic pericardial effusion. Idiopathic pericardial effusion has not been reported in cats.

Idiopathic pericardial effusion was diagnosed in eight of 42 dogs (19%) with pericardial effusion in a retrospective study from the Veterinary Teaching Hospital, Colorado State University.[43] Idiopathic pericardial effusion was provisionally diagnosed in 24 of 87 dogs with pericardial effusion at the UMVMC from January 1999 to December 2001, but mesothelioma was eventually confirmed in four of these cases. Consequently, 20 of 87 cases (23%) with pericardial effusion in the UMVMC study population were finally diagnosed as having idiopathic pericardial effusion, which is similar to the data from Colorado State University. Average age among the cases with idiopathic pericardial effusion in the UMVMC study population was 9.4 years (±2.2 years), average weight was 28.9 kg (±14.5 kg), and there was no apparent sex predisposition (11 males:9 females). Five of the 20 dogs (25%) were golden retrievers, and the breed was over-represented (odds ratio, 4.2; 95% confidence interval, 1.6 to 11.2).

The initial treatment for idiopathic pericardial effusion is pericardiocentesis to remove as much pericardial fluid as possible. The author's preferred approach is to restrain the animal in left lateral recumbency and to approach the pericardium from the right side (See Chapter 103).

The gross appearance of pericardial fluid is usually indistinguishable from blood. To confirm that the catheter is in the pericardial space, an aliquot of fluid is placed in an ACT tube. Blood will normally clot in an ACT tube within 60 to 90 seconds. In contrast, sanguineous effusions in body cavities are rapidly depleted of clotting factors and thrombocytes, and pericardial fluid will consequently not clot. If no clots form within the activated clotting tube after 3 to 5 minutes, all of pericardial fluid is aspirated and samples are collected for fluid analysis and culture. The catheter is then removed.

In virtually all cases with pericardial effusion, pericardiocentesis results in rapid and marked hemodynamic improvement. Clinical signs, pulse quality, and mucous membrane perfusion improve, and heart rate decreases. However, ventricular and supraventricular arrhythmias (including atrial fibrillation) are common after pericardiocentesis. These arrhythmias seldom require therapy and usually resolve spontaneously. The author prefers to hospitalize and monitor cases for 12 to 24 hours after pericardiocentesis.

The author usually treats an initial episode of idiopathic pericardial effusion by pericardiocentesis alone, followed by pericardiectomy in cases that develop recurrent effusions. Recurrent effusions, effusive-constrictive, and constrictive pericarditis are well-recognized complications after pericardiocentesis in cases with idiopathic pericardial effusion.[72–75] Among the 20 cases diagnosed with idiopathic pericardial effusion in the UMVMC study population, six died or were euthanized after developing recurrent effusions with tamponade within 44 days of their initial episode. Cardiac tamponade with pulmonary thromboembolism was the cause of death in one dog. Postmortem examinations were not performed in the remaining five cases, and the possibility that some dogs might have had cardiac tumors that eluded detection during echocardiography cannot be excluded. Among the remaining 14 dogs, four developed recurrent effusions necessitating pericardiectomy, and a further six developed effusive-constrictive pericarditis between 3 months and 3 years after their initial episode. Median survival time (MST) among the 20 cases was 663 days, indicating a generally good prognosis in cases with idiopathic pericardial effusion. However, the complication rate among these cases was high, and this is consistent with the results of others.[73,74]

The complication rate among cases with idiopathic pericardial effusion would probably be lower if pericardiectomy was performed at the time of the initial episode rather than after recurrent effusion. Pericardiectomy would avoid the risk of recurrent life-threatening cardiac tamponade and the potential for

developing effusive-constrictive and constrictive pericarditis. In addition, surgery permits examination of thoracic and intrapericardial structures to rule out other causes of pericardial effusion, including tumors and foreign bodies. Although pericardiectomy is by no means devoid of morbidity and mortality, it is an extremely successful procedure for idiopathic pericardial effusion.[76–79] Consequently, it is likely that pericardiectomy will increasingly form part of the initial treatment for cases with idiopathic pericardial effusion, especially as minimally invasive methods for the procedure become more widespread.[80,81]

Colchicine, nonsteroidal anti-inflammatories, and corticosteroids are prescribed for humans with recurrent idiopathic pericarditis. Colchicine and nonsteroidal anti-inflammatories are recommended in most cases, and the use of corticosteroids is limited to very severe cases. Colchicine for the treatment of recurrent pericarditis in humans is promising, although data from large controlled prospective studies are lacking.[82,83] The safety and efficacy of colchicine, nonsteroidal anti-inflammatories, corticosteroids, and any other medical therapies in the management of idiopathic pericardial effusion in small animals have yet to be established.

205.3.2.2 Mesothelioma

Mesothelioma is emerging as an increasingly important cause of pericardial effusion. Mesothelioma was confirmed in four of 87 dogs (5%) in the UMVMC study population of dogs with pericardial effusion. Average age among the affected cases at time of presentation was 9.5 years (±2.2 years), average weight was 37.5 kg (±11.1 kg), and males and females were equally represented. No breed predisposition has been reported, and affected breeds in the UMVMC population were Akita, golden retriever, Labrador retriever, and springer spaniel. Mesothelioma causing pericardial effusion has been described in a cat,[84] but pericardial mesothelioma is rare in this species.

The clinical course of pericardial effusion due to mesothelioma in the UMVMC study population followed a characteristic pattern. Presenting and clinical signs were no different from other cause of pericardial effusion. In all four cases, a provisional diagnosis of idiopathic pericardial effusion was made after various diagnostic procedures, including echocardiography and pericardial fluid analysis failed to disclose a cause for the pericardial effusion. Pericardiocentesis was performed, and this was repeated at 77 days (± 46 days) when the dogs developed recurrent effusions with tamponade. Pericardiectomies were then performed in all cases; histopathology of the excised pericardia was consistent with idiopathic pericarditis in three cases, and mesothelioma in one. Severe and unremitting pleural effusions requiring repeated thoracocentesis began at 103 days (±44 days) after pericardiectomy. Intracavitary cisplatin was administered in two dogs, but this did not appear to significantly change the course of the disease. Thoracocentesis was necessary every 2 to 3 weeks until death or euthanasia, and MST from the initial episode of pericardial effusion was 312 days (range, 206 to 352). In all cases, mesothelioma that had spread throughout the thoracic cavity was confirmed on postmortem examination.

The signalment and clinical course among cases with pericardial effusion due to mesothelioma in the UMVMC study population are strikingly similar to those described by others.[77,85–87] It is extremely difficult to distinguish between idiopathic pericardial effusion and pericardial effusion due to mesothelioma, even with pericardial histopathology and immunohistochemistry.[87,88] The clinical course of the disease is suggestive, and accumulation of significant amounts of pleural effusion within 120 days of pericardiectomy increases the index of suspicion for mesothelioma.[87] In addition to being a diagnostic challenge, mesothelioma is difficult to treat. However, long-term survival has been reported in a dog in which a histopathologic diagnosis of pericardial mesothelioma was made after pericardiectomy for

recurrent pericardial effusion. Treatment in that case was initiated 48 hours after surgery with intracavitary cisplatin and intravenous doxorubicin, and the dog was free of disease 27 months later.[89] Intracavitary cisplatin has successfully resolved pleural effusions in some dogs with pleural mesothelioma.[90]

205.3.2.3 Cardiac Hemangiosarcoma

In a retrospective study from the Veterinary Teaching Hospital, Colorado State University, cardiac hemangiosarcoma was diagnosed in 14 of 42 dogs (33%) with pericardial effusion.[43] At the UMVMC, cardiac hemangiosarcoma was diagnosed either by echocardiography or echocardiography and histopathology in 53 of 87 dogs (61%) in the study population with pericardial effusion. Cardiac hemangiosarcoma with pericardial effusion was nearly three times more prevalent than the second most common form of pericardial effusion, idiopathic pericardial effusion. Average age among the affected dogs was 9.8 years (±2.1 years), and their average weight was 32.0 kg (±12.2 kg). Males slightly outnumbered females (31 males:22 females), but the difference was not statistically significant when compared with the general hospital population. Sixteen of the 57 dogs (28%) were golden retrievers and the breed was over-represented (odds ratio, 5.3; 95% confidence interval, 2.9 to 9.4).

Two features of these data suggest that important changes have occurred in the epidemiology of cardiac hemangiosarcoma. First, the prevalence of cardiac hemangiosarcoma in the UMVMC study population was nearly twice that of the Colorado State University study population. The reasons for this are not clear; however, regional differences in the epidemiology of cardiac hemangiosarcoma may exist, or the prevalence of the disease may have increased over time. Second, the golden retriever was the only over-represented breed among the cases with cardiac hemangiosarcoma in the UMVMC study population. Cardiac hemangiosarcoma has previously been recognized most frequently in German shepherds.[43,91,92] More recently, cardiac hemangiosarcoma has also been seen commonly in golden retrievers at the Veterinary Hospital, University of Pennsylvania.[93]

Treatment for all forms of hemangiosarcoma is challenging, and a diagnosis of cardiac hemangiosarcoma confers a grave prognosis. By the time of diagnosis, cardiac hemangiosarcoma usually has metastasized and should be considered a systemic disease.[77] At the UMVMC, the majority of owners of dogs with cardiac hemangiosarcoma elect to have their dogs treated by pericardiocentesis alone on one or more occasions. Pericardiocentesis is predictably associated with marked clinical improvement, but clinical signs of tamponade typically recur within a few days, often resulting in death or prompting euthanasia. In the UMVMC study population, MST among dogs with cardiac hemangiosarcoma treated by pericardiocentesis alone (n = 30) was just 11 days (range, 0 to 208). Percutaneous balloon pericardiotomy has been described in the dog,[94,95] and the procedure may provide longer periods of palliation in cases with cardiac hemangiosarcoma.

More aggressive approaches to the treatment of cardiac hemangiosarcoma include various combinations of pericardiectomy, tumor resection, splenectomy in cases with splenic metastases, and chemotherapy.[91,96–100] Survival data for cases managed in this manner are limited. In a case report of right atrial hemangiosarcoma treated with chemotherapy alone, survival time was 20 weeks.[98] In dogs treated by surgery alone (tumor resection and pericardiectomy or creation of a pericardial window, or pericardiectomy alone), reported survival times range from 2 days to 8 months.[91,99,100] No survival data are available that compare surgery alone, with surgery and chemotherapy for dogs with cardiac hemangiosarcoma. Further, no compelling evidence suggests that survival times in dogs with either splenic or cardiac

hemangiosarcoma can be significantly prolonged with adjuvant chemotherapy. Nevertheless, the management of cardiac hemangiosarcoma should always involve consultation with an oncologist to take advantage of continually emerging modalities for the treatment of this highly malignant tumor.[101]

205.3.2.4 Heart Base Tumors

The majority of heart base tumors in dogs are aortic body tumors. English bulldogs, boxers, and Boston terriers are predisposed, although aortic body tumors also occur in nonbrachycephalic breeds. In various studies, brachycephalic breeds have accounted for between 39% and 85% of dogs with aortic body tumors.[70,102,103] Chronic hypoxia induces hyperplasia and neoplasia of chemoreceptors, which may explain the predisposition of brachycephalic breeds to aortic body tumors.[102] Among the predisposed breeds, males may be at increased risk for developing aortic body tumors, but differences in sex predisposition are not statistically significant in all studies.[70,102,103] The age range at time of diagnosis of aortic body tumors is 6 to 15 years with an average of 10 years.[61,70] Between 5% and 10% of tumors at the heart base are ectopic thyroid tumors.[62] Aortic body tumors are reported in cats, but they are rare in this species.[67–70]

Most aortic body tumors are benign and locally expansive, although local invasiveness and metastases occur in both dogs and cats.[61,67–69,104,105] Two studies report metastases mostly to the lungs and liver in approximately 10% to 12% of dogs with aortic body tumors.[102,103] In a third study, 58% (14 of 24) of aortic body tumors were benign, 25% (6 of 24) were locally invasive, and 21% (5 of 24) were metastatic. Sites of metastases included the lungs, left atrium, pericardium, and kidneys.[70] The biologic behavior of ectopic thyroid tumors at the heart base is less well described, and both ectopic thyroid adenomas and adenocarcinomas with metastases have been reported.[63–66]

Heart base tumors were diagnosed either by echocardiography or echocardiography and histopathology in six dogs among the 87 cases (7%) with pericardial effusion in the UMVMC study population. Affected breeds were Great Dane, Labrador retriever, German shorthaired pointer, boxer, English springer spaniel, and Old English sheepdog. Average age was 11.1 years (±2.2 years), and average weight was 31.4 kg (±13.0 kg). One dog was male and five were female. The number of dogs with heart base tumors in the UMVMC study population is small, but the epidemiologic data are reasonably in accord with those of others, with the exception of sex distribution. The prevalence of heart base tumors is consistent with a recent review of the epidemiology of cardiac tumors in dogs. In that study, aortic body tumors were approximately tenfold less common than cardiac hemangiosarcoma.[57]

Complete surgical resection of heart base tumors is seldom possible because the tumors are highly vascular, located close to major blood vessels, and usually extensive by the time of diagnosis. However, palliation with pericardiectomy either alone or in combination with tumor resection often results in prolonged survival with an excellent quality of life.[106,107] No evidence indicates that adjuvant chemotherapy improves the prognosis for dogs with heart base tumors. In a recent retrospective study in dogs with aortic body tumors in which surgery was performed, the following factors were evaluated for effect on survival time: sex; breed; presence or absence of respiratory distress; the presence of an arrhythmia other than respiratory sinus arrhythmia; the presence of pleural, pericardial, or peritoneal effusion; evidence of pulmonary metastases; treatment with pericardiectomy; and treatment with chemotherapy. No attempt was made to achieve tumorfree margins in the dogs in that study. Among the various factors evaluated, only treatment with pericardiectomy had a significant effect on survival, and the survival advantage was remarkable. MST

among dogs after pericardiectomy was 730 days, whereas those that did not have a pericardiectomy had a MST of only 42 days.[106]

205.3.2.5 Other Causes of Acquired Pericardial Effusion

Bacterial, fungal, and viral infections are occasionally associated with pericardial effusions in small animals. Most cases of pericardial effusions due to bacterial infections are thought to arise as a consequence of intrapericardial foreign body penetration, usually by migrating foxtails (*Hordeum* spp.). Foxtail migration is a common and often serious problem in the western United States.[108,109] Bacterial pericarditis has also been described in a puppy after a dog bite and in a young adult dog after thoracic trauma.[110,111] In contrast to most other causes of pericardial effusion, pericardial fluid cytology and culture is crucial in the diagnosis of septic cases. In the largest series of infectious pericardial effusion reported in dogs (five cases), treatment involved pericardiectomy and removal of any foreign bodies, chest drainage, and antibiotic therapy for up to 6 months. All dogs recovered without complications, suggesting that dogs with bacterial pericarditis have a good prognosis when treated aggressively with a combination of surgical and medical therapy.[108]

Systemic coccidioidomycosis in dogs has been associated with pericardial disease. In most cases the fungal infection results in effusive-constrictive or constrictive pericarditis. Coccidioidomycosis should be considered, especially in dogs with pericardial disease that reside in or have a travel history that includes areas where the soil fungus *Coccidioides immitis* is endemic, such as the Southwestern United States.[75,112] Treatment involves pericardiectomy, chest drainage, and antifungal therapy (usually beginning with Amphotericin B). Based on limited published information and experience, the prognosis for cases of coccidioidomycosis with pericardial involvement is poor.[112] A case of effusive-constrictive pericarditis due to *Aspergillus niger* has been reported in a dog.[113]

FIP is one of the more common diseases associated with pericardial effusion in the cat.[40] Pericardial effusions that are occasionally voluminous are present in some cats suffering from this systemic and invariably fatal viral disease.

Left atrial rupture is an uncommon cause of pericardial effusion that occurs in smaller breed dogs with chronic degenerative disease of the mitral valve. Affected cases show clinical signs of acute tamponade, and a loud left apical murmur is usually apparent despite muffling of the heart sounds. Echocardiography discloses intrapericardial fluid, a mass caudal to the left ventricle due to thrombus formation, and substantial mitral regurgitation. Pericardiocentesis is immediately necessary in most cases. Further, the possibility of continued hemorrhage exists, necessitating blood transfusion and emergency thoracotomy to remove larger clots from the pericardial space and to repair the left atrium. The prognosis in such cases is grave.[114,115]

Cardiac lymphosarcoma and rhabdomyosarcoma with pericardial effusion have been reported in both dogs and cats, but these are rare.[40,116–118] Among the various cardiac tumors, cardiac lymphosarcoma is unique because cytology of the pericardial fluid establishes the diagnosis in many cases, and the tumor is amenable to combination chemotherapy.[117,119]

Pericardial effusions secondary to coagulation disorders rarely result in clinically significant tamponade. However, a case of pericardial effusion and cardiac tamponade secondary to anticoagulant rodenticide

toxicity has been reported in a dog.[120] Pericardial effusions secondary to disseminated intravascular coagulation, warfarin toxicity, and other coagulopathies have been reported in cats.[40]

Pericardial effusion is frequently detected in cases with CHF in small animals, but usually not in sufficient quantity to cause significant hemodynamic compromise. Pericardial effusion secondary to uremia has been recognized in both dogs and cats.[40,43]

205.3.3 Constrictive and Effusive-Constrictive Pericarditis

In cases with constrictive and effusive-constrictive pericarditis, cardiac filling is compromised by a nondistensible, thickened, fibrotic pericardium. In human medicine, these diseases are defined as follows: constrictive pericarditis consists of fibrotic fusion of visceral and parietal pericardial layers. Effusive-constrictive pericarditis is an unusual variant of constrictive pericarditis. It describes a condition in which constriction of the heart by the visceral pericardium or epicardium exists, and a tense effusion also occurs within the pericardial space. In cases with effusive-constrictive pericarditis, elevated right atrial pressure persists after pericardiocentesis because of the unyielding epicardium.[121,122]

Several reports exist of tamponade in dogs resulting from relatively small amounts of effusion contained within a fibrotic and nondistensible fibrous and parietal pericardium. The visceral pericardium or epicardium is usually spared or only mildly affected in these cases. Many cases are idiopathic, or develop months or years after an episode of idiopathic pericardial effusion. Other causes include metallic foreign bodies, *Coccidioides immitis*, *Aspergillus niger*, actinomycosis, and osseous metaplasia of the pericardium.[75,113,123,124] Some authors define effusive-constrictive pericarditis more liberally to include this combination of relatively little pericardial effusion with constriction due primarily to an unyielding parietal and fibrous pericardium.[37]

Dogs with effusive-constrictive pericarditis typically present with signs of right-sided CHF. Common complaints are abdominal distention and muscle wasting. Findings on physical examination include abdominal distention with a fluid wave, jugular distention, and muffled heart sounds. These presenting and clinical signs are essentially identical to dogs with chronic tamponade due to pericardial effusion. The similarities extend to electrocardiography where normal sinus rhythm or sinus tachycardia and low-voltage QRS complexes are commonly found. The appearance of the cardiac silhouette on thoracic radiography ranges from normal to moderately enlarged and rounded, and the caudal vena cava may appear wide. The presence of pleural effusion in some cases may complicate evaluation of the size and shape of the cardiac silhouette. Radiopaque intrapericardial foreign bodies may be detected. Echocardiography discloses pericardial effusion that separates the myocardium and fibrous pericardium by just a few millimeters (Figure 205-13, *A*). Echocardiographic signs of tamponade (late diastolic to systolic inversion of the right atrium and diastolic collapse of the right ventricle) are usually present (Figure 205-13, *B*). Pericardial thickness cannot be accurately assessed except in extreme cases.

A diagnosis of effusive-constrictive pericarditis can usually be established with confidence based on the previously mentioned constellation of findings. Treatment involves pericardiectomy, and clinicians at the UMVMC have found that the prognosis after pericardiectomy is excellent for idiopathic cases. Slight epicardial fibrosis and roughness that does not require any surgical intervention is present in most cases. Adhesions between the visceral and parietal pericardium are extremely uncommon. Severe involvement of the epicardium and adhesions between the parietal and visceral pericardium confer a much poorer prognosis. Cases with fungal pericarditis caused by *Coccidioides immitis* appear particularly prone to develop extensive

1116 1117

involvement of both the visceral and parietal pericardium. Epicardial stripping is necessary in such cases, and the procedure is associated with high perioperative morbidity and mortality.

Figure 205-13 Echocardiogram from a dog with effusive-constrictive pericarditis. Dog had signs of right-sided congestive heart failure 25 months after pericardiocentesis had been performed for idiopathic pericardial effusion. **A,** Long axis four-chamber view from right parasternal location, shows small amount of pericardial effusion *(PE)* that separates fibrous pericardium from myocardium by just a few millimeters (reader should compare with centimeter scale on right side of echocardiogram). **B,** Late diastolic to systolic inversion of right atrium *(arrow)*, confirming the presence of tamponade. *PlE,* Pleural effusion; *RA,* right atrium; *RV,* right ventricle; *LA,* left atrium; *LV,* left ventricle.

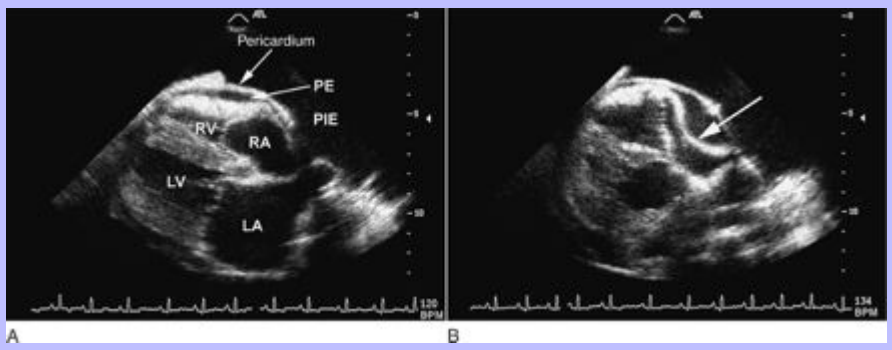


Figure 205-14 Hemodynamic abnormalities associated with constrictive pericarditis. **A,** Elevation and equilibration of end-diastolic pressure *(EDP)* in pulmonary artery *(PA)*, right ventricle *(RV)*, and right atrium *(RA)*. Right atrial pressure waveform has a *M*-shaped pattern due to reduced X descent and a prominent Y descent. **B,** Simultaneous recordings of left ventricular *(open arrow)* and right ventricular *(solid arrow)* pressures before and after saline infusion. Under control conditions, pressure waveforms show slight elevations in end-diastolic pressures. However, true circumstances of the case become apparent with rapid intravenous infusion of 500 mL saline. This procedure results in elevation and equilibration of left and right ventricular diastolic pressure, and a dip-and-plateau pattern in diastole emerges. (From Sisson D, Thomas WP: Pericardial diseases and cardiac tumors. In Fox PR et al (eds): Textbook of Canine and Feline Cardiology, 2nd ed. Philadelphia, WB Saunders Co, 1999, p 679. With permission.)

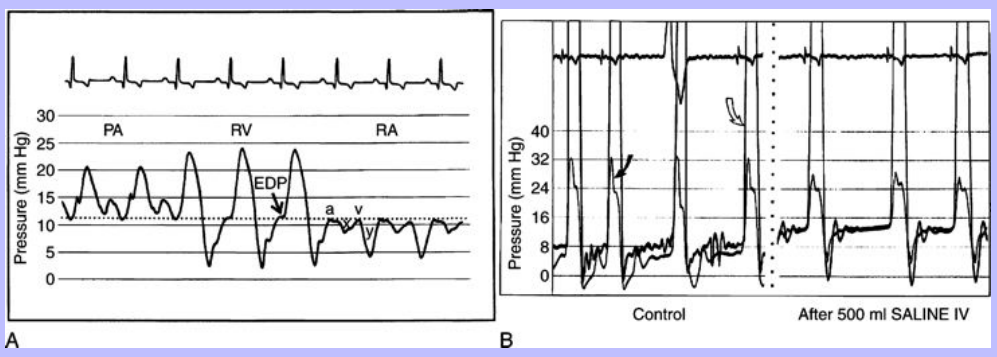

Constrictive pericarditis is both rare and difficult to diagnose in small animals. In this disease, a stiff fibrotic pericardium encases the heart. Presenting and clinical signs, thoracic radiographs, and electrocardiography are similar to other causes of chronic tamponade and effusive-constrictive pericarditis. However, echocardiography demonstrates neither pericardial effusion nor right atrial and ventricular collapse. Constrictive pericarditis in dogs can develop as a consequence of any form of chronic pericarditis. However, it appears to occur most frequently as a severe complication of systemic coccidioidomycosis. 1117 1118

Certain echocardiographic findings that are suggestive of constrictive pericarditis have been described in humans. M-mode echocardiography may demonstrate abrupt flattening of mid-to-late diastolic movement of the left ventricular posterior wall, reflecting a sudden decline in diastolic filling. Rapid early closure of the mitral valve may be detected, as well as premature pulmonary valve opening because of increased right-sided diastolic pressure. Several other echocardiographic features have been described including a diastolic septal bounce; mild atrial enlargement and vena cava dilation; and alterations in the flow characteristics in

pulmonary veins, vena cava, hepatic vein, and across the mitral valve. Transthoracic echocardiography may demonstrate a thickened pericardium in severe cases. However, transesophageal echocardiography, magnetic resonance imaging, and computer tomography scanning are superior to transthoracic echocardiography to detect pericardial thickening.[125] None of the echocardiographic or other imaging modalities for the diagnosis of constrictive pericarditis have been evaluated in small animals.

Hemodynamic data obtained by cardiac catheterization are generally necessary to establish a diagnosis of constrictive pericarditis in small animals. Usually elevation and equilibration (or near equilibration) of the diastolic pressures of all cardiac chambers occurs. The right atrial pressure trace is often described as having an *M* or *W* pattern. This pattern arises because the A and V waves are separated by a reduced X descent, whereas the Y descent is prominent (Figure 205-14, *A*). The ventricular pressure trace shows a dip-and-plateau pattern (or "square-root" sign) in diastole. A rapid intravenous fluid infusion may be necessary to fully reveal the characteristic hemodynamic features of constrictive pericarditis (Figure 205-14, *B*).[27,75,125]

Treatment for constrictive pericarditis involves surgical stripping of the fibrotic, fused, and adherent pericardium from the underlying myocardium (epicardial decortication). This technically difficult procedure is associated with high perioperative morbidity and mortality.

206 CHAPTER • 206 Canine Heartworm Disease

Clarke Atkins

Heartworm infection (HWI) (dirofilariasis), caused by *Dirofilaria immitis,* primarily affects members of the family Canidae. Dirofilariasis is widely distributed, being recognized in northern and southern temperate zones, in the tropics, and in the subtropics. Infections are recognized in most of the United States, although the distribution favors the Southeast and Mississippi River Valley (Figure 206-1). In some endemic areas in the United States, infection rates approach 45%, and in some hyperendemic tropical regions, virtually all dogs are infected. Dirofilariasis is generally infrequent in Canada. A recent survey of veterinarians indicated that in 2001 there were approximately 240,000 cases diagnosed in the United States.[1]

Species known to have been infected with *D. immitis* include the domestic dog, wolves, foxes, coyotes, domestic cats, ferrets, muskrats, sea lions, nondomestic cats, coatimundi, and humans. The species of greatest interest to the practicing veterinarian include the dog and domestic cat. Because the consequences, treatment, and prognoses differ between the two species, clinical aspects of canine and feline heartworm disease (HWD) will be discussed separately.

When HWI is severe or prolonged, it may result in the pathologic process, called *HWD*. HWD may vary from asymptomatic (radiographic lesions only) to severe, life-threatening, chronic pulmonary artery, lung, and cardiac disease. In chronic HWI, glomerulonephritis, anemia, and thrombocytopenia may also be recognized. Severe dirofilariasis may, in addition, produce acute and fulminant multisystemic presentations, such as caval syndrome (CS) and disseminated intravascular coagulation (DIC).

206.1 LIFE CYCLE

D. immitis is transmitted by over sixty species of mosquitoes, although important mosquito vectors probably number less than 12. Understanding the complex life cycle of *D. immitis* is imperative for veterinary practitioners in heartworm endemic areas (Figure 206-2). Adult heartworms (L5) reside in the pulmonary arteries and, to a lesser extent in heavy infections, the right ventricle. After mating, microfilariae (L1) are produced by mature adult female heartworms (L5) and are released into the circulation. These L1 are ingested by feeding female mosquitoes and undergo two moults (L1 to L2 to L3) over an 8-to 17-day period. It is important to note that this process is temperature dependent; in times of the year when insufficient numbers of days occur in which the ambient temperature is adequate, moulting in the mosquito does not occur during the lifetime of the female mosquito and transmission cannot occur.[2,3] The resultant L3 is infective and is transmitted by the feeding mosquito to the original or another host, most often a male dog. Another moult occurs in the subcutaneous, adipose, and skeletal muscular tissues shortly after infection (1 to 12 days), with a final moult to L5 3 months (50 to 68 days) after infection. This immature adult (1 to 2 cm in length) soon enters the vascular system, migrating to the heart and lungs, where final maturation (mature male adults range from 15 to 18 cm and females from 25 to 30 cm) and mating occur. Under optimum conditions, completion of the life cycle takes 184 to 210 days. The canine host typically becomes microfilaremic 6 to 7 months after infection. Microfilariae (L1), which are variably present in infected dogs, show both seasonal and diurnal periodicity, with greatest numbers appearing in the peripheral blood during the evening hours and during the summer. Adult heartworms in dogs are known to live up to 5 years and microfilariae up to 30 months. Dillon has recently emphasized that the disease process in HWD begins with the moult to L5 (as soon as 2 to 3 months postinfection), at which time immature adults (L5) enter the vascular system, initiating vascular and possibly lung disease, with eosinophilia and eosinophilic

infiltrates and signs of respiratory disease.[4] It is important to note that this antedates the profession's current ability to diagnose HWI.

Figure 206-1 American Heartworm Society map, demonstrating relative prevalence of heartworm infection (HWI) in the United States and Canada in 1998. (From Seward L [ed]: Proceedings of the American Heartworm Symposium '98. Batavia, Ill., The American Heartworm Society, 1990.)

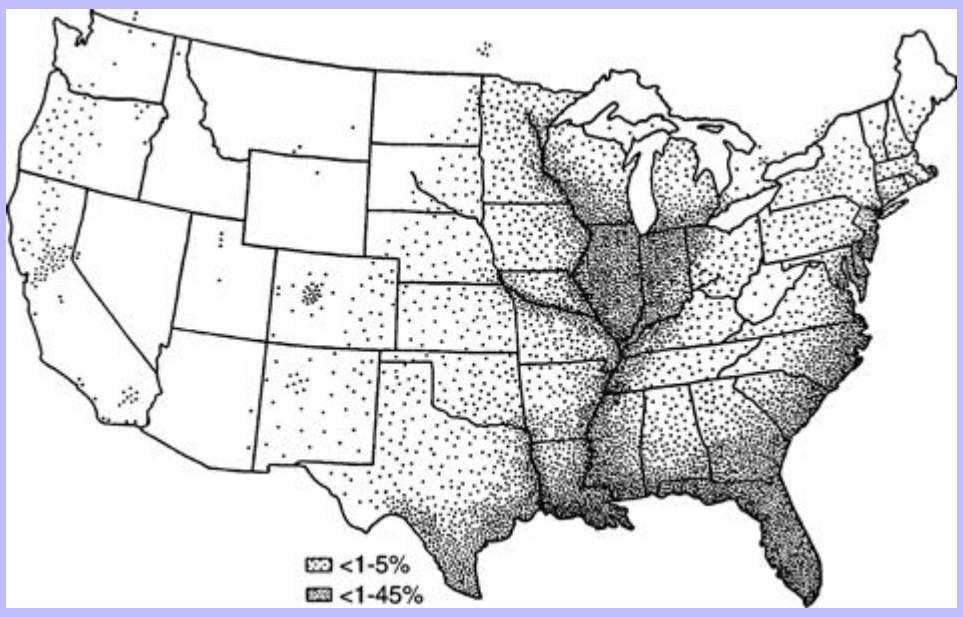

Figure 206-2 Life cycle of *Dirofilaria immitis* in the dog. (From Atkins CE: Heartworm disease. *In* Allen DG [ed]: Small Animal Medicine. Philadelphia, JB Lippincott Co, 1991, pp 341–363.)

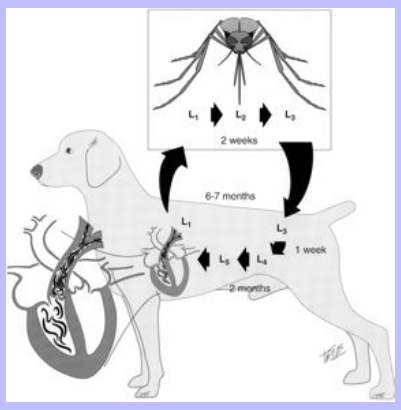

206.2 PATHOPHYSIOLOGY

Heartworm is a misnomer because the adult actually resides in the pulmonary arterial system for the most part, and the primary insult to the health of the host is a manifestation of damage to the pulmonary arteries and lung. The severity of the lesions and hence clinical ramifications are related to the relative number of worms (ranging from one to over 250), the duration of infection, and the host and parasite interaction. Immature and mature adult heartworms reside primarily in the caudal pulmonary vascular tree, occasionally migrating into the main pulmonary arteries, the right heart, and even the great veins in heavy infections.

1119 1120

Obstruction of pulmonary vessels by living worms is of little clinical significance, unless worm burdens are extremely high. The major effect on the pulmonary arteries is produced by worm-induced (toxic substances, immune mechanisms, and trauma) villous myointimal proliferation, inflammation, pulmonary hypertension (PHT), disruption of vascular integrity, and fibrosis. This may be complicated by arterial obstruction and vasoconstriction caused by dead worm thromboemboli and their products. Pulmonary vascular lesions begin to develop within days of worm arrival (as early as 3 months postinfection), with endothelial damage and sloughing, villous proliferation, and activation and attraction of leucocytes and platelets. The immigration of such cells and the release of trophic factors induce smooth muscle cell proliferation and migration with collagen accumulation and eventual fibrosis. Proliferative lesions eventually encroach upon and even occlude vascular lumina. Endothelial swelling with altered intracellular junctions increases the permeability of the pulmonary vasculature. Worms, which have died naturally or have been killed, elicit an even more severe reaction, inciting thrombosis, granulomatous inflammation, and rugous villous inflammation. Grossly, the pulmonary arteries are enlarged, thick-walled, and tortuous, with roughened endothelial surfaces. These changes are only partially reversible.[5]

Although the role of exercise in exacerbation of the signs of thromboembolic HWD is accepted, its role in the development of pulmonary vascular disease and PHT is less clear. Although Rawlings[6] was unable to show an effect of 2.5 months' controlled treadmill exercise on PHT in heavily infected dogs, Dillon[7] showed more severe PHT in lightly infected, mildly exercised dogs than in more heavily infected but unexercised dogs receiving no exercise at 6 months postinfection.

Diseased pulmonary arteries are thrombosed, thickened, dilated, tortuous, noncompliant, and functionally incompetent, thereby resisting recruitment during increased demand; hence exercise capacity is diminished. Vessels to the caudal lung lobes are most severely affected. Pulmonary vasoconstriction results secondary to vasoactive substances released from heartworms. Furthermore, hypoxia (induced by ventilation-perfusion mismatching secondary to eosinophilic pneumonitis, pulmonary consolidation, or both), further contributes to vasoconstriction. The result is PHT and compromised cardiac output.[8] Pulmonary hypertension is exacerbated with exercise or other states of increased cardiac output. The right heart, which is an efficient volume pump but does not withstand pressure overload, first compensates by eccentric hypertrophy *(dilatation and wall thickening)* and, in severe infections, ultimately decompensation (right heart failure). In addition, hemodynamic stresses, geometric changes, and cardiac remodeling may contribute to secondary tricuspid insufficiency, thereby complicating or precipitating cardiac decompensation. Pulmonary infarction is uncommon because of the extensive collateral circulation provided the lung and because of the gradual nature of vascular occlusion. Because of increased pulmonary vascular permeability, perivascular edema may develop. Although, along with an inflammatory infiltrate, this may be evident radiographically as increased interstitial and even alveolar density, in and of itself, it is seemingly of minimal clinical significance and does not indicate left heart failure (in other words, furosemide is not indicated).

Spontaneous or postadulticidal thromboembolization (PTE) with dead worms may precipitate or worsen clinical signs, producing or aggravating PHT, right heart failure or, in rare instances, pulmonary infarction. Dying and disintegrating worms worsen vascular damage and enhance coagulation. Pulmonary blood flow is further compromised and consolidation of affected lung lobes may occur. With acute and massive worm death, this insult may be profound, particularly if associated with exercise. Exacerbation by exercise likely reflects increased pulmonary artery flow with escape of inflammatory mediators into the lung parenchyma through badly damaged and permeable pulmonary arteries (see Figure 207-7). Dillon has suggested that the lung injury is similar to that seen in adult respiratory distress syndrome (ARDS).[4]

Pulmonary parenchymal lesions also result by mechanisms other than post-thromboembolic consolidation. Eosinophilic pneumonitis is most often reported in true occult HWD, when immune-mediated destruction of microfilariae in the pulmonary microcirculation produces amicrofilaremia. This syndrome results when antibody-coated microfilariae, entrapped in the pulmonary circulation, incite an inflammatory reaction (eosinophilic pneumonitis).[9] A more sinister but uncommon form of parenchymal lung disease, termed *pulmonary eosinophilic granulomatosis*, has been associated with HWD. The exact cause and pathogenesis are unknown, but it is felt to be similar to HWD-related allergic pneumonitis.[10] It is postulated that microfilariae trapped in the lungs are surrounded by neutrophils and eosinophils, eventually forming granulomas and associated bronchial lymphadenopathy.

Antigen-antibody complexes, formed in response to heartworm antigens, commonly produce glomerulonephritis in heartworm-infected dogs.[11] The result is proteinuria (albuminuria) but uncommonly renal failure. Heartworms may also produce disease by aberrant migration. This uncommon phenomenon has been associated with neuromuscular and ocular manifestations, because worms have been described in tissues such as muscle, brain, spinal cord, and anterior chamber of the eye. In addition, arterial thrombosis with L5 has been observed when worms migrate aberrantly to the aortic bifurcation or more distally in the digital arteries.[12] Adult heartworms may also migrate in a retrograde manner from the pulmonary arteries to the right heart and venae cavae, producing CS, a devastating process, described following.[13]

206.3 CLINICAL SIGNS

The clinical signs of chronic HWD depend on the severity and duration of infection and, in most chronic cases, reflect the effects of the parasite on the pulmonary arteries and lungs, and secondarily, the heart. It is important to point out that the vast majority of dogs with HWI are asymptomatic. Historical findings in affected dogs variably include weight loss, diminished exercise tolerance, lethargy, poor condition, cough, dyspnea, syncope, and abdominal distension (ascites). Physical examination may reveal evidence of weight loss, split second heart sound (13%), right-sided heart murmur of tricuspid insufficiency (13%), and cardiac gallop.[14] If right heart failure is present, jugular venous distension and pulsation typically accompanies hepatosplenomegaly and ascites. Cardiac arrhythmias and conduction disturbances are uncommon in chronic HWD (<10%). With pulmonary parenchymal manifestations of HWD, cough and pulmonary crackles may be noted and, with granulomatosis (a rare occurrence), muffled lung sounds, dyspnea, and cyanosis are also reported. When massive pulmonary thromboembolization occurs, the additional signs of fever and hemoptysis may be noted.

206.4 DIAGNOSIS

206.4.1 Microfilarial Detection

Ideally the diagnosis is made by routine evaluation prior to the onset of symptoms (i.e., HWD). Dogs in areas in which heartworms are endemic should undergo a heartworm test yearly, particularly if on no heartworm preventative or if diethylcarbamazine is used (see discussion of controversies, following). This was accomplished most commonly in the past by the microscopic identification of microfilariae on a direct blood smear, above the buffy coat in a microhematocrit tube, using the modified Knott test, or after millipore filtration. The accuracy of these tests, typically used for routine screening and for the diagnosis of suspected HWI, is improved by multiple testing. The modified Knott test and millipore filtration are more sensitive because they concentrate microfilariae, improving chances of diagnosis. The direct smear technique allows examination of larval motion, helping in the distinction of *D. immitis* from *Dipetalonema reconditum* (now termed *Acanthocheilonema reconditum*); other useful diagnostic criteria are included in Table 206-1. This distinction is important because the presence of the latter parasite does not require expensive and potentially harmful arsenical therapy, as does *D. immitis*. None of these tests can rule out HWI conclusively because of the potential for amicrofialremic infections (5% to 67%) and the fact that false-negative results may occur, particularly if microfilarial numbers are small, a small amount of blood is collected, or direct smears are relied upon. The number of circulating microfilariae in the peripheral blood do not correlate well with the number of adult heartworms and therefore cannot be used to determine the severity of infection. In the most practices, microfilarial testing has been largely supplanted by (or supplemented with) immunodiagnositic antigen testing (i.e., enzyme-linked immunosorbent assay [ELISA]). The modified Knott test should always be performed, however, in antigen-positive dogs to determine microfilarial status and in instances when owners continue to use diethylcarbamazine as a preventative. Some veterinarians choose to combine the antigen and microfilarial tests. This practice is most useful in dogs receiving diethylcarbamazine or no preventative (macrolides typically render the dog amicrofilaremic). Up to 1% of infected dogs are microfilaria positive and antigen negative.[15]

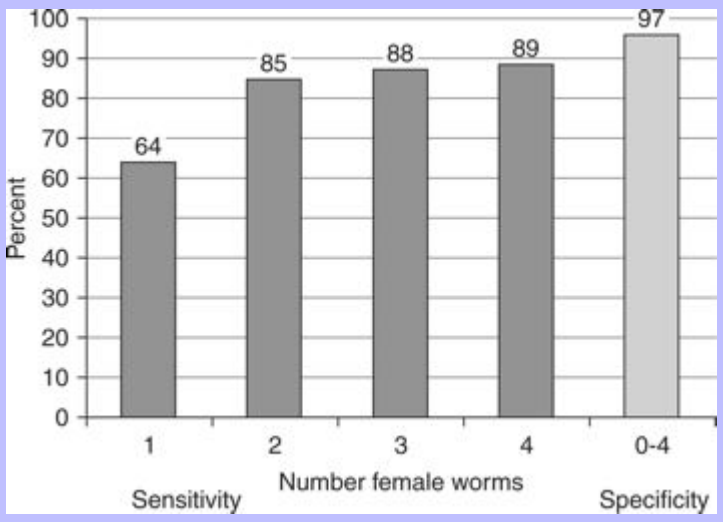
206.4.2 Immunodiagnostic Tests

In dogs not having received macrolide preventative therapies, the prevalence of amicrofilaremic infections is 5% to 67% (typically 10% to 20%).[16] This may be observed in prepatent (young) infections, in single-sex infections, with immune-mediated destruction of microfilaria, and with drug-induced amicrofilaremia. Dogs receiving macrolide preventatives are typically amicrofilaremic. Hence immunodiagnostic tests (heartworm ELISA antigen tests) are now regularly used for both screening and in cases suspected of having HWI. These tests have rapidly gained popularity because of their high sensitivity and specificity and ease of performance (Table 206-2).[17–20] The weakness of these tests is that they detect antigen from adult female heartworms and hence will produce negative results during the first ~6 (5 to 8) months of any infection, in all-male infections and in infections, with low female worm burdens. In fact, a recent study of the performance of three commercial test kits in detecting low worm burden (<4), naturally acquired infections demonstrated an overall (median for three test kits) sensitivity of 79% and a median specificity of 97%.[21] The sensitivity was relatively low (64%) for infections of only one female worm but improved with increasing female worm burden (median of 85%, 88%, and 89% for two, three, and four female worms, respectively for the three test kits evaluated). Of course with higher worm burdens, better sensitivity is experienced. Nevertheless, despite overall excellent results in detection of small worm burdens, false-negative results do occur (Figure 206-3).[21]

1121

1122

Figure 206-3 Comparison of sensitivity and specificity of three commercial heartworm test kits on known sera from naturally infected dogs with low worm burdens (zero to four adult female heartworms). Black bars represent median sensitivity of the three tests for sera of dogs with one, two, three, and four adult female heartworms. Grey bar represents the median specificity of the three tests for sera from dogs infected with zero to four adult female heartworms. (From Atkins CE: Comparison of results of 3 commercial heartworm antigen tests in dogs with low heartworm burdens. *J Am Vet Med Assoc*, 2003:222, 1221.)



Certain ELISA antigen tests are designed to quantitatively predict worm burdens, based on antigen concentrations. Semiquantitative ELISA (Snap™ Canine Heartworm PF) has been used to successfully predict antigen load and hence approximate worm burden. Rawlings and colleagues[22] have shown this to be useful in predicting thromboembolic complications, with dogs bearing greater worm burdens being more likely to experience such complications after adulticide. This application is most useful, however, in instances of low antigen concentration (suggesting low worm burden), because high antigen concentrations might be recognized when all or most worms are dead, having released a large amount of antigen into the circulation. ELISA technology also allows determination of the efficacy of adulticide therapy. ELISA antigen concentration typically falls to undetectable levels 8 to 12 weeks after successful adulticide therapy, so a positive test persisting beyond 12 weeks post-therapy has been suggested to indicate persistent infection.[23] However, antigen tests may remain positive for longer periods, and this author does not assume a failure in adulticidal therapy unless the antigen test is positive 6 months after adulticidal therapy.

As previously suggested, macrolide therapy with ivermectin, milbemycin oxime, moxidectin, and selamectin results in clearance of microfilaria within 6 to 8 months.[23–25] In addition, embryostasis may be permanent. Thus the use of direct smears, the Knott test, and the millipore filter (microfilarial tests) in dogs receiving

monthly heartworm preventatives (macrolides) is inappropriate. Therefore the only effective testing modality in the ever-increasing number of dogs receiving monthly preventative is the use of antigen assays. A general approach to the diagnosis of HWI is demonstrated in Figure 206-4.

206.4.3 Radiography

Although not an effective screening test for HWI, thoracic radiography offers an excellent method for detecting HWD, for determining its severity, and for evaluating pulmonary parenchymal changes. Radiographic abnormalities, which develop relatively early in the disease course, are present in approximately 85% of cases. According to the study of 200 heartworm-infected dogs by Losonsky and colleagues,[26] radiographic features (Figure 206-5) include right ventricular enlargement (60%), increased prominence of the main pulmonary artery segment (70%), increased size and density of the pulmonary arteries (50%), and pulmonary artery tortuousity and "pruning" (50%). If heart failure is present, enlargement of the caudal vena cava, liver, and spleen, as well as pleural effusion, ascites, or both, may be evident. Thrall and Calvert[27] suggested that pleural effusion is uncommon in heart failure due to HWD, demonstrating that marked enlargement of the cranial lobar pulmonary artery was a more sensitive indicator of HWD-associated heart failure than is enlargement of the caudal vena cava.

Thoracic radiographs obtained in the ventrodorsal projection are preferable for cardiac silhouette evaluation, ease, and often minimizing patient stress. However, the dorsoventral projection is superior for the evaluation of the caudal lobar pulmonary vessels that are considered abnormal if larger than the diameter of the ninth rib where the rib and artery intersect (Figure 206-6). The cranial pulmonary artery is best evaluated in the lateral projection and should normally not be larger than its accompanying vein or the proximal one third of the fourth rib (Figure 206-7).

The pulmonary parenchyma can best be evaluated radiographically. With pneumonitis, the findings include a mixed interstitial to alveolar density, which is typically most severe in the caudal lung lobes (Figure 206-8). In eosinophilic nodular pulmonary granulomatosis, the inflammatory process is arranged into the interstitial nodules, associated with bronchial lymphadenopathy and, occasionally, pleural effusion. With pulmonary thromboembolism, the radiographic findings of coalescing interstitial and alveolar infiltrates, particularly in the caudal lung lobes, reflect the increased pulmonary vascular permeability and inflammation described previously (see Figure 206-13). Consolidation may accompany massive embolization, pulmonary infarction, or both.

206.4.4 Electrocardiography

Electrocardiography is useful in detecting arrhythmias but is generally insensitive in detection of cardiac chamber enlargement in HWD when compared with radiography and echocardiography. If radiography does not suggest HWD, it is unlikely that the electrocardiogram (ECG) will be useful in the absence of arrhythmias. With the exception of CS and heart failure, arrhythmias are rare (2% to 4%).[28] Nevertheless, the finding of a right ventricular enlargement pattern (Chapter 202) is supportive evidence for HWD. Lombard and Ackerman[28] demonstrated that ECG abnormalities were present in 38% to 62% of dogs with moderate and severe echocardiographic changes of HWD, while Calvert and Rawlings[29] found that only 6% of 276 dogs with dirofilariasis had ECG changes of right ventricular enlargement. Calvert and Rawlings[30] also showed that the most sensitive ECG parameters for detection of HWD are lead II S waves deeper than 0.8 mv, mean electrical axis greater than 103 degrees, and greater than three ECG parameters of right heart enlargement.

The latter ECG finding (> three criteria) is considered to be the most accurate. P-pulmonale (tall P waves, indicative of right atrial enlargement) is unusual in HWD.

Figure 206-4 An algorithmic approach to the diagnosis of heartworm infection (HWI) in the dog.

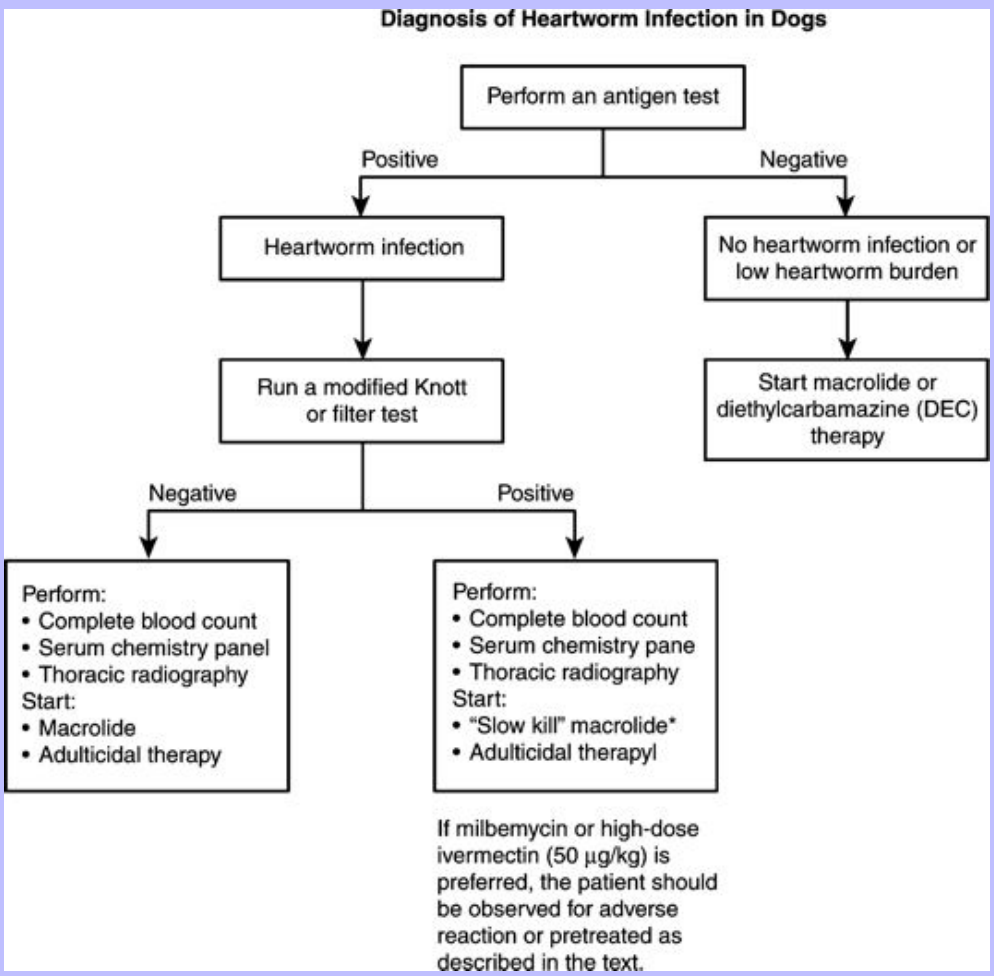


Figure 206-5 The relative frequency of cardiovascular radiographic findings of heartworm disease (HWD). (Losonsky JM, Thrall DE, Lewis RE: Thoracic radiographic abnormalities in 200 dogs with heartworm infestation. *Vet Radiol* 24:120, 1983.)

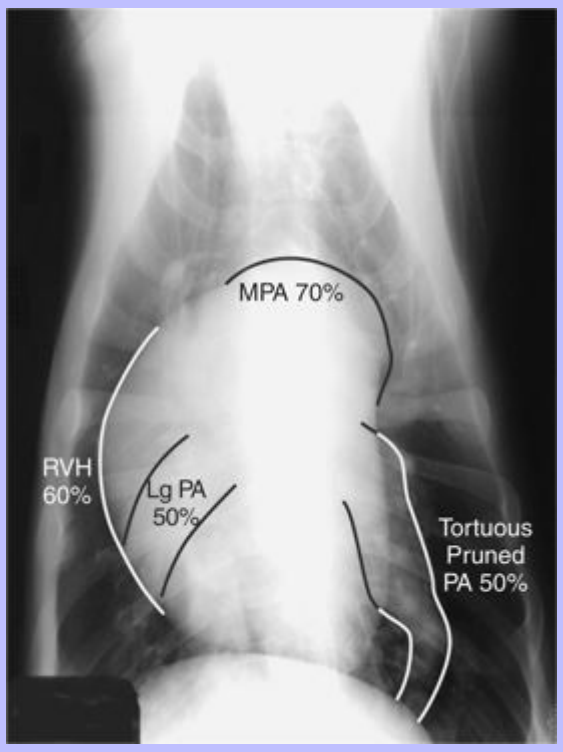

Figure 206-6 Lateral thoracic radiograph obtained from a dog with chronic heartworm disease (HWD). Reader should note right ventricular enlargement (evident in the apex having been lifted from the sternum), enlarged apical pulmonary artery, and an interstitial infiltrate in the caudal lung lobes.

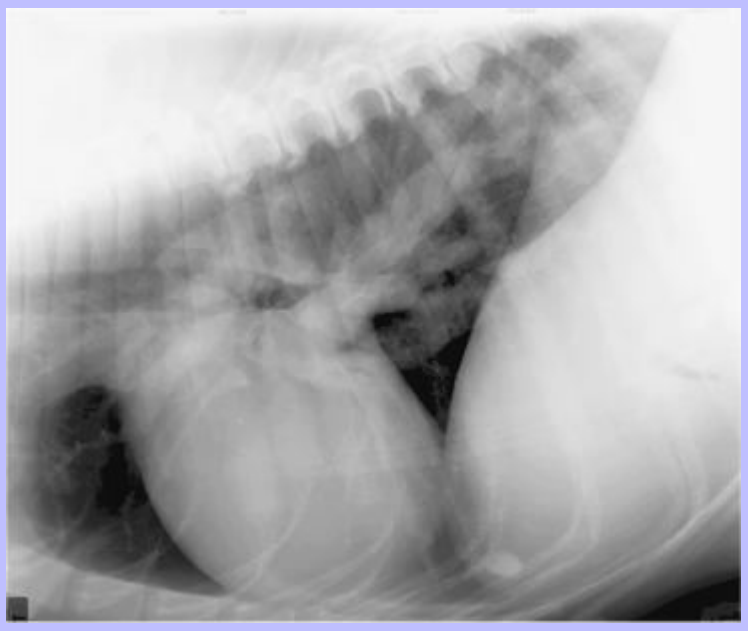

1123

Figure 206-7 Dorsoventral thoracic radiograph obtained from a dog with chronic heartworm disease (HWD). Reader should note the enlarged main pulmonary artery, right ventricular enlargement, and enlarged, tortuous caudal lobar pulmonary arteries. (See Figure 206-5 for schematic of radiographic abnormalities.)

206.4.5 Echocardiography

Echocardiography is relatively sensitive in the detection of right heart enlargement, because the right ventricular end diastolic dimension and septal and right ventricular free wall thickness are all increased (Figure 206-9). Lombard reported abnormal (paradoxical) septal motion in four of 10 dogs with HWD. The ratio of left to right ventricular internal dimensions is a useful calculation, being reduced from a normal value of 3 to 4 to a mean value of 0.7 in dogs with HWD. In some instances, two-dimensional echocardiography can be used to demonstrate worms in the pulmonary artery (see Chapter 207). Although heartworms can occasionally be demonstrated in the right ventricle, this method is insensitive except in dogs with CS or very heavy worm burdens, because the worms infrequently inhabit this location.[31]

Figure 206-8 Lateral thoracic radiograph obtained from a coughing dog with chronic heartworm disease (HWD). The diffuse interstitial to alveolar infiltrate is severe and represents eosinophilic pneumonitis. Cardiac and pulmonary arterial changes are less severe than seen in Figures 206-6, 206-7, and 206-13.

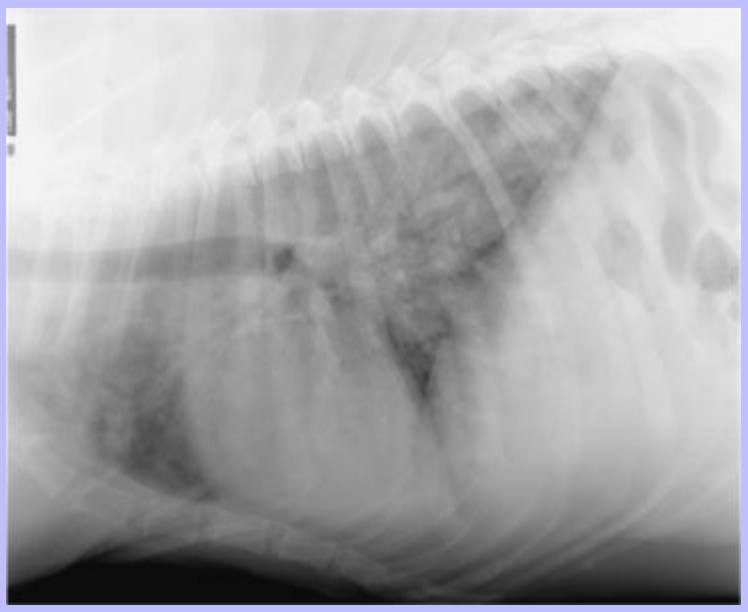

Figure 206-9 A short-axis, two-dimensional echocardiogram obtained from a dog with chronic heartworm disease (HWD). Reader should note the enlarged right ventricular lumen *(RV)* and right ventricular papillary muscle *(arrow)*. The septum is flattened and bows toward the small left ventricle *(LV)*. The electrocardiogram (ECG) at the bottom of the figure demonstrates that this is a diastolic frame.

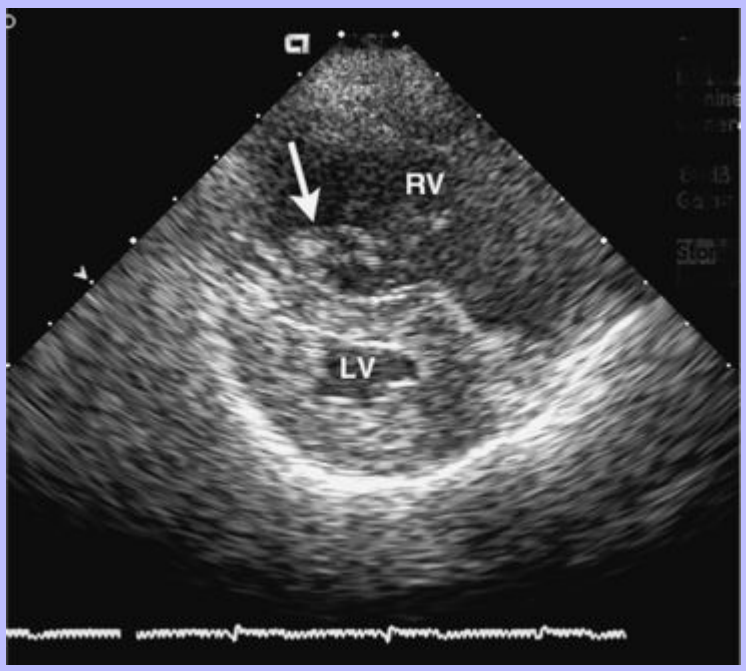


206.4.6 Clinical Pathology

Hematological and serum chemical abnormalities, although of limited use in making a diagnosis of HWD, are frequently useful in providing supportive evidence and for evaluating concurrent disease processes that may or may not be related to HWD. Calvert and Rawlings[30] report that the dog with HWD in Georgia typically is found to have a low-grade, nonregenerative anemia (present in 10% of mildly to moderately affected dogs and up to 60% of severely affected dogs), neutrophilia (20% to 80% of cases), eosinophilia (~85% of cases), and basophilia (~60% of cases). Thrombocytopenia, which may be noted in chronic HWD, CS, and DIC, is most common 1 to 2 weeks after adulticidal therapy. In severe HWD, especially if heart failure is present, liver enzyme activities may be increased (10% of cases), and occasionally hyperbilirubinemia is noted. Azotemia, seen in only 5% of cases, may be prerenal in origin if dehydration or heart failure are present or may be secondary to glomerulonephritis. In 10% to 30% of cases, albuminuria is noted. If glomerular disease is severe, hypoproteinemia (hypoalbuminemia) has the potential to complicate the clinical picture. Not surprisingly, the most severe clinicopathologic findings are associated with the most severe clinical findings.

Evaluation of tracheobronchial cytology is at times useful, particularly in the coughing dog with eosinophilic pneumonitis, occult HWD, and minimal radiographic evidence of HWD. Microscopic examination reveals evidence of an eosinophilic infiltrate. In microfilaremic dogs, L1 may occasionally be detected in this manner. 1124
Abdominal fluid analysis in cases of congestive heart failure (CHF) typically reveals a modified transudate. 1125
Dogs with HWD and right heart failure have central venous pressure (CVP) that ranges from 12 to more than 20 cm H_2O, but ascites develop at lower CVPs if hypoalbuminemia is present.

206.5 MEDICAL MANAGEMENT

The medical management of HWI is complex because of the complicated parasite life cycle, the marked variability in clinical manifestations and severity of HWD, prophylactic considerations, adulticidal and microfilaricidal considerations, and the relative toxicity and complications associated with adulticidal therapy. For these reasons, the diagnosis, prevention, and treatment of HWI remains a challenge.

206.5.1 Prophylaxis

Prevention of HWI is an obvious and attainable goal for the veterinary profession. Prevention failure results from ignorance on the part of owners as to the presence or potential severity of HWI, lack of owner compliance, or from inadequate instruction on preventative measures by the attending veterinarian.[1,32–34] Studies of owner compliance have revealed that approximately 55% of dog owners that use veterinary care purchase heartworm preventative, and enough medication is dispensed only to meet the needs of approximately 56% of those dogs. Hence the proportion of “cared for” dogs in the population that receive adequate heartworm prophylaxis is less than one third.[33] If one takes into consideration doses purchased but not administered and dogs that are never taken to a veterinarian, the percentage of protected dogs falls drastically. This was emphasized in North Carolina in 1999, when Hurricane Floyd caused extensive flooding and disruption in the poorest part of the state. Of dogs rescued from the floodwaters, 67% were infected with heartworms (personal communication, Dr. Kelli Ferris, North Carolina State University, 2003). In addition, evidence suggests that the veterinary profession is failing in its education of clients. New and colleagues,[35] upon questioning veterinary clients purchasing macrolide preventatives, found that 38% did not realize that their prescribed drug's spectrum was broader than solely preventing HWI.

206.5.2 Diethylcarbamazine

Diethylcarbamazine (DEC), which long enjoyed popularity as the preventative of choice, has now been largely replaced by the safer and more convenient macrolide preventatives. This product is safe (*only* in *amicrofilaremic* dogs) and effective; however, it must be given daily, making owner compliance problematic. Diethylcarbamazine is thought to kill L3 and early L4 tissue migrating larvae but only has a small temporal window of therapeutic efficacy, thus explaining the need for frequent administration. Preventative should be administered daily from the onset of mosquito season, continuously until 1 to 2 months after a killing frost. In some geographic regions, the persistence of mosquitoes dictates yearlong prophylaxis, although this is controversial for much of the United States (see discussion of controversies, following).

Diethylcarbamazine must only be administered to dogs free of microfilariae, thus dictating a yearly heartworm test prior to reinstitution of preventative therapy. Inadvertent administration of diethylcarbamazine to microfilaremic dogs produces an adverse, possibly immune-mediated reaction in approximately 30%.[36] Signs associated with this adverse drug reaction usually occur within 1 hour of medication and include depression,

ptyalism, vomiting, diarrhea, weak pulse, pale mucous membranes with poor capillary refill time, and bradycardia. Subsequently some dogs may become recumbent, dyspneic, and tachycardic, and 18% of reactors succumb. Restated, 6% of microfilaremic dogs to which diethylcarbamazine is administered will die due an adverse reaction.

Not infrequently, owners inadvertently miss one or more doses of DEC preventative. If 1 day of therapy is omitted, no problem exists and drug administration should continue. In the event of a more prolonged lapse in diethylcarbamazine treatment, reinstitution of medication should be advised, with the realization that infection may have occurred during the prophylactic hiatus.

These dogs should be reevaluated in 6 to 7 months to determine if infection has resulted. If a dog is found to be microfilaremic when receiving diethylcarbamazine, prophylaxis should be continued; however, if inadvertently stopped, reinstitution may result in the aforementioned adverse reaction.

206.5.3 Macrolide Antibiotics

The introduction of the macrolide agents (macrocyclic lactones) ivermectin (Heartgard®), milbemycin oxime (Interceptor®), moxidectin (ProHeart® and ProHeart® 6), and selamectin (Revolution™) has provided the veterinary profession with effective heartworm preventatives in a variety of formulations. These agents, because they interrupt larval development during the first 2 months after infection, have a large window of efficacy and are administered monthly or less frequently. Macrolide agents are superior to DEC in convenience. They produce less severe reactions when inadvertently given to microfilaremic dogs, allow a grace period for inadvertent lapses in administration, are more effective with treatment lapses of up to 2 to 3 months when used continuously for the next 12 months,[37] and have a dual role as microfilaricides.[20,37–39] Recently it has been shown that some macrolides have adulticidal activity, if used continuously for prolonged periods.[39–41] (Note: ProHeart® 6 is no longer on the market.)

206.5.4 Ivermectin

Ivermectin, a chemical derivative of avermectin B_1 that is obtained from *Streptomyces* spp., is effective against a range of endo-and ectoparasites and is marketed as a once-monthly heartworm preventative. It is also marketed in a form with pyrantel pamoate to improve efficacy against intestinal parasites (Table 206-3). Macrolides provide a wide window of efficacy and provide some protection when lapses in therapy occur. Ivermectin is effective as a prophylactic with lapses of up to 2 months. Protection is extended, with continuous 12-month administration postexposure, with lapses of 3 months (98% efficacy) and of 4 months (95% efficacy).[37] As stated previously, ivermectin is microfilaricidal at preventative doses (6 to 12 μg/kg/month), resulting in a gradual decline in microfilarial numbers. Despite this gradual microfilarial destruction, generally mild, adverse reactions (transient diarrhea) can occur if administered to microfilaremic dogs.[37] Some breeds (collies and Shetland sheep dogs) are susceptible to ivermectin (and other macrolide) toxicosis at high doses, suffering neurologic signs. This has typically resulted with the use of concentrated livestock preparations, with clinical signs recognized with doses greater than 16 times the recommended dose.[25] For this reason, only preparations designed for pet use should be administered to dogs. When used appropriately, ivermectin is virtually 100% effective in preventing HWI. Additionally, recent studies have shown ivermectin to have partial adulticidal properties when used continuously for 16 months[40] and virtually 100% effective with continuous administration for 30 months.[41] (See discussion of controversies, following.)

206.5.5 Milbemycin

Milbemycin oxime is a member of a family of milbemycin macrolide antibiotics derived from a species of *Streptomyces*. At 500 to 999 µg/kg, it has efficacy against developing filarial larvae, arresting development in the first 6 weeks. It can therefore be given at monthly intervals with a *reachback effect* of 2 months when doses are inadvertently delayed. With 12 months' continuous treatment postexposure, this "safety net" can be extended to 3 months (97% efficacy), falling to 41% with lapses of 4 months.[37] At the preventative dose, milbemycin is a broad-spectrum parasiticide, being also effective against certain hookworms, roundworms, and whipworms (see Table 206-3). In microfilaremic dogs, milbemycin has greater potential for adverse reactions than do other macrolides, because it is a potent microfilaricide at preventative doses.[20] Adverse reactions, similar to those observed with ivermectin at microfilaricidal doses, may be observed in microfilaremic dogs receiving milbemycin at preventative doses.[42] As with microfilaricidal doses (50 µg/kg) of ivermectin, Benadryl (2 mg/kg intramuscularly) and dexamethasone (0.25 mg/kg intravenously) may be administered prior to milbemycin to prevent adverse reactions, particularly in dogs with high microfilarial counts. Milbemycin is also safe for use in collies at the preventative dose. With appropriate use, milbemycin is virtually 100% efficacious as a heartworm prophylactic.

1125 1126

Table • 206-3 Comparison Clinical Spectrum of Commercially Available Macrolides

DRUG	HW	MICROFILARIAE	ADULTICIDE	HOOKWORMS	WHIPWORMS	ROUNDWORMS	TAPEWORMS	FLEAS & EGGS	TICKS
Ivermectin (chewable)	+	+	+	+*		+*			
Milbemycin (flavored tablet)	+	++		+	+	+		–/+†	
Moxidectin (tablet or injectable)	+	+		+‡					
Selamectin (topical)	+	+	(+)	+				+/+	+

For adulticidal effects, assumes 31 months' continuous therapy for ivermectin and 18 months' continuous therapy for selamectin. *HW*, Heartworm preventative; (), partially effective or incompletely studied.

* Ivermectin/pyrantel pamoate.

† Milbemycin/lufenuron.

‡ Injectable formulation (removed from the market in late 2004).

206.5.6 Moxidectin

The macrolide preventative, moxidectin, has been more recently marketed as a narrow-spectrum heartworm preventative (see Table 206-3) and shown to be safe and virtually 100% effective at 3 µg/kg orally, given monthly or bimonthly up to 2 months postinfection.[43] Moxidectin, at this dose, is gradually microfilaricidal and did not produce adverse reactions in a small number of microfilaremic dogs treated with the prophylactic dose.[38] At 15 µg/kg, 98% reduction in microfilarial numbers was documented 2 months post-treatment.

Lastly, moxidectin appears to be safe in collies.[44] A new liposomal formulation of moxidectin, which provides the potential to improve owner compliance, gives 6 months' protection with one subcutaneous injection. With 12 months' (two injections) continuous treatment, injectable moxidectin is 97% effective at preventing infection after a 4-month lapse in preventative therapy.[45] (This product was removed from the market in late 2004 pending further study.)

206.5.7 Selamectin

Selamectin is a semisynthetic macrolide. It is unique in its broad spectrum and in the fact that it is applied topically once monthly (see Table 206-3). Its efficacy is similar to that of other macrolides (virtually 100%, when used as directed).[46] At 6 to 12 mg/kg topically, this preventative is effective at preventing heartworms infection and kills fleas and flea eggs, sarcoptic mange mites, ticks, and ear mites.[46] Bathing and swimming, as soon as 2 hours after application, does not alter efficacy. Safety has been shown at tenfold topical doses, with oral consumption of single doses and, in ivermectin-sensitive collies, at recommended doses and fivefold overdoses for 3 months.[47] Like other macrolides, selamectin has at least a 2-month *reach-back* effect and with 12 months' continuous administration is 99% protective after 3-month lapses in prophylaxis.[46,48] Selamectin has microfilaricidal activity similar to other macrolides.[48] Chronic, continuous selamectin administration has adulticidal efficacy, although no published data indicate it is as effective in this role as ivermectin.

In summary, the macrolides offer a convenient, effective, and safe method of heartworm prophylaxis with varying spectra and methods of administration (see Table 206-1). They each have microfilaricidal efficacy and render female heartworms sterile. Hence microfilarial tests for HWI cannot be reliably used in dogs receiving these products. Prophylaxis should be commenced at 6 to 8 weeks of age in endemic areas or as soon thereafter as climatic conditions dictate.[19,49] Although safer than DEC in microfilaremic dogs, before first-time administration any dog over 6 months of age and at risk of infection should be tested (antigen test, followed by a microfilaria test, if antigen positive). Additionally, even though protective for at least 8 weeks postexposure, macrolides should be administered precisely as indicated by the manufacturer. If accidental lapses of more than 10 weeks occur, the preventative should be reinstituted at recommended doses and maintained for 12 consecutive months.[25] Macrolides can also be used to “rescue” dogs that have lapsed in their DEC daily therapy for up to 60 to 90 days.[19,49] In the event of a lapse in preventative administration during a time of known exposure risk, an antigen heartworm test should be performed 7 months after the last possible exposure to determine if infection has occurred.

The necessary duration of protection is controversial. The American Heartworm Society indicates that in colder climates, yearlong prevention is not necessary, advocating beginning macrolides within 1 month of the anticipation of transmission season[25] and continuing 1 month beyond the transmission season.[19,49] On the other hand, some experts believe that yearlong prevention should be embraced, regardless of geographic location.[50] This author advocates yearlong prevention, at least below the Mason-Dixon line in North America.

Table • 206-4 Manufacturer's Recommendations for the Use of Melarsomine Dihydrochloride, Based on Patient Status

CLASS 1 HEARTWORM INFECTION (ASYMPTOMATIC, NO RADIOGRAPHIC LESIONS)	CLASS 2 SYMPTOMATIC HEARTWORM DISEASE (MILD TO MODERATE SIGNS)	CLASS 3 SYMPTOMATIC HEARTWORM DISEASE (SEVERE SIGNS)	CLASS 4 CAVAL SYNDROME
Two doses melarsomine 24 hours apart (2.5 mg/kg IM)	Two doses melarsomine 24 hours apart (2.5 mg/kg IM)	One dose melarsomine (2.5 mg/kg IM), followed in approximately 1 month with 2 injections 24 hours apart	Melarsomine not indicated for acute care

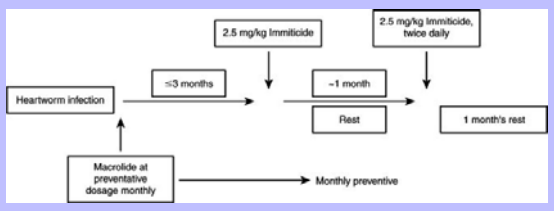
206.6 THERAPY

206.6.1 Melarsomine

In most cases of HWD, it is imperative to rid the patient of the offending parasite. Thiacetarsemide, for decades the only drug approved for this purpose, is no longer available. It has been replaced by melarsomine (Immiticide®), an organoarsenic superior in safety and efficacy to thiacetarsemide.[1] With two doses (2.5 mg/kg intramuscularly every 24 hours), the efficacy is over 96%. Melarsomine has a mean retention time five times longer than thiacetarsemide, and its metabolites are free in the plasma (on which heartworms feed).[51,52] In a study of 382 dogs with HWI receiving melarsomine, none required cessation of therapy due to hepatorenal toxicity (as compared with 15% to 30% with thiacetarsemide), and no case of severe PTE was observed.[53]

Despite the enhanced safety of this product, adverse reactions are still noted.[14,16,54] In fact, successful pharmacologic adulticidal therapy, by definition, dictates thromboembolic events. The clinician can diminish the severity of this complication by restricting exercise after melarsomine administration. Perhaps the drug's biggest asset is the possibility of flexible dosing ("split-dose"—three injections over 1 month or longer), allowing the potential for a safer 50% initial worm kill, followed by subsequent injections to approach 100% efficacy. Studies have shown that patients treated with the split-dose regimen have a higher seroconversion to a negative antigen status than patients treated with either caparsolate or the standard melarsomine dosing regimen.[55,56]

Figure 206-10 An algorithmic approach to the management of heartworm infection (HWI) in the dog. (Atkins CE, Miller M: Is there a better way to administer heartworm adulticidal therapy? *Vet Med*, April 310-317, 2003.)



A split-dose protocol can be used in severely afflicted individuals or in those in which pulmonary thromboembolism is anticipated (Table 206-4). This method allows for destruction of only one half the worms initially (one intramuscular injection of 2.5 mg/kg), thereby lessening the chance for embolic complications. This single dose is followed by a two-dose regimen in 1 to 3 months, if clinical conditions permit. Although the manufacturer recommends this protocol for severely affected dogs, the author uses it for all cases unless financial constraint or underlying concern for arsenic toxicity exists (e.g., pre-existent severe renal or hepatic disease; Figure 206-10).[54] Disadvantages to the split-dose method include additional expense, increased total arsenic dose, and the need for 2 months' exercise restriction.

In 55 dogs with severe HWD that were treated in this manner, 96% had a good or very good outcome with more than 98% negative for antigenemia 90 days post-therapy.[53] Of the 55 severely affected dogs, 31% had "mild or moderate PTE," but no fatalities resulted. The most common sign was fever, cough, and anorexia 5 to 7 days post-treatment. This was associated with mild perivascular caudal lobar pulmonary radiographic densities and subsided spontaneously or after corticosteroid therapy.

206.6.2 Microfilaricidal and Preventative Therapy in Heartworm-Positive Dogs

At the time of diagnosis (usually by a positive heartworm antigen test) a minimum data base is completed. This includes a microfilaria test, chemistry panel, complete blood count (CBC), urinalysis, and thoracic radiographic evaluation. If liver disease is suspected from clinical and laboratory find-ings, serum bile acid evaluation may be useful in evaluating liver function. At this time, monthly macrolide preventative is prescribed (see Figure 206-10). This approach, which differs from the recommendations of the American Heartworm Society, is used to prevent further infection, to eliminate microfilariae (chronic therapy renders the dog of no further risk to infect itself or other dogs and cats), and to destroy developing L4 (not yet susceptible to adulticidal therapy). In microfilaremic dogs, the first macrolide dose is administered in the hospital or at home, with observation, so an adverse reaction might be recognized and treated promptly.

1127 1128

Corticosteroids with or without antihistamines (dexa-methasone at 0.25 mg/kg intravenously and Benadryl at 2 mg/kg intramuscularly or 1 mg/kg of prednisolone orally 1 hour before +/– 6 hours after administration of the first dose of preventative) may be administered to reduce the potential for adverse reaction in highly microfilaremic patients. It is important to emphasize that adverse reactions are unusual with macrolides at preventative doses.

Depending on the time of year, up to 2 to 3 months might be allowed to lapse before adulticidal therapy is administered. Although monthly macrolide administration prevents further infection, this delay allows larval maturation to adulthood, ensuring that the only stage of the life cycle present is the adult, which is vulnerable to melarsomine therapy. This is more important if the diagnosis is made during or at the end of a mosquito exposure season. If the diagnosis is made in the spring or late winter, when infective larvae have matured, adulticidal therapy may be immediately administered (see Figure 206-10).

206.6.3 Procedure

The first injection of Melarsomine is administered by deep intramuscular injection (2.5 mg/kg) in the lumbar musculature (as described in the package insert) and the injection site recorded. Before injection, the needle is changed and care is taken to inject deep into the muscle and nowhere else. Patients are typically, but not necessarily, hospitalized for the day. The need for exercise restriction for 1 month is emphasized, and sedation is provided if necessary. Owners are also advised as to adverse reactions (fever, local inflammation, lassitude,

inappetence, cough, dyspnea, collapse), to call if they have concerns, and to return for a second series of two injections in approximately 1 month.

If serious systemic reaction results, the second stage of the adulticidal treatment is delayed or, occasionally, even canceled. Typically, however, even with severe reactions, the entire treatment protocol is completed within 2 to 3 months (see Figure 206-10). After a minimum of 1 month, the melarsomine injection procedure is repeated, again with a record of the injection site. If significant local reaction was noted after the first injection, subsequent injections are accompanied by dexamethasone or oral nonsteroidal anti-inflammatory drugs (NSAIDs) to minimize pain at the injection site. The next day (approximately 24 hours after the first injection) the process is repeated with melarsomine injection into the opposite lumbar area. Client instructions are similar to those previously given, with reemphasis of the need for 1 months' strict restriction of exercise. Antigen testing is repeated 6 months after the second series of injections, with a positive test result indicating incomplete adulticidal efficacy. It is emphasized that despite the proven efficacy of melarsomine, not all worms are killed in every patient. The worm burden is typically markedly reduced, but if as few as one to three adult female worms remain, positive antigen tests are likely. Whether to repeat adulticidal therapy, under these circumstances is decided on a case-by-case basis with input from the owners.

206.6.4 Macrolides

It is now known that certain macrolides have adulticidal properties.[39–41] Ivermectin, when administered monthly for 31 consecutive months, has nearly 100% adulticidal efficacy in young HWIs.[41] Selamectin, when administered continuously for 18 months, killed approximately 40% of transplanted worms.[39] Milbemycin and sustained release moxidectin appear to have minimal adulticidal efficacy.[39,40] Although there may be a role for this therapeutic strategy in cases in which financial constraints or concurrent medical problems prohibit melarsomine therapy, the current recommendations are that macrolides not be adapted as the primary adulticidal approach (see discussion of controversies, following).

206.6.5 Exercise Restriction

Cage rest is an important aspect of the management of HWD after adulticidal therapy, after PTE, or during therapy of heart failure. This can often be best, or only, accomplished in the veterinary clinic. If financial constraints preclude this, crating or housing in the bathroom or garage at home, tranquilization, or both, with only gentle leash walks are useful alternatives. Nevertheless, some owners do not or cannot restrict exercise, resulting in or worsening thromboembolic complications.

206.6.6 Surgical Therapy

Sasaki, Kitagawa, and Ishihara[57] have described a method of mechanical worm removal using a flexible alligator forceps (Figure 206-11). This method was 90% effective in 36 dogs with mild and severe HWD. Only two of the severely affected dogs (n = 9) died of heart and renal failure over 90 days postoperatively. These data suggest that, in skilled hands, the technique is safe. Subsequent studies by Morini and colleagues[58] demonstrated superior results as compared with melarsomine, producing less PTE and CS. It is important to note that the majority of dogs treated surgically required subsequent melarsomine administration for adequate worm destruction. Advantages to this technique include its diminished potential arsenic toxicity (subsequent adulticidal therapy would be administered to an asymptomatic dog) and relative freedom from thromboembolic complication. Disadvantages include the need for general anesthesia, a degree of operator

skill, fluoroscopy, and subsequent arsenic administration. Nevertheless, it remains a potential alternative for the management of high-risk patients.

1129

206.7 ANCILLARY THERAPY

206.7.1 Corticosteroids

The anti-inflammatory and immunosuppressive effects inherent to corticosteroids are useful for treatment of some aspects of HWD. Prednisone, the steroid most often advocated, reduces pulmonary arteritis but actually worsens the proliferative vascular lesions of HWD, diminishes pulmonary arterial flow, and reduces the effectiveness of thiacetarsemide. For these reasons, corticosteroids are indicated in HWD only in the face of pulmonary parenchymal complications (eosinophilic pneumonitis, eosinophilic granulomas, and PTE), to treat or prevent adverse reactions to microfilaricides, and possibly to minimize tissue reaction to melarsomine. For allergic pneumonitis, prednisone (1 mg/kg/day) is administered for 3 to 5 days and discontinued or tapered as indicated.[9,16] The response is generally favorable. Prednisone has also been advocated, along with cage rest, for the management of PTE at 1 to 2 mg/kg per day, continued until radiographic and clinical improvement is noted.[16] Because of the potential for steroid-induced fluid retention, such therapy should be used cautiously in the face of heart failure. In addition, caution is warranted because early studies demonstrated that

postadulticidal corticosteroid therapy reduced pulmonary blood flow and worsened intimal disease in a model of HWI[59]; corticosteroids are also procoagulant.[16] As mentioned with adulticidal (previously discussed) and microfilaricidal (discussed following) therapies, corticosteroids may be used to minimize potential adverse reactions to melarsomine and to macrolides given to rapidly kill microfilariae.

206.7.2 Aspirin

Antithrombotic agents have received a good deal of attention in the management of HWD.[59–63] Potential benefits include reduction in severity of vascular lesions, reduction in thromboxane-induced pulmonary arterial vasoconstriction and PHT, and minimization of postadulticidal PTE.[61] Aspirin has shown success in diminishing the vascular damage caused by segments of dead worms,[61] reduced the extent and severity of myointimal proliferation caused by implanted living worms,[62] and improved pulmonary parenchymal disease and intimal proliferation in dogs receiving thiacetarsemide after previous living heartworm implantation.[59] More recent studies, however, have produced controversial results. Four dogs with implanted heartworms, receiving adulticide and administered aspirin, showed no improvement in pulmonary angiographic lesions, and treated dogs had more severe tortuousity than did controls and dogs receiving heparin.[60] Boudreau and colleagues[63] demonstrated that the aspirin dose required to decrease platelet reactivity by at least 50% was increased by nearly 70% with HWI (implantation model) and by nearly 200% with a model (dead worm implantation) of PTE. There were not significant differences in severity of pulmonary vascular lesions in aspirin-treated versus control dogs. For these reasons, the American Heartworm Society does not endorse antithrombotic therapy for routine treatment of HWD.[20] Calvert and colleagues[16] have, however, successfully used the combination of aspirin and strict cage confinement with adulticidal therapy for severe HWD.

If used, aspirin is administered daily beginning 1 to 3 weeks prior to and continued for 4 to 6 weeks after adulticide administration. With protracted aspirin therapy, packed cell volume (PCV) and serum total protein, should be monitored periodically. Aspirin is avoided or discontinued in the face of gastro-intestinal (GI) bleeding (melena or falling PCV), persistent emesis, thrombocytopenia (50,000/mm^3), and hemoptysis.[16]

206.7.3 Heparin Therapy

Low-dose calcium heparin has been studied in canine HWD and shown to reduce the adverse reactions associated with thiacetarsemide in dogs with severe clinical signs, including heart failure.[64] In this study, calcium heparin administered at 50 to 100 IU/kg subcutaneously every 8 to 12 hours for 1 to 2 weeks before and 3 to 6 weeks after adulticidal therapy, reduced thromboembolic complications and improved survival, as compared with aspirin and indobufen. Dogs in both groups also received prednisone at 1 mg/kg/day. It is emphasized that this therapy has not been studied with melarsomine adulticidal therapy. Calvert and colleagues[16] advocate sodium heparin (50 to 70 U/kg) in dogs with thrombocytopenia, DIC, or both, continuing until the platelet count is greater than 150,000/mm^3, for at least 7 days, and possibly for weeks.

206.7.4 Microfilaricidal Therapy

Despite the fact that no agent is approved by the Food and Drug Administration for the elimination of microfilaria, microfilaricidal therapy is traditionally instituted 4 to 6 weeks after adulticide administration.[16] The macrolides offer a safe and effective alternative to levamisole and dithiazanine. Microfilariae are rapidly

cleared with ivermectin at 50 µg/kg (approximately eight times preventative dose) or milbemycin at 500 mg/kg (preventative dose), although this represents an extra-label use of ivermectin. Adverse reactions, the severity of which is likely related to microfilarial numbers, were observed in 6% of 126 dogs receiving ivermectin at the microfilaricidal dose.[65] Signs included shock, depression, hypothermia, and vomiting. With fluid and corticosteroid (dexamethasone at 2 to 4 mg/kg intravenously) therapy, all dogs recovered within 12 hours. One fatality, however, was observed 4 days after microfilaricidal therapy. Similar findings and frequency have been reported with milbemycin at the preventative dose.[38] Dogs so treated should be hospitalized and carefully observed for the day. Dogs less than 16 kg, harboring more than 10,000 microfilaria per milliliter of blood, are more apt to suffer adverse reactions.[61] Benadryl (2 mg/kg intramuscularly) and dexamethasone (0.25 mg/kg intravenously) can be administered prophylactically to prevent adverse reactions to microfilaricidal doses of macrolides.

A slower microfilarial kill rate can also be achieved with ivermectin, moxidectin, and selamectin at preventative doses.[23,38,39,66] Using either the rapid or "slow kill" approach rids the patient of microfilariae and sterilizes the female heartworm.

The American Heartworm Society recommends that macrolide therapy, at preventative doses, be instituted 3 to 4 weeks after adulticidal therapy.[25] Accelerated microfilarial destruction can be achieved using recommended doses of milbemycin or by reducing the dosing interval for the other topical or oral formulations to every 2 weeks. Filter or modified Knott tests are rechecked in 5 months when using a slow kill or after 2 to 3 macrolide doses when using a accelerated dose.[25] This interval for testing can be reduced if milbemycin or high-dose ivermectin (50 µg/kg) is chosen.

This author chooses an alternative approach (see Figures 206-4 and 206-10), beginning the administration of a macrolide preventative at the time of diagnosis, often days to weeks prior to adulticidal therapy. With the slow kill microfilaricides (ivermectin, moxidectin, or selamectin at preventative doses), little chance exists of an adverse reaction; however, the owner is warned of the possibility and advised to administer the medication on a day when he or she will be at home. If milbemycin is used, it is usually administered in the hospital and may be preceded by administration of dexamethasone and Benadryl (as described previously in adulticidal therapy).

206.8 COMPLICATIONS AND SPECIFIC SYNDROMES

206.8.1 Asymptomatic Heartworm Infection

Most dogs with HWI are asymptomatic, even though many of these have HWD (radiographic and pathologic lesions). Treatment is as described previously, using melarsomine in the split-dose regimen, along with a macrolide preventative. 1129 1130

Asymptomatic dogs may, however, become symptomatic after adulticidal therapy due to PTE and lung injury (as described elsewhere). The risk of PTE can be imperfectly predicted by semiquantitation of the worm burden, using certain antigen tests, and by the severity of radiographic lesions.[22] Clearly a dog with severe radiographic lesions will not tolerate thromboembolic complications well, but not all dogs with radiographic signs have heavy worm burdens. For example, a dog with moderate to severe radiographic lesions and high antigenemia may not be at high risk for postadulticidal PTE, because it is quite possible that the worms have died, explaining both the antigenemia (release from dead worms) and radiographic abnormalities (chronic HWD). This conclusion might also be valid in the dogs with severe radiographic lesions and negative or low antigenemia (assumes most or all worms have died, and antigen has been cleared). Alternatively, antigenic

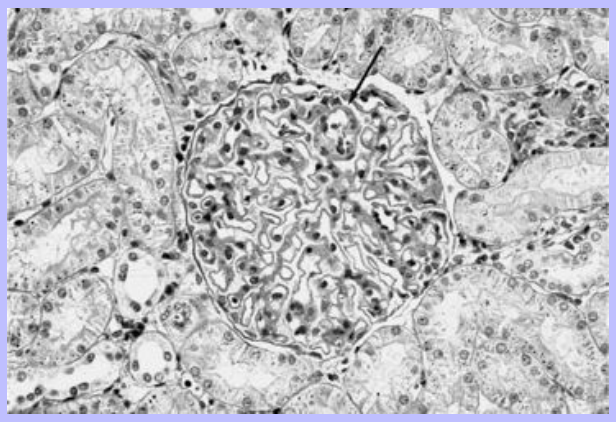
evidence of a heavy worm burden in a dog with minimal radiographic signs might still portend a severe reaction after melarsomine, because the findings suggest large worm numbers but without natural worm attrition (i.e., a relatively young infection with minimal disease). Of course, low worm burden and minimal radiographic lesions would suggest the least risk of an adverse reaction to adulticide.

It bears emphasis that with each scenario, guesswork is involved and precautions should be taken. When the risk is greatest, aspirin (5 to 7 mg/kg daily—begun 3 weeks prior to and continued until 3 weeks after adulticide) or even heparin may be used,[16] and cage confinement is most important. The owners should be educated as to the risk, the suggestive signs, and the importance of prompt veterinary assistance in case of an adverse reaction.

206.8.2 Glomerulonephritis

The majority of dogs suffering from chronic HWI have glomerulonephritis, which can be severe (Figure 206-12).[11] Therefore when a dog demonstrates glomerular disease, HWI should be considered as a differential diagnosis. Although it is generally felt that the glomerular lesions produced by HWI are unlikely to produce renal failure, a therapeutic dilemma results when one is found in a dog with proteinuria, azotemia, and HWI. Logic suggests that adulticidal therapy is indicated because HWI contributes to glomerular disease, but it likewise carries risks. The approach embraced by this author is to hospitalize the patient and to administer intravenous fluids (lactated Ringer's solution at 2 to 3 mL/kg/hr) for 48 hours (beginning 12 hours prior to the first melarsomine dose). The patient is then released, and a recheck appointment for blood urea nitrogen (BUN) and creatinine determination after 48 hours is advised. The second and third injections are tentatively scheduled for 1 to 3 months, with the treatment decision based on renal function and the overall response to initial adulticidal therapy.

Figure 206-12 An H&E stained, 3 µm section of a glomerulus from a dog with chronic heartworm disease (HWD) and resultant membranoproliferative glomerulonephritis. The capillary walls are thickened, and an overall increase in cellularity is seen. The reader should note a thick-walled capillary containing intraluminal microfilariae. (Photograph courtesy Dr. Greg Grauer.)



206.8.3 Allergic Pneumonitis

Allergic pneumonitis, which is reported to affect 14% of dogs with HWD, is a relatively early development in the disease course.[9,16] In fact, the pathogenesis probably involves immunologic reaction to dying microfilariae in the pulmonary capillaries. Clinical signs include cough and sometimes dyspnea and other typical signs of HWD, such as weight loss and exercise intolerance. Specific physical examination findings may be absent or may include dyspnea and audible crackles in more severe cases. Radiographic findings include those typical of HWD but with an infiltrate, usually interstitial, but occasionally with an alveolar component, often worse in the caudal lung lobes (see Figure 206-8). Eosinophils and basophils may be found in excess in peripheral blood and in airway samples.

Corticosteroid therapy (prednisone or prednisolone at 1 to 2 mg/kg per day) results in rapid attenuation of clinical signs, with radiographic clearing in less than a week. The dose can then be stopped in 3 to 5 days if clinical signs subside. Although microfilaricidal therapy is typically not indicated because infections are often occult, macrolide prophylaxis is indicated to avoid further infection. Adulticidal therapy can be used after clinical improvement.

206.8.4 Eosinophilic Granulomatosis

A more serious, but rare, manifestation, pulmonary eosinophilic granulomatosis, responds less favorably. This syndrome is characterized by a more organized, nodular inflammatory process, associated with bronchial lymphadenopathy and, occasionally, pleural effusion. With pulmonary granulomatosis, cough, wheezes, and pulmonary crackles are often audible; when very severe, lung sounds may be muffled and associated with dyspnea and cyanosis. Treatment with prednisone at twice the dose for allergic pneumonitis is reported to induce partial or complete remission in 1 to 2 weeks. The prognosis remains guarded because recurrence within several weeks is common. Prednisone may be combined with cyclophosphamide or azathioprine in an effort to heighten the immunosuppressive effect. The latter combination appears to be the most effective. Adulticide therapy should be delayed until remission is attained. As the prognosis for medical success is guarded; surgical excision of lobar lesions has been advocated.[67]

206.8.5 Pulmonary Embolization

Spontaneous thrombosis or PTE associated with dead and dying worms—the most important heartworm complication—may precipitate or worsen clinical signs, producing or aggravating PHT, right heart failure or, in rare instances, hemoptysis and pulmonary infarction. Acute fatalities may result from fulminant respiratory failure, exsanguination, DIC, or may be unexplained and sudden (arrhythmia or massive pulmonary embolism). The most common presentation, however, is a sudden onset of lethargy, anorexia, and cough 7 to 10 days after adulticidal therapy—often after failure to restrict exercise. Dyspnea, fever, mucous membrane pallor, and adventitial lung sounds (crackles) may be noted on physical examination.

Thoracic radiographs (Figure 206-13) reveal significant pulmonary infiltrates, most severe in the caudal lung lobes. The degree of worsening, as compared with pretreatment radiographs, is typically dramatic. The infiltrate, typically alveolar, is most severe in the caudal lobes, and occasionally areas of consolidation are noted. Laboratory abnormalities vary with the severity of signs but may include leukocytosis, left shift, monocytosis, eosinophilia, and thrombocytopenia. The degree thrombocytopenia may provide prognostic information.

Figure 206-13 Lateral thoracic radiograph obtained from a dog with chronic heartworm disease (HWD), postadulticide. The reader should note right ventricular enlargement, enlarged apical pulmonary arteries partially obscured by pulmonary infiltrate, and an interstitial and alveolar infiltrate, most severe in the caudal lung lobes.

Medical management of thromboembolic lung disease is largely empiric and somewhat controversial. It is generally agreed that strict cage confinement, oxygen administration via oxygen cage or nasal insufflation (50 to 100 mL/kg), and prednisone (1 mg/kg/day for 3 to 7 days) are indicated in the most severe cases.[14,16,68] Some advocate careful fluid therapy (see recommendations for CS), measuring CVP to avoid precipitation of heart failure, to maximize tissue perfusion and combat dehydration.[68] The use of heparin (75 IU/kg subcutaneously three times a day until platelet count has normalized [5 to 7 days]) and aspirin (5 to 7 mg/kg/day) has been advocated by some[30] but remains controversial.[4]

Figure 206-14 Adult male Labrador retriever with congestive heart failure (CHF) due to heartworm disease (HWD). The reader should note the distended abdomen (ascites) and cardiac cachexia.

Other therapeutic strategies might include cough suppressants, antibiotics (if fever is unresponsive), and, although speculative at this time, vasodilators (amlodipine, hydralazine, diltiazem; see discussion of heart failure in Chapter 197).[69,70] If vasodilatory therapy is used, one must monitor blood pressure because hypotension is a potential side effect. Clinical improvement may be rapid and release from the hospital considered after several days' treatment. For less severely affected dogs, careful confinement and prednisone at home are often adequate.

206.8.6 Congestive Heart Failure

Right heart failure results from increased right ventricular afterload (secondary to chronic pulmonary arterial disease and thromboemboli with resultant PHT). When severe and chronic, PHT may be complicated by secondary tricuspid regurgitation and right heart failure. Congestive signs (ascites) are worsened in the face of hypoproteinemia (see Figure 206-14). Calvert suggests that up to 50% of dogs with severe pulmonary vascular complication to HWD will develop heart failure.[16] Clinical signs (see Figure 206-13) variably include weight loss, exercise intolerance, ashen mucous membranes with prolonged capillary refill time, ascites, dyspnea, jugular venous distension and pulsation, arrhythmias with pulse deficits, and adventitial lung sounds (crackles and possibly wheezes). Dyspnea may be due to pulmonary infiltrates (PIE or PTE, but not cardiogenic pulmonary edema), abdominal distension, or pleural effusion.

Treatment aims include reduction of signs of congestion, reducing PHT, and increasing cardiac output. This involves dietary, pharmacologic, and procedural interventions. Moderate salt restriction is logical and probably useful in diminishing diuretic needs. This author chooses a diet designed for senior patients or early heart disease, because salt restriction should only be moderate. Diuretics may be useful in preventing recurrence of ascites but are typically not able to mobilize large fluid accumulations effectively. This then requires periodic abdominal or thoracic paracentesis (or both) when discomfort is apparent. Furosemide is

typically used at 1 to 4 mg/kg daily, depending on severity and patient response. Additional diuretics, which provide a supplemental effect by using differing parts of the nephron, include spironolactone (1 to 2 mg/kg orally twice a day) and chlorothiazide (2 mg/kg orally daily to every other day). The ACE-inhibitors (e.g., enalapril, benazepril, lisinopril, ramipril), by their effect on the renin-angiotensin-aldosterone system, may be of use as mixed vasodilators, in blunting pathologic cardiac remodeling, and in reducing fluid retention, particularly cases of refractory ascites. Adulticide therapy is delayed until clinical improvement is noted. No evidence indicates that digoxin improves survival in HWD. Because of the risk of toxicity and pulmonary vasoconstriction associated with its use, it is not routinely used by is author in the management of HWD-induced heart failure. However, digoxin may be beneficial in the presence of supraventricular tachycardia or refractory heart failure. Aspirin, theoretically useful because of its ability to ameliorate some pulmonary vascular lesions and vasoconstriction, may be used 5 mg/kg/day orally.

The arterial vasodilator, hydralazine, has been shown by Lombard[69] to improve cardiac output in a small number of dogs with HWD and heart failure. It has also been demonstrated to reduce pulmonary artery pressure and vascular resistance, right ventricular work, and aortic pressure without changing cardiac output or heart rate in dogs with experimental HWD (but without heart failure).[70] Clinical experience has shown perceived improvement with the vasodilators diltiazem and amlodipine as well. Research and clinical experience suggest that hydralazine, amlodipine, and diltiazem might have a role in this setting, but further studies are necessary to define their role, if any. In heart failure the author uses hydralazine at 0.5 to 2 mg/kg orally twice a day, diltiazem at 0.5 to 1.5 mg/kg orally three times a day, or amlodipine at 0.1 to 0.25 mg/kg/day orally. The risk of hypotension with these therapies must be realized and blood pressure monitored.

1131
1132

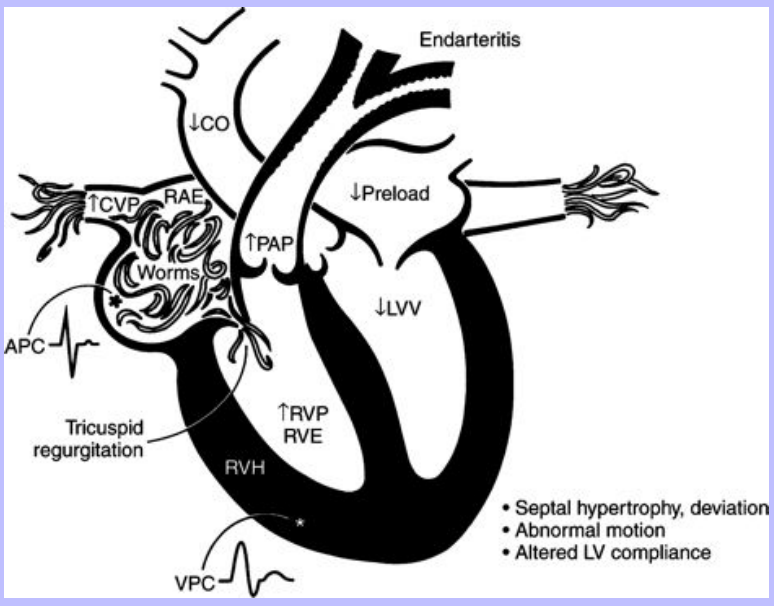
Often heart failure follows adulticidal therapy, but if it is present prior to adulticidal therapy, the difficult question arises as when (or whether) to administer melarsomine. If clinical response to heart failure management is good, adulticidal therapy may be offered in 4 to 12 weeks, as conditions allow. Melarsomine is generally avoided if heart failure is refractory. Antiarrhythmic therapy is seldom necessary, although slowing the ventricular response to atrial fibrillation with digoxin, Diltiazem, or both (see Chapters 197 and 202) may be necessary in some cases.

206.8.7 Caval Syndrome

Heartworm CS is a relatively uncommon but severe variant or complication of HWD. Most studies have shown a marked sex predilection, with 75% to 90% of CS dogs being male. It is characterized by heavy worm burden (usually >60, with the majority of the worms residing in the right atrium and venae cavae) and a poor prognosis.[18]

Studies performed in the author's laboratory indicate that retrograde migration of adult heartworms to the cavae and right atrium, from 5 to 17 months after infection, produces partial inflow obstruction to the right heart and, by interfering with the valve apparatus, tricuspid insufficiency (with resultant systolic murmur, jugular pulse, and CVP increase).[71] Affected dogs also exhibit pre-existent heartworm-induced PHT, which markedly increases the adverse hemodynamic effects of tricuspid regurgitation. These combined effects substantially reduce left ventricular preload and hence cardiac output. Cardiac arrhythmias may further compromise cardiac function (Figure 206-15).

Figure 206-15 Schematic demonstrating pathogenesis of cardiac dysfunction in heartworm caval syndrome (CS). CS complicates chronic heartworm disease (HWD) when retrograde worm migration from the pulmonary arteries occurs, with the majority of worms relocating in the venae cavae and right atrium. Tricuspid valvular function is altered, resulting in incompetence. Tricuspid regurgitation is superimposed on pulmonary hypertension. Left ventricular preload is diminished. Congestive and low-output heart failure ensues. Septal deviation to the left and abnormal, rightward septal motion contributes to preload starvation of the left ventricle. Right ventricular inflow obstruction due to heartworms and cardiac arrhythmias may further contribute to cardiac dysfunction but are probably less important. *CO,* Cardiac output; *PAP,* pulmonary hypertension; *CVP,* central venous pressure; *RAE,* right atrial enlargement; *APC,* atrial premature complex; *VPC,* ventricular premature complex; *RVH,* right ventricular hypertrophy; *RVP,* right ventricular pressure; *RVE,* right ventricular enlargement; *LVV,* left ventricular volume; *Arrows,* increased or decreased. (From Atkins CE: Pathophysiology of heartworm caval syndrome: recent advances. *In* Otto GF: Proc Amer Heartworm Symposium '89. Batavia, Ill., American Heartworm Society, 1990, pp 27–31.)



This constellation of events precipitates a sudden onset of clinical signs, including hemolytic anemia caused by trauma to red blood cells (RBCs) as they pass through a sieve of heartworms occupying the right atrium and venae cavae, as well as through fibrin strands in capillaries if DIC has developed. Intravascular hemolysis, metabolic acidosis, and diminished hepatic function with impaired removal of circulating pro-coagulants contribute to the development of DIC. The effect of this traumatic insult to the erythron is magnified by increased RBC fragility, due to alterations in the RBC membrane in dogs with HWD. Hemoglobinemia, hemoglobinuria, and hepatic and renal dysfunction also are observed in many dogs. The cause of hepatorenal dysfunction is not clear, but it probably results from the combined effects of passive congestion, diminished perfusion, and the deleterious effects of the products of hemolysis. Without treatment, death frequently ensues within 24 to 72 hours due to cardiogenic shock, complicated by anemia, metabolic acidosis, and DIC.

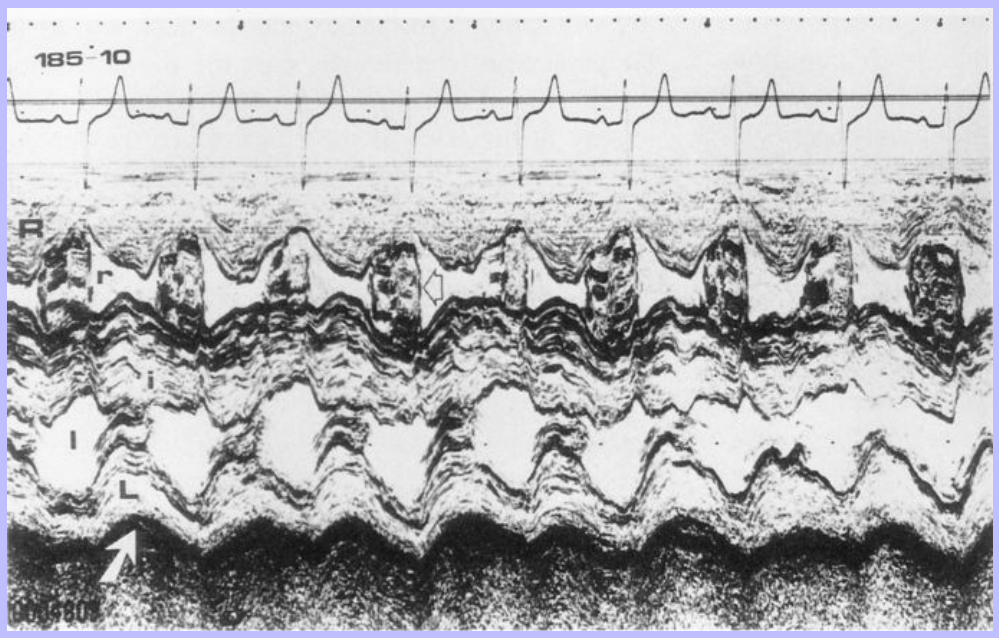
A sudden onset of anorexia, depression, weakness, and occasionally coughing are accompanied in most dogs by dyspnea and hemoglobinuria. Hemoglobinuria has been considered pathognomonic for this syndrome. Physical examination reveals mucous membrane pallor, prolonged capillary refill time, weak pulses, jugular distension and pulsation, hepatosplenomegaly, and dyspnea. Thoracic auscultation may disclose adventitial lung sounds; a systolic heart murmur of tricuspid insufficiency (87% of cases); loud, split S2 (67%); and cardiac gallop (20%). Other reported findings include ascites (29%), jaundice (19%), and hemoptysis (6%). Body temperature varies from subnormal to mildly elevated.[18]

1132 1133

Hemoglobinemia and microfilaremia are present in 85% of dogs suffering from CS.[18] Moderate (mean PCV, 28%) regenerative anemia characterized by the presence of reticulocytes, nucleated RBC, and increased mean corpuscular volume (MCV) is seen in the majority of cases. This normochromic, macrocytic anemia has been associated with the presence of target cells, schistocytes, spur cells, and spherocytes. Leukocytosis (mean white blood cell [WBC] count, approximately 20,000 cells/cm^3) with neutrophilia, eosinophilia, and left shift has been described. Dogs affected with DIC are characterized by the presence of thrombocytopenia and hypofibrinoginemia, as well as prolonged one stage prothrombin time (PT), partial thromboplastin time (PTT), activated coagulation time (ACT), and high fibrin degradation product concentrations. Serum chemistry analysis reveals increases in liver enzymes, bilirubin, and indices of renal function. Urine analysis reveals high bilirubin and protein concentrations in 50% of cases and more frequently, hemoglobinuria.

CVP is high in 80% to 90% of cases (mean, 11.4 cm H_2O). Electrocardiographic abnormalities include sinus tachycardia in 33% of cases and atrial and ventricular premature complexes in 28% and 6%, respectively. The mean electrical axis tends to rotate rightward (mean, +129 degrees), with an S1,2,3 pattern evident in 38% of cases. The S wave depth in CV6LU (V_4) is the most reliable indicator of right ventricular enlargement (>0.8 mv) in 56% of cases. Thoracic radiography reveals signs of severe HWD with cardiomegaly, main pulmonary arterial enlargement, increased pulmonary vascularity, and pulmonary arterial tortuousity recognized in descending order of frequency (see Figures 206-5 to 206-7). Massive worm inhabitation of the right atrium with movement into the right ventricle during diastole is evident echocardiographically. This finding on M-mode and two-dimensional echocardiograms is nearly pathognomonic for CS in the appropriate clinical setting (Figure 206-16). The right ventricular lumen is enlarged and the left diminished in size, suggesting PHT accompanied by reduced left ventricular loading. Paradoxical septal motion, caused by high right ventricular pressure, is commonly observed. No echocardiographic evidence of left ventricular dysfunction exists. Cardiac catheterization documents pulmonary, right atrial, and right ventricular hypertension and reduced cardiac output.

Figure 206-16 An *M*-mode echocardiogram of a dog with recent onset caval syndrome (CS), demonstrating thickening of the right ventricular and intraventricular septal walls, right ventricular eccentric hypertrophy, and a small left ventricle. An echogenic mass *(clear arrow)* of heartworms can be seen "falling" into the right ventricle with each diastole. Paradoxical septal motion is evident. The white arrow denotes the pericardium. *R,* Right ventricular wall; *r,* right ventricular lumen; *i,* intraventricular septum; *l,* left ventricular lumen; *L,* left ventricular posterior wall. (From Atkins CE: Heartworm caval syndrome. Semin Vet Med Surg 2:64–71, 1987.)



Prognosis is poor unless the cause of the crisis—the right atrial and caval heartworms—is removed. Even with this treatment, mortality can approximate 40%.

Fluid therapy is needed to improve cardiac output and tissue perfusion, to prevent or help to reverse DIC, to prevent hemoglobin nephropathy, and to aid in the correction of metabolic acidosis. Overexuberant fluid therapy, however, may worsen or precipitate signs of CHF. In the author's clinic, a left jugular catheter is placed and intravenous fluid therapy instituted with 5% dextrose in water or one-half strength saline and 2.5% dextrose. The catheter should not enter the anterior vena cava because it will interfere with worm embolectomy. A cephalic catheter may be substituted for the somewhat inconvenient jugular catheter, but this does not allow monitoring of CVP. The intravenous infusion rate for fluids is dependent on the condition of the animal. A useful guideline is to infuse as rapidly as possible (up to 1 cardiovascular volume during the first

1133
1134

hour) without raising the CVP or without raising it above 10 cm H_2O if it was normal or near normal at the outset. Initial therapy should be aggressive (10 to 20 mL/kg/hr for the first hour) if shock is accompanied by a normal CVP (<5 cm H_2O), and it should be curtailed to approximately 1 to 2 mL/kg/hr if CVP is 10 to 20 cm H_2O. Whole blood transfusion is not indicated in most cases because anemia usually is not severe, and transfused coagulation factors may worsen DIC. Sodium bicarbonate is not indicated unless metabolic acidosis is severe (pH, 7.15 to 7.20). Broad-spectrum antibiotics and aspirin (5 mg/kg daily) should be administered. Treatment for DIC is described elsewhere in this text.

The technique for surgical removal of caval and atrial heartworms was developed by Jackson and colleagues.[72] This procedure should be undertaken as early in the course of therapy as is practical. Often, sedation is unnecessary, and the procedure can be accomplished with only local anesthesia. The dog is restrained in left lateral recumbency after surgical clipping and preparation. The jugular vein is isolated distally. A ligature is placed loosely around the cranial aspect of the vein until it is incised, after which the ligature is tied. Alligator forceps (20 to 40 cm, preferably of small diameter) are guided gently down the vein while being held loosely between the thumb and forefinger. The jugular vein can be temporarily occluded with umbilical tape. If difficulty is encountered in passage of the forceps, gentle manipulation of the dog by assistants to further extend the neck will assist in passage of the forceps past the thoracic inlet; medial direction of the forceps may be necessary at the base of the heart. Once the forceps have been placed, the jaws are opened, the forceps are advanced slightly, the jaws are closed, and the worms are removed. One to four worms are usually removed with each pass. This process is repeated until five to six successive attempts are unsuccessful. An effort should be made to remove 35 to 50 worms. Care should be taken not to fracture heartworm during extraction. After worm removal, the jugular vein is ligated distally, and subcutaneous and skin sutures are placed routinely. Other catheters, such as urethral stone basket catheters, horsehair brushes, snares and flexible alligator forceps have also been used.[73] Fluoroscopic guidance, when available, is useful in this procedure.

Successful worm retrieval is associated with a reduction in the intensity of the cardiac murmur and jugular pulsations, rapid clearing of hemoglobinemia and hemoglobinuria, and normalization of serum enzymatic aberrations. Immediate and latent improvement in cardiac function occurs over the next 24 hours. It is important to realize that removal of worms does nothing to reduce right ventricular afterload (PHT), and hence fluid therapy must be monitored carefully before and after surgery to avoid precipitation or worsening of right heart failure. Cage rest should be enforced for a period of time suitable for individual care.

Worm embolectomy through a jugular venotomy is frequently successful in stabilizing the animal, allowing adulticide therapy to be instituted to destroy remaining heartworms in a minimum of 1 month. Careful scrutiny of BUN and serum liver enzyme concentrations should precede the latter treatment. Aspirin therapy is continued for 3 to 4 weeks after adulticide therapy. Substantial improvement in anemia should not be expected for 2 to 4 weeks after worm embolectomy. Macrolide preventative therapy, as described previously, is administered at the time of release from the hospital.

206.8.8 Aberrant Migration

Although heartworms in the dog typically inhabit the pulmonary arteries of the caudal lung lobes, they may find their way to the right ventricle, and rarely (see Caval Syndrome) the right atria and venae cavae. Much less frequently, immature L5 may aberrantly migrate to other sites, including the brain, spinal cord, epidural space, anterior chamber of the eye, the vitreous, the subcutis, and the peritoneal cavity. In addition, the worms may inhabit the systemic circulation, producing systemic thromboembolic disease.[12] Treatment of aberrantly

migrating heartworms requires either nothing (e.g., peritoneal cavity), surgical excision of the offending parasite, adulticidal therapy, or symptomatic treatment (e.g., seizure control with brain migration). The method for surgical removal from internal iliac and femoral arteries has been described.[12]

206.9 PROGNOSIS

The prognosis for asymptomatic HWI is generally good and, although the prognosis for severe HWD has to be guarded, a large percentage of such cases can be successfully managed.[74] Once the initial crisis is past and adulticidal therapy has been successful, resolution of underlying manifestations of chronic HWD begins. The prognosis is poorest with severe DIC, CS, massive embolization, eosinophilic granulomatosis, severe pulmonary artery disease, and heart failure. After adulticidal therapy, intimal lesions regress rapidly.[75–77] Improvement is noted as early as 4 weeks post-treatment in the main pulmonary artery, with all pulmonary arteries having undergone marked resolution within 1 year. Radiographic and arteriographic lesions of HWD begin to resolve within 3 to 4 weeks, and PHT is reduced within months and may be normal within 6 months of adulticide therapy. Pulmonary parenchymal changes are worsened during the 6 months after adulticidal therapy and then begin to lessen in severity, with marked resolution within the next 2 to 3 months. Persistence of such lesions is suggestive of persistent infection. Corticosteroid therapy hastens the resolution of these lesions. Likewise irreversible renal disease is uncommon, with glomerular lesions resolving within months of successful adulticidal therapy. Signs of heart failure are also reversible with symptomatic therapy, cage rest, and successful clearing of infection.

206.10 CONTROVERSIES IN CANINE HEARTWORM DISEASE

206.10.1 Yearly Testing

The remarkable efficacy of macrolide preventatives and the reduced danger of microfilaria-induced reactions with their use (see following section on preventatives), have caused some to question the need for yearly testing.[51] Many experts, however, continue to advocate this practice.[18] The issue of yearly testing is clearly important because it deals with financial and ethical, in addition to medical, issues. The veterinary profession must walk the fine line between adequate testing, by which we protect the public, and excessive testing, by which the public may feel “gouged.” This is difficult because only sparse scientific detail exists to answer this question, and the answer likely differs by geographic region and even within regions, based on socioeconomic strata and client compliance.

Arguments can be put forth both for and against yearly testing.[18] Proponents might argue that this practice gets animals into the clinic yearly (vaccination may not [see Chapters 163 and 164]), thereby ensuring yearly examination and resultant health benefits and income, and provides inexpensive insurance against unrecognized infection caused by poor compliance or dogs that surreptitiously expectorate medications when orally administered. In addition, yearly antigen testing is very specific (i.e., little risk of false-positive results), prevents long-term infections from becoming established during the period between heartworm checks, and would seem to limit liability to the practicing veterinarian. They might well also point out that a recent reports have demonstrated poor compliance for heartworm prophylaxis nationwide,[32–34] and even though macrolide preventatives provide the safety net of the so-called reach-back effect (or retroactive efficacy) discussed elsewhere, that this benefit is realized only with lapses of less than 3 to 4 months, varies between products, and requires continuous administration for 1 year after the lapse.[37] Finally, yearly testing for heartworm

antigen is useful to pick up latent (infections that have progressed too far to be eliminated with preventative but are not patent at the time that preventative was prescribed) or incompletely eradicated infections.

On the other hand, the opponent of yearly testing might point out that if, as a profession, we emphasize the efficacy and importance of preventive agents, we may lose credibility by also promoting yearly testing. Additionally the macrolide preventatives are very efficacious, possessing reach-back potential, in the hands of conscientious clients, and the risk of severe adverse reactions in dogs not known to be infected and receiving macrolides is small. The reason that adverse reactions are less likely is because most dogs will be rendered pharmacologically amicrofilaremic or will have small microfilarial burdens. In addition, the reactions to macrolides in microfilaremic dogs are less severe than to DEC. Furthermore, the argument can be made that the small worm burdens, most likely to result when preventative lapses are brief, will be minimally harmful and might even escape detection by immunologic tests, and that the chances of false-positive tests increase with low prevalence (as would be expected in a population of pets receiving preventative and yearly evaluation).

The American Heartworm Society addressed this question in 1995.[78] It stated "…after the initial retest, if it appears that monthly chemoprophylaxis is being given as prescribed, retesting at intervals greater than 1 year may be sufficient. However, reasonable doubt that administration has been adequate would justify retesting at shorter intervals, perhaps on an annual basis." Unfortunately little data exist on owner compliance with preventatives, and the data that have been generated are alarming. Cummings and colleagues[33] surveyed dispensing records of 50 veterinary practices in heartworm-endemic areas in the United States and found that, based on the practices' own recommendations, only enough medication was dispensed to adequately protect 41% of the canine clients. This was largely due to the fact that medication was dispensed for less than 50% of the dogs in the practices. It is important to add that this study did not identify compliance failure in which dispensed medications were not administered or in which administered medication was not swallowed. These data suggest that the majority of our canine patients should undergo yearly testing. Positive test results in this population should be carefully scrutinized, however.

206.11 YEARLONG PREVENTION

Because of the necessity of the mosquito as an intermediate host for HWI, it has been logical and accepted practice to discontinue preventatives during the winter months in the more northern climates. In warmer climates, where mosquitoes may be encountered 12 months of the year, yearlong prophylaxis has been the practice. With the advent of monthly, very effective prophylactic agents, and with improved understanding of the temperature dependence of heartworm transmission by mosquitoes, this yearlong practice has been called into question.[3] Although no supportive data exist, it might be assumed that the ease of administration of monthly preventatives may improve owner compliance and that the reach-back effect will make up for short lapses in therapy or unexpected exposures at the beginning or end of the transmission season, thereby making the effective period of prevention longer. More importantly, recent studies have shown that transmission, even in heartworm-endemic areas, does not occur during the final quarter of the year.[2] This is because the mosquito, which is generally assumed to live 30 days, requires a minimum average daily ambient temperature to allow larval development to the infectious (L3) stage. This requirement is defined in heartworm development units (HDUs). An HDU is the degree days (in °C) that the average ambient temperature surpasses the developmental threshold of 14° C (57° F).[2] Restated, for each day that the average ambient temperature exceeds the threshold, an HDU is attained; if the average temperature is 16° C for 1 day, for example, then 2 HDUs are attained. For development of infective larvae, 130 HDUs must be attained and, to be effective, these must be attained in the lifetime of the female mosquito (~30 days). If the average temperature is 16° C, for example, it would take 65 days for L3 to develop,

thereby making transmission impossible. On the other hand, a 24° C average temperature would allow the molt to L3 to occur in 13 days, well within the mosquito's life expectancy.

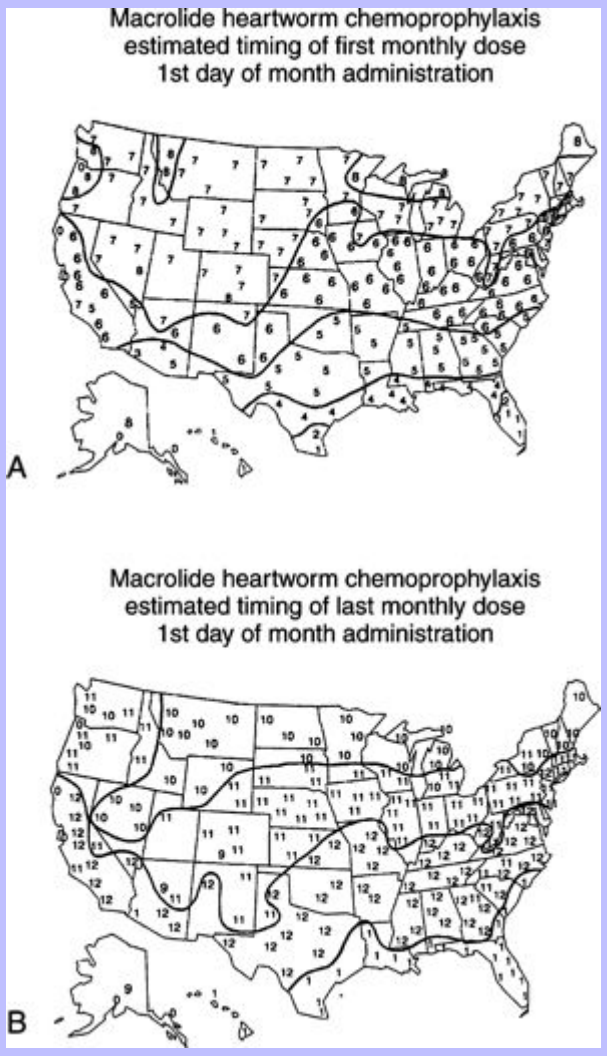
In a very innovative approach to this question, Knight and Lok[3] surveyed temperature extremes in 200 weather stations over a 30-year period and calculated the *worst case scenario* for transmission of heartworms. The resultant isotherm maps (Figure 206-17), constructed from this information indicate the month to begin and to cease heartworm preventative therapy by geographic region. In only Hawaii, Florida, and the southern tips of North Carolina, South Carolina, Georgia, Alabama, Mississippi, and Louisiana is yearlong preventative deemed necessary.

Therefore arguments may be drawn against this theory for yearlong prevention, or at least for a longer prevention season than indicated by the isotherm maps published by Knight and Lok.[3] First, though fascinating and backed by scientific fact, this represents only a theory, and one that can never be proven. It cannot be proven because this would require testing the hypothesis in every locale in the country in an infinite number of years and seasonal variation. Second, some aspects of the HDU model fall under question:

- Do all female mosquitoes really live only 30 days?
- Do some mosquito species live longer than others?
- Are there not other climatic factors such as humidity that play a role in larval development?
- Are there not microclimates within isotherm regions that might allow more HDUs to be attained?
- Might not mosquitoes seek microclimates (indoors perhaps) with temperatures to allow heartworm larval development?

Third, owner compliance has been shown to be less than optimal.[32–34] Fourth, the macrolide reach-back effect, which protects dogs for which compliance is imperfect, is less than 100% after a 4-month lapse in therapy, varies among preventatives, and requires 12 to 14 months of continuous therapy after the lapse.[37] Fifth, sometimes significant differences exist in adjacent isotherm regions, rendering decision making confusing and potentially hazardous. For example, in Florida, adjacent regions exist that require 10 or 12 months of preventative treatment. How does an owner or veterinarian know which protocol to use? Furthermore, in some areas, the change from current recommendations to those based on the isotherm maps is minimal. For example, in Wisconsin, current recommendations would dictate starting heartworm preventative in May and continuing through November, whereas the isotherm map suggests July through October, a difference of two doses. Sixth, animals travel, often to warmer climates during “nontransmission” seasons. Seventh, because some macrolides and macrolide combination drugs have broad spectra, their use in other parasite control might argue for their use for longer than just the projected heartworm transmission season. Lastly, the savings to clients is relatively small. If a client in North Carolina goes from yearlong prevention to the Knight-Lok recommendation (12-month administration to 7-month administration), the savings for a 25 lb dog is about $16.00 per year.

Figure 206-17 Isotherm maps demonstrating the month to begin **(A)** and stop **(B)** heartworm monthly preventative therapy based on data from nearly 200 weather stations (see text for detailed description). A zero (*0*) indicates no preventative necessary. (From Knight DH, Lok JB: Seasonal timing of heartworm chemoprophylaxis in the United States. In Proc Heartworm Sympos '95. Batavia, Ill., American Heartworm Society, 1996, pp 37–42.)



The Knight-Lok model has provided new and useful information, indicating that the risk in other than prime heartworm season is less than previously believed, and that in some instances heartworm prophylaxis is excessive. The Knight-Lok model should stand as a suggestion for the timing of prophylaxis, with practice erring to the conservative. This means extending the isotherm map suggestion 1 month in either direction and taking the

earliest implementation date and the latest cessation date surrounding one's geographic region. As a profession, we are faced with the dilemma of providing the best care with fiscal responsibility. The fact that our previous assumptions have come under some reassessment should be brought to the clients' attention, using the points made previously. It then falls upon the shoulders of the client to determine if the risk of possible, but generally unlikely, infection is worth the savings.

206.12 MACROLIDES AS ADULTICIDES

It is now proven that ivermectin (and possibly selamectin) has adulticidal efficacy that can approach 100% with prolonged, continuous administration.[40,41,48] Ivermectin was demonstrated to be successful as an adulticide in experimental, young infections with 31 months' continuous administration.[41] The exact role of macrolides in the management of HWI, other than as preventatives, is unclear and likely to be a major controversy in upcoming years.

The appeal of macrolides for this use is that it takes the veterinarian out of the *complication loop*. Complications might indeed still occur but would not likely be temporally linked to the macrolide administration (as they are to arsenic use). In addition, reduced cost, patient discomfort, and inconvenience are appealing. Arguments against the use of ivermectin in this way include the following:

- Represents an off-label use of ivermectin
- Requires continuous more than 30 months' compliance from a client that often has allowed HWI to occur—often by poor compliance
- Lack of knowledge about the timing and degree of exercise restriction necessary; safe use might require 31 months of continuous exercise restriction
- Absence of a controlled kill as seen with melarsomine, reducing the ability to effectively monitor for adverse effects
- Lack of knowledge as to the effect of chronic antigen release from slowly dying adult heartworms on the kidneys and lungs
- Knowledge that macrolide “slow adulticidal therapy” does not alleviate the lung disease associated with HWI[79]
- Fact that proven efficacy is only in young (<8 months old) experimental HWIs[41]
- Concern that heartworm resistance to ivermectin might develop in dogs treated in this manner[50]

At the 2001 American Heartworm Symposium, the audience and a panel of experts were polled as to their belief as to the role of ivermectin as an adulticide in their own practices.[80] Five percent of the audience and none of the expert panelists used only ivermectin for adulticidal therapy. Approximately one third of both groups did not or would not use ivermectin as an adulticide under any circumstances. Finally, approximately 70% of the expert panel and 50% of the audience stated that they would use ivermectin for this purpose only under mitigating circumstances of financial or medical constraint.

The author recommends that melarsomine be the primary adulticidal tool and recommends or accepts the use of ivermectin in instances where a preventative is necessary in a heartworm-positive dog and the owner cannot afford arsenic therapy or in which medical conditions preclude its use; in the event of residual infection after appropriate treatment with melarsomine (assumes low worm burden); and, obviously, in unrecognized infections.

207 CHAPTER • 207 Feline Heartworm Disease

Clarke Atkins

207.1 LIFE CYCLE

The life cycle of *Dirofilaria immitis* is similar in the cat and the dog (see Figure 206-2). Cats differ, however, in that they are not generally the preferred target for feeding mosquitoes, that to be infected the mosquito has to have first fed on a canid, and that, as an unnatural host, cats are inherently resistant to heartworm infection (HWI). Infections in cats therefore tend to be infrequent and small. In addition, the life cycle takes longer in the cat, such that patency (noted in <20% of cats) does not occur until 7 to 8 months postinfection.

207.2 PATHOPHYSIOLOGY

The domestic cat, though an atypical host, can be parasitized by *D. immitis*, with resultant heartworm disease (HWD). The clinical manifestations of the disease are different and often more severe in this species, but the infection rate is only 5% to 20% of that of the dog.[1] Experimental infection of the cat is more difficult than in the dog; less than 25% of L3 reach adulthood. This resistance is also reflected in natural infections, in which feline heartworm burdens are usually less than 10 and typically only 2 to 4 worms.[2] Other indications of the cat's inherent resistance to this parasite are a shortened period of worm patency, high frequency of amicrofilaremia or low microfilaria counts, and shortened life span of adult heartworms (2 to 3 years).[2] Nevertheless, studies have shown a prevalence as high as 14% in shelter cats[1] and a study performed at North Carolina State University (NCSU) revealed HWD in nine of 100 cats had cardiorespiratory signs.[3] Furthermore, antibody testing showed 26% of these cats to had been exposed to HWI.[3] Similar to dogs, the male cat is at higher risk for HWI than is the female. Aberrant worm migration appears to be a greater problem in cats than in dogs.

As in the dog, immature L5 may create pulmonary and pulmonary vascular disease in cats prior to maturation. Uniquely, the disease process develops even in cats that ultimately resist a mature infection, and as in dogs, clinical signs and disease antedate clinicians' ability to diagnose the disease through conventional means. The pulmonary arterial response to adult heartworms is more severe than that of the dog, although pulmonary hypertension has infrequently been reported. Dillon demonstrated pulmonary enlargement within 1 week of transplantation of adults, suggesting an intense host-parasite interaction.[4] A severe myointimal and eosinophilic response produces pulmonary vascular narrowing and tortuosity, thrombosis, and possibly hypertension (Figure 207-1).[5] Because the feline pulmonary artery tree is smaller than that of the dog and has less collateral circulation, embolization, even with small numbers of worms, produces disastrous results with infarction and even death. Although uncommon, cor pulmonale and right heart failure can be associated with chronic feline HWD and is manifested by pleural effusion (hydro-or chylothorax), ascites, or both. The lung per se is also insulted by HWI, with eosinophilic infiltrates in the lung parenchyma (pneumonitis) and pulmonary arteries (Figure 207-2). The pulmonary vessels may leak plasma, producing pulmonary edema (possibly acute respiratory distress syndrome, ARDS), and type II cells proliferate, both potentially altering O_2 diffusion.[4] In addition, radiographic findings suggest air trapping, compatible with bronchoconstriction. The end result to this multifaceted insult is diminished pulmonary function, hypoxemia, dyspnea, cough, and even death.

207.3 CLINICAL SIGNS

Cats with HWI may be asymptomatic and, when present, clinical manifestations may be either peracute, acute, or chronic.[3,4,6–8] Acute or peracute presentation is usually due to worm embolization or aberrant migration, and signs variably include salivation, tachycardia, shock, dyspnea, hemoptysis, vomiting and diarrhea, syncope, dementia, ataxia, circling, head tilt, blindness, seizures, and death. Postmortem examination often reveals pulmonary infarction with congestion and edema. More commonly, the onset of signs is less acute (chronic form). Reported historical findings in chronic feline HWD include anorexia, weight loss, lethargy, exercise intolerance, signs of right heart failure (pleural effusion; rare), cough, dyspnea, and vomiting. The author and colleagues have found dyspnea and cough to be relatively consistent findings and, when present, should cause suspicion of HWD in endemic areas.[8] Chylo-and pneumothorax have also been recognized as unusual manifestations of feline HWD.

In a report of 50 natural cases of feline HWI in North Carolina, presenting signs were most commonly related to the respiratory system (32 cats; 64%), with dyspnea (24 cats; 48%) being most often noted, followed by cough (19 cats; 38%) and wheezing (Figure 207-3).[8] Vomiting was reported in 17 (38%) cats and was noted frequently in 8 (16%). Five (10%) heartworm-infected cats were reported to have exhibited vomiting without concurrent respiratory signs and vomiting was a presenting sign in seven (14%). Neurologic signs (including collapse or syncope [10%]) were reported in seven (14%) cats. Five (10%) of the cats were dead at the time of presentation. Murmurs were infrequently noted in cats that did not have concurrent heart disease, independent of HWI. Heart failure was present in one cat, but it had concurrent hypertrophic cardiomyopathy. HWI was considered to be an incidental finding in 14 (28%) of the cats in this study.

1137
1138

Figure 207-1 H&E stain demonstrating large pulmonary artery with obstruction of lumen due to severe medial smooth muscle hypertrophy and hyperplasia, subintimal and intimal fibrosis, endarteritis, and possibly thrombosis. The reader should also note the periarterial interstitial (probably eosinophilic) pneumonia.

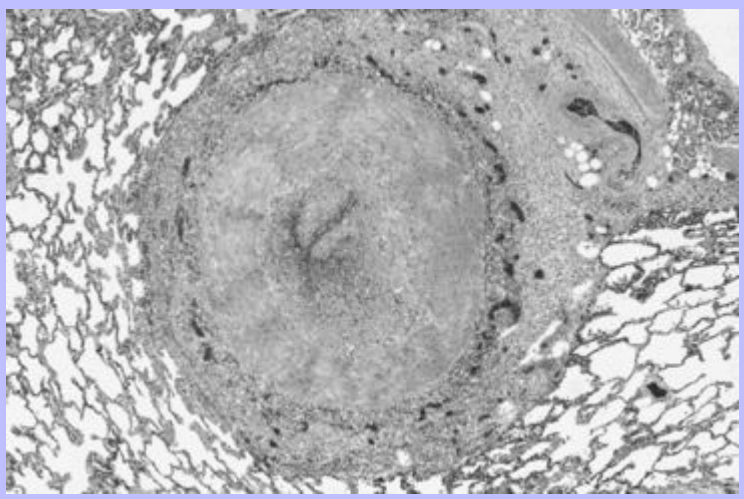

Figure 207-2 Small pulmonary artery from the cat seen in Figure 207-1 showing mild medial hypertrophy. The reader should note the extreme perivascular cuff of inflammatory cells around the vessel, representing an eosinophilic infiltrate.

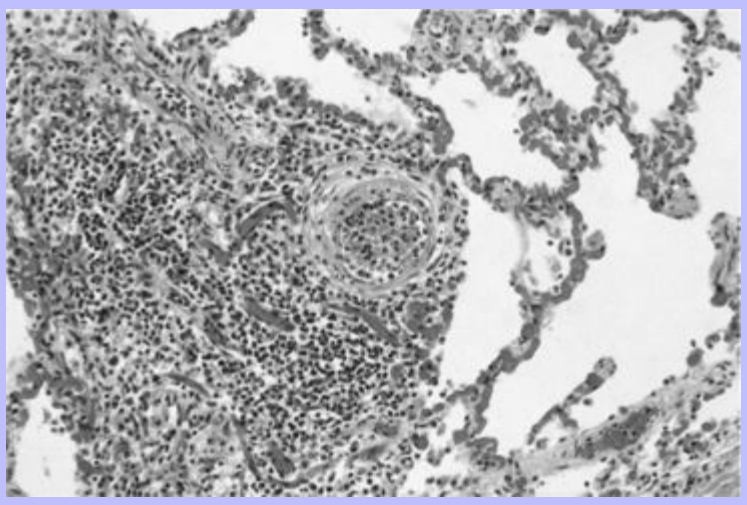
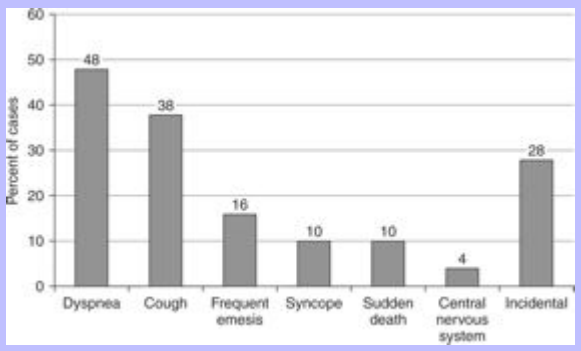


Physical examination is often unrewarding, although a murmur, gallop, or diminished or adventitial lung sounds (or a combination of these findings) may be noted. In addition, cats may be thin, dyspneic, or both. If heart failure is present, jugular venous distension, dyspnea, and rarely ascites are detected.

Figure 207-3 Clinical signs recorded in 50 cats with proven heartworm infection (HWI). *Freq,* Frequent; *CNS,* central nervous system signs (e.g., seizures, ataxia, circling). (From Atkins CE et al: Heartworm infection in cats: 50 cases [1985–1997]. J Vet Med Assoc 217:355–358, 2000.)



207.4 DIAGNOSIS

The diagnosis of HWI and HWD in cats poses a unique and problematic set of issues.[4] First, the clinical signs are often quite different from those of the dog. In addition, the overall incidence in cats is low, so suspicion is lessened, eosinophilia is transient or absent, electrocardiographic findings are minimal, and most cats are amicrofilaremic.

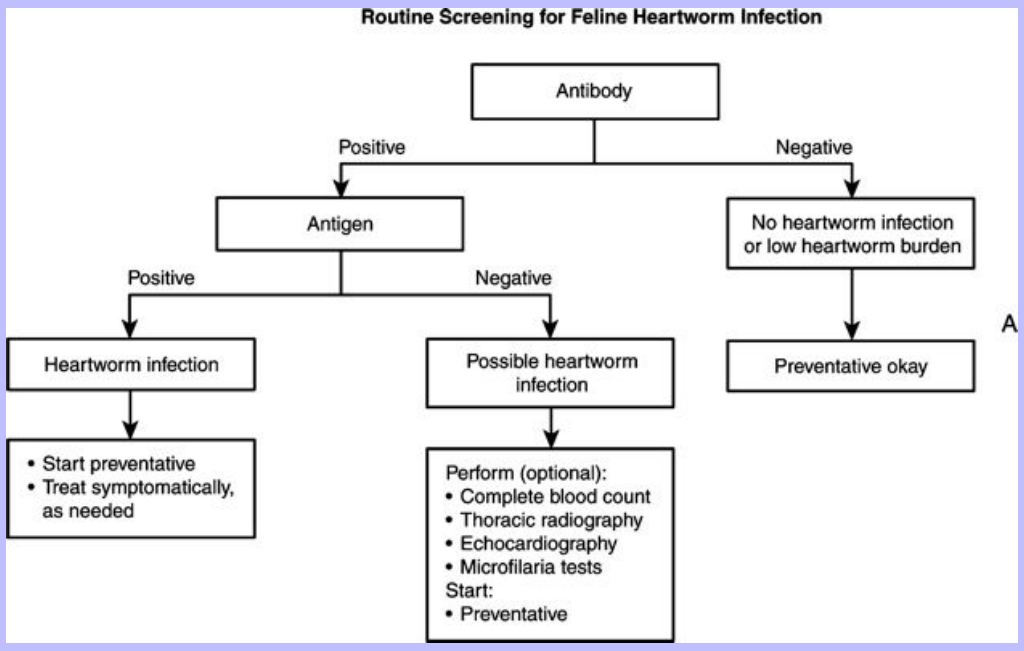
No compelling medical reasons exist to screen cats for HWI prior to administration of macrolide preventatives because the risk of adverse reactions associated with microfilarial death is small (cats are amicrofilaremic or have small microfilarial numbers, and adverse reactions are minimized with macrolide preventatives). Nevertheless, screening allows the clinician to alert pet owners if their cats have been exposed (antibody positive) so that they might pursue confirmation of the diagnosis, if they wish. It also minimizes public relations problems if the cat develops HWD while on preventative. In addition, routine screening allows the clinician to understand the risk of heartworm exposure in the practice area. The author's approach to routine screening of cats for heartworms differs somewhat from that when suspicion of infection exists (Figure 207-4, *A* and *B*).

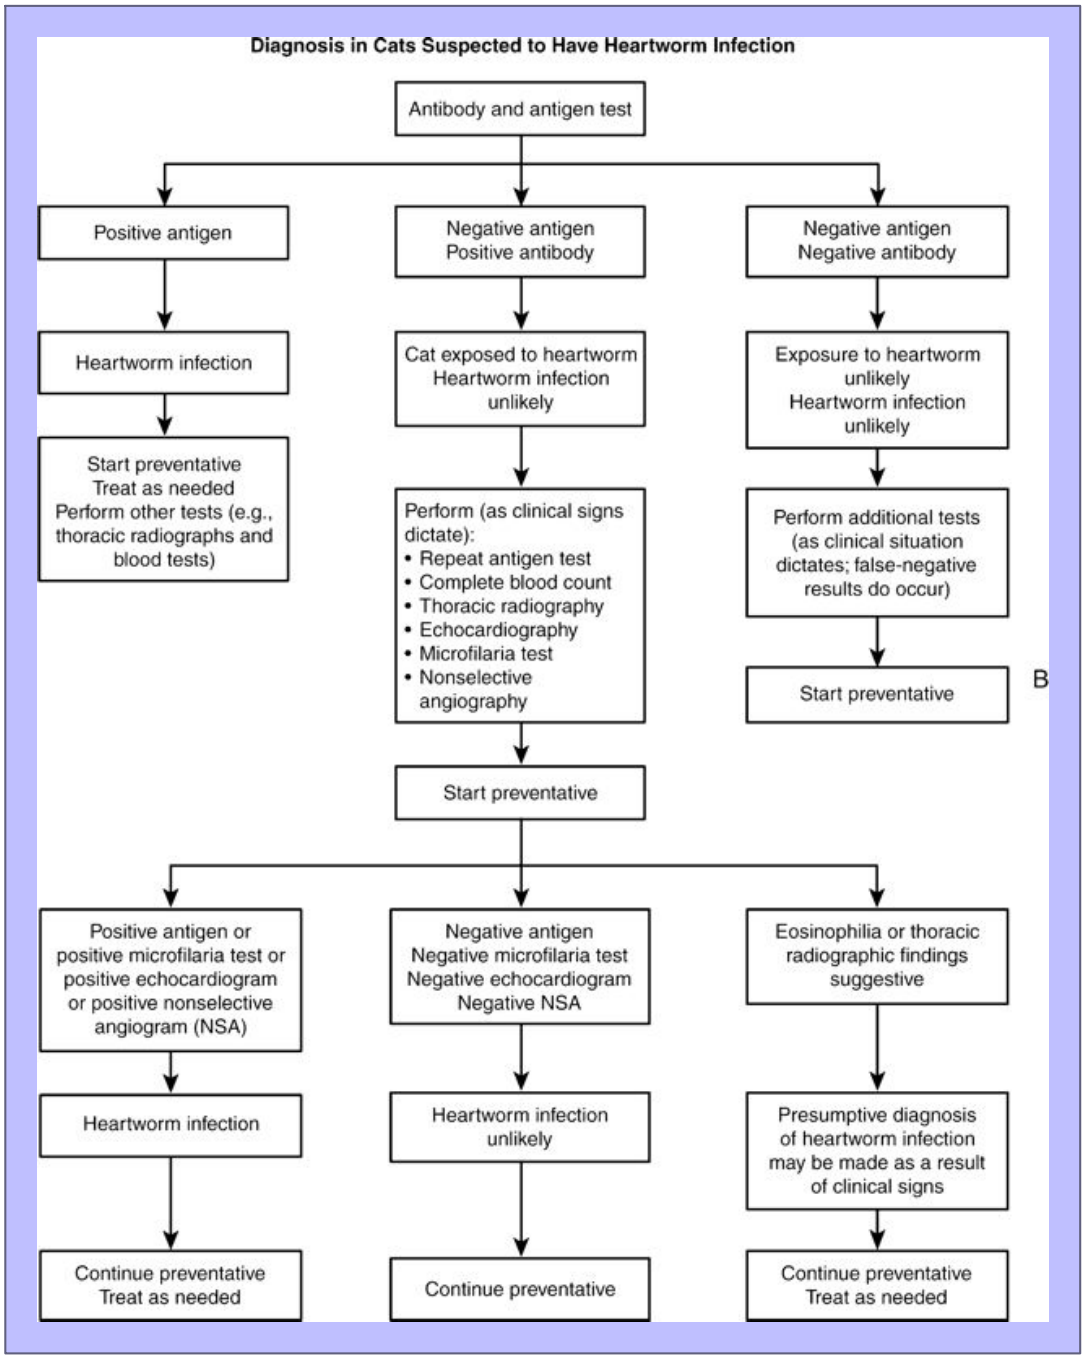
Immunodiagnostic methods (Table 206-2) are also imperfect in cats because of the low worm burdens (1 to 12; mean, 3) and hence, antigenic load. In a recent study, enzyme-linked immunosorbent assay (ELISA) antigen tests were positive on sera from 36% to 93% of 31 cats harboring 1 to 7 female heartworms, with sensitivity increasing as female worm burden increased.[9] Cats with male worm or worms were not detected as positive. Therefore false-negative tests occur frequently, depending on test used, maturity and gender of worms, and worm burden. All tests were, however, virtually 100% specific. It is important to realize that infection with signs may be present prior to the presence of detectable antigen (from gravid adult females). McCall and colleagues[10] report that, in natural infections, the antigen test detects less than 50% of cases. Snyder and colleagues[11] present differing data (from natural infections in which blood was obtained as long as 2 hours posteuthanasia) that show that the antigen test is more sensitive than previous reports (74%) indicated. Recently an antigen test (IDEXX's SNAP® Feline Heartworm Antigen Test) has been marketed for cats. This is an adaptation of the canine test, with a reported increase in sensitivity of 15% over conventional antigen tests. Although less specific, heartworm antibody tests may be of use in the detection of feline HWI, even when antigen tests are negative. The antibody test may also be useful as a marker for exposure to HWI, even if the cat never develops a mature infection. Two in-clinic feline heartworm antibody tests are available (HESKA™ SOLO STEP™ FH and Synbiotics' WITNESS® FH).

1138 1139

Thoracic radiographs have been suggested as an excellent screening test in cats. However, Schafer and Berry[12] showed that the most sensitive radiographic criterion (left caudal pulmonary artery greater than 1.6 times the ninth rib at the ninth intercostal space on the ventrodorsal projection) was only detected 53% of cases. Furthermore, even though most cats with clinical signs have some radiographic abnormality, the findings are not specific to HWD. In addition, a study by Selcer and colleagues[13] demonstrated that radiographic findings were often transient, and radiographic abnormalities were found in cats that ultimately resisted heartworm maturation and were negative on postmortem. Radiographic findings include enlarged caudal pulmonary arteries (Figure 207-5), often with ill-defined margins, pulmonary parenchymal changes that include focal or diffuse infiltrates (interstitial, bronchointerstitial, or even alveolar), perivascular density, and occasionally, atelectasis (Figures 207-6 and 207-7). Pulmonary hyperinflation may also be evident, and the misdiagnosis of feline bronchial disease can easily be made (see Figures 207-5, *A*, and 207-6, *A*). Pulmonary angiography has also been used to demonstrate radiolucent linear intravascular foreign bodies and enlarged, tortuous, and blunted pulmonary arteries (Figure 207-8).

Figure 207-4 **A,** Algorithm demonstrating the author's approach to screening cats for heartworm infection (HWI). **B,** Algorithm demonstrating the author's approach to the diagnosis of HWI in cats in which infection is suspected.





Echocardiography, in the author's experience, is more sensitive in cats than in dogs.[3,14] Typically, a *double-lined echodensity* is evident in the main pulmonary artery, one of its branches, the right ventricle, or occasionally at the right atrioventricular (AV) junction (Figure 207-9). The author and colleagues found heartworms by echocardiography in 78% of nine cases,[3] as did Selcer and colleagues in 16 experimental infections.[13]

207.5 TREATMENT AND PREVENTION

The question arises as to whether heartworm prophylaxis is warranted for cats because they are not the natural host and because the incidence is low. Necropsy studies of feline HWI in the Southeast have yielded a prevalence of 2.5% to 14%, with a median of 7% (Figure 207-10).[1] When considering the question of institution of prophylaxis, it is worth considering that this prevalence approximates or even exceeds that of feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV) infections.[15] A 1998 nationwide antibody survey of over 2000 largely asymptomatic cats revealed an exposure prevalence of nearly 12% (Figure 207-11).[16] It is also noteworthy that, based on owners' information, nearly one third of cats diagnosed with HWD at NCSU were housed solely indoors.[8] Lastly, the consequences of feline HWD are potentially dire, with no clear therapeutic solutions. Therefore the author advocates preventative therapy in cats in endemic areas. Three drugs with FDA approval are marketed for use in cats (Table 207-1). Ivermectin is provided in a chewable formulation, milbemycin as a flavored tablet, and selamectin (a broad-spectrum parasiticide) comes in a topical formulation. The spectrum and the formulation of these products varies; hence the clients' individual needs are easily met in most cases (Table 207-1).

1139
1140

Because the vast majority of cats are amicrofilaremic, microfilaricidal therapy is unnecessary in this species. The use of arsenical adulticides is problematic. Thiacetarsemide (sodium caparsolate), if available, poses risks even in normal cats. Turner, Lees, and Brown[17] reported death due to pulmonary edema and respiratory failure in 3 of 14 normal cats given thiacetarsemide (2.2 mg/kg twice over 24 hours). Dillon and colleagues[18] could not confirm this acute pulmonary reaction in 12 normal cats receiving thiacetarsemide, but one cat did die after the final injection. More importantly, a significant, though unquantified, percentage of cats with HWI develop pulmonary thromboembolism (PTE) after adulticidal therapy.[4–7] This occurs several days to 1 week after therapy and is often fatal. In 50 cats with HWI, seen at NCSU, 11 received thiacetarsemide. There was no significant difference in survival between those receiving thiacetarsemide and those receiving symptomatic therapy.[8]

1140
1142

Figure 207-5 **A,** Lateral thoracic radiograph from a cat with heartworm disease (HWD). A fine interstitial pattern is seen in the caudal lung lobes, and the chest is somewhat hyperinflated. This radiographic pattern is similar to and hence confused with that of feline bronchial disease. **B,** Dorsoventral thoracic radiograph from the same cat shown in **A**. Again, the changes are not dramatic, but the right caudal lobar pulmonary artery is enlarged (>1.6 times the ninth rib at the ninth intercostals space; *arrows*). The opposite pulmonary artery can be seen to be somewhat tortuous.

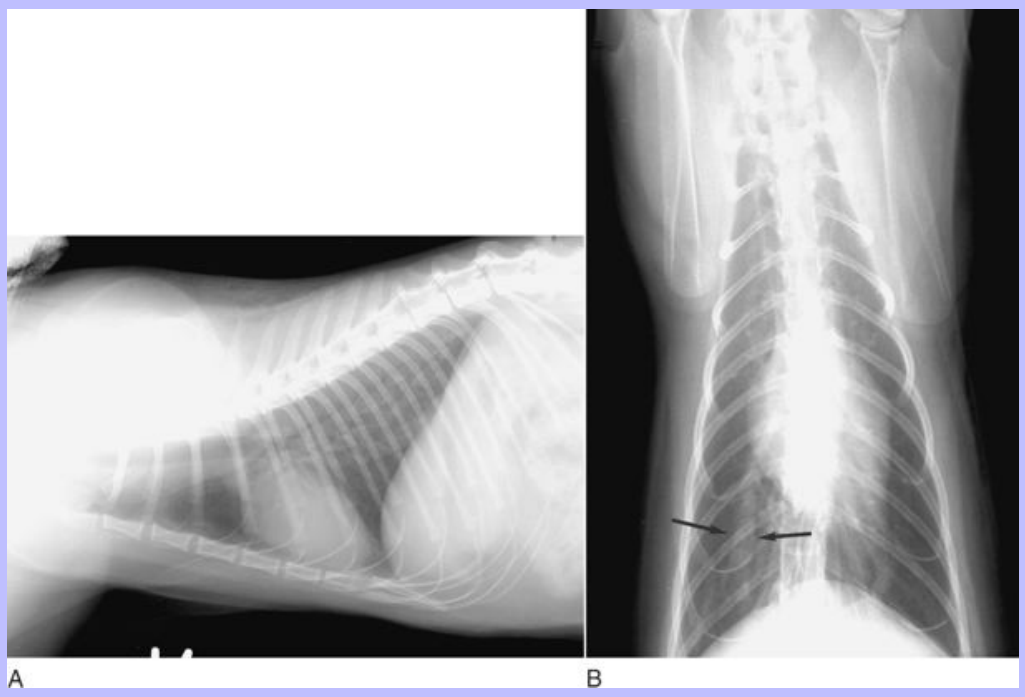


Figure 207-6 **A,** Lateral thoracic radiograph of a cat with heartworm disease (HWD) and cough. The reader should note the hyperinflated chest, flat diaphragm, and moderate interstitial pulmonary infiltrate. The right ventricle is mildly enlarged. **B,** Dorsoventral thoracic radiograph from the same cat shown in **A**. The pulmonary infiltrate is more readily appreciated in this view in the right caudal lung lobe. The reader should note the enlarged right caudal lobar pulmonary artery.

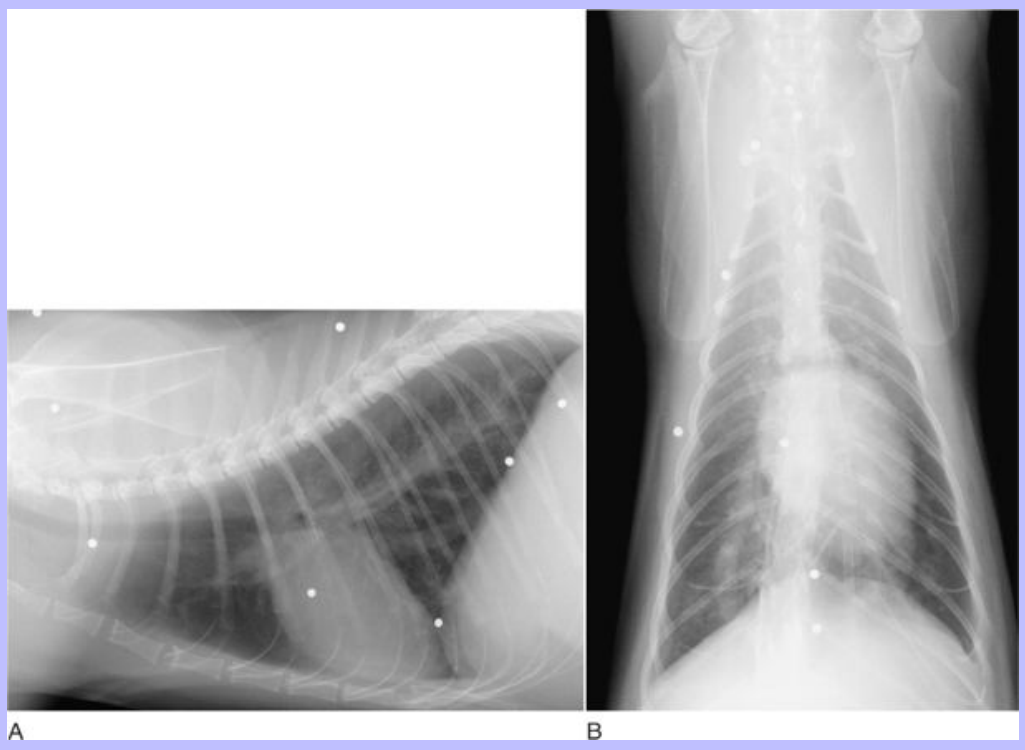

Figure 207-7 Lateral thoracic radiograph of a cat with severe respiratory distress and heartworm disease (HWD). The reader should note the alveolar infiltrate in the ventral thorax and the less severe interstitial infiltrate more dorsally in caudal lung lobes. This severe lung disease is probably due to heartworm death and may represent acute respiratory distress syndrome (ARDS).

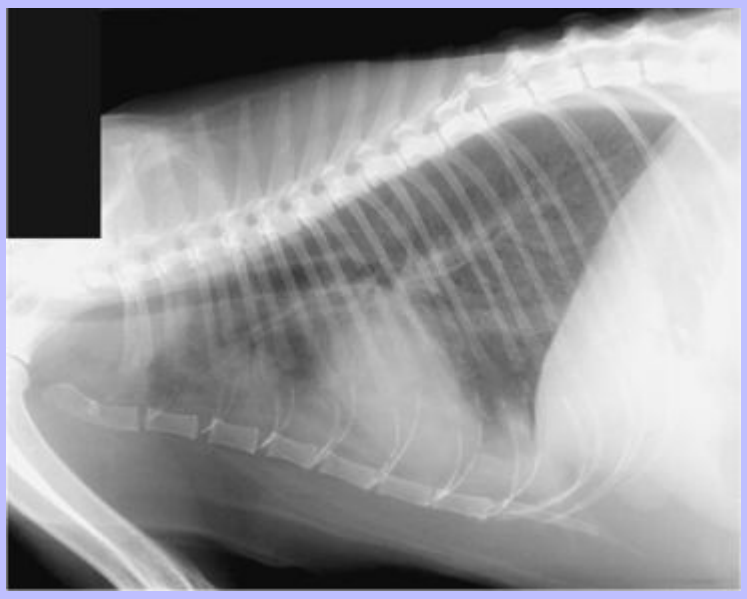

Figure 207-8 Nonselective angiogram obtained from cat with heartworm disease (HWD). The reader should note the enlarged main pulmonary artery *(open arrow)* and the enlarged, tortuous, and blunted caudal pulmonary arteries *(arrows)*. Careful scrutiny reveals linear radiolucencies in the right caudal pulmonary artery. (Photograph courtesy Dr. Kathy Spaulding. From Atkins CE: Heartworm disease. In Allen DG [ed]: Small Animal Medicine. Philadelphia, JB Lippincott Co, 1991, pp 341–363.)

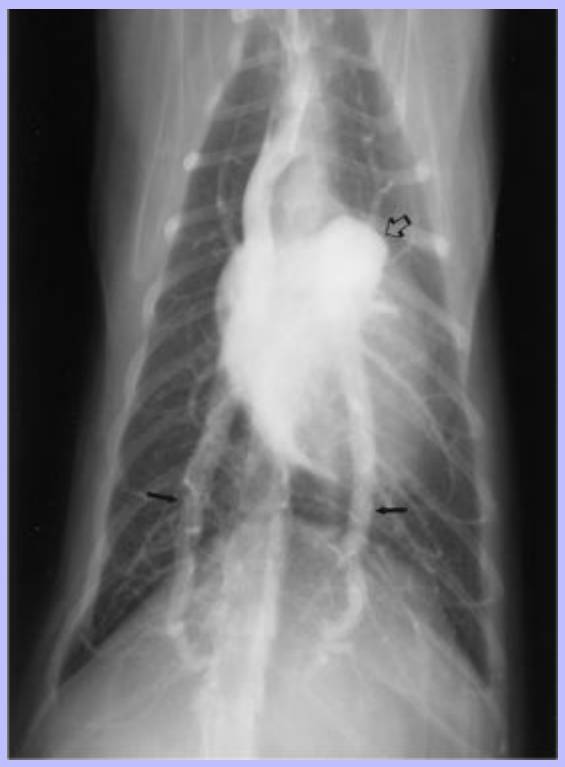

Figure 207-9 A short-axis, two-dimensional echocardiogram obtained from an 18-year-old castrate male, feline cancer patient with an asymptomatic murmur. An adult heartworm can be identified by two echo-dense parallel lines, in the right pulmonary artery *(arrow)*. *Ao,* Aorta; *RPA,* right pulmonary artery; *LPA,* left pulmonary artery.

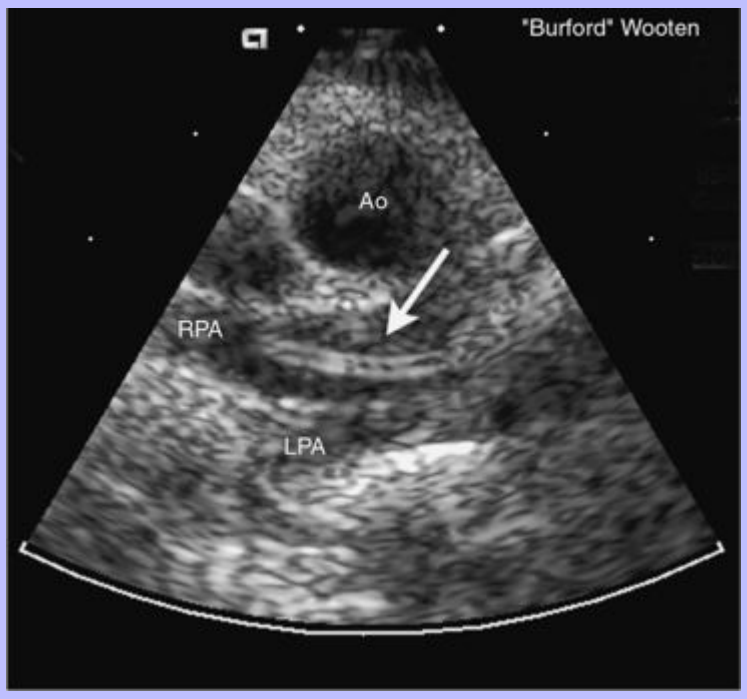
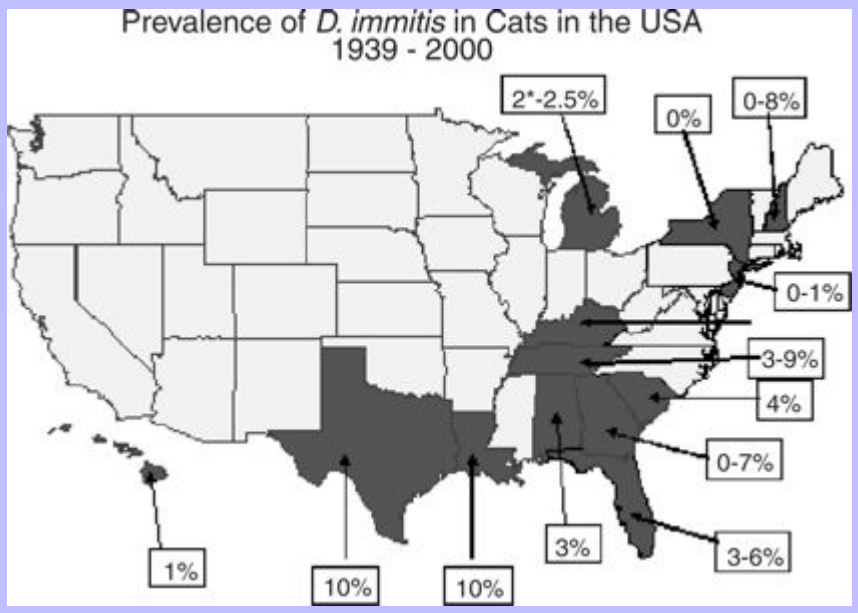


Data on melarsomine in experimental (transplanted) HWI in cats are limited and contradictory. Although an abstract report exists in which one injection (2.5 mg/kg; one half the recommended canine dose) of melarsomine was used in experimentally infected cats without treatment-related mortality, the worm burdens after treatment were not significantly different from those found in untreated control cats.[19] Diarrhea and heart murmurs were frequently noted in treated cats. A second abstract report, using either the standard canine protocol (2.5 mg/kg twice over 24 hours) or the *split dose* (one injection, followed by two injections, 24 hours apart, in 1 month) described in Chapter 206, gave more favorable results.[20] The standard treatment and split-dose regimens resulted in 79% and 86% reduction in worm burdens, respectively, and there were no adverse reactions. Although promising, these unpublished data need to be interpreted with caution because the transplanted worms were young (<8 months old and more susceptible), and the control cats experienced a 53% worm mortality (average worm burden was reduced by 53% by the act of transplantation). Additionally, the clinical experience in naturally infected cats has been generally unfavorable, with an unacceptable mortality. Because of the inherent risk, lack of clear benefit, and the short life expectancy of heartworms in this species, this author does not advocate adulticidal therapy in cats. Surgical removal of heartworms has been successful and is attractive because it minimizes the risk of thromboemboli. The mortality seen in the only published case series was, unfortunately, unacceptable (two of five cats).[21] This procedure may hold promise for the future, however.

Cats with HWI should be placed on a monthly preventative and short-term corticosteroid therapy (prednisone at 1 to 2 mg/kg every 48 hours, three times a day) used to manage respiratory signs. If signs recur, alternate-day steroid therapy (at the lowest dose that controls signs) can be continued indefinitely. For embolic emergencies, 1142
oxygen, corticosteroids (dexamethasone at 1 mg/kg intravenously or intramuscularly, or prednisolone sodium 1143
succinate at 50 to 100 mg intravenously/cat), and bronchodilators (aminophylline at 6.6 mg/kg intramuscularly every 12 hours, theophylline sustained release at 25 mg/kg orally, or terbutaline at 0.01 mg/kg subcutaneously) may be used. Bronchodilators have logic, based on the ability of agents, such as the xanthines (aminophylline and theophylline), to improve function of fatigued respiratory muscles. In addition, the finding of hyperinflation of lung fields may indicate bronchoconstriction, a condition for which bronchodilation would be indicated. Nevertheless, this author does not routinely use bronchodilators in feline HWD.

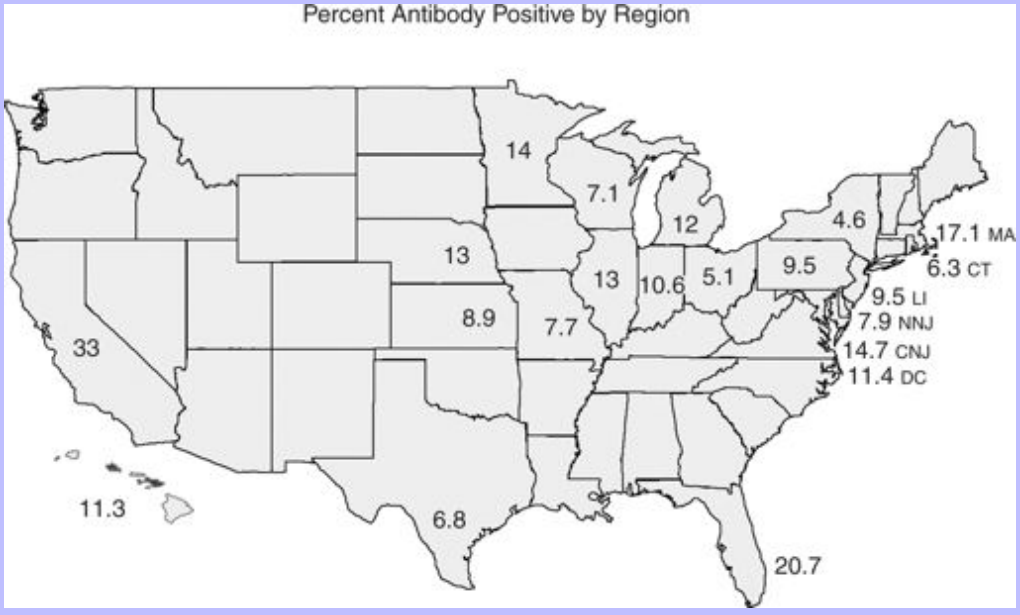
Figure 207-10 Necropsy prevalence of heartworm infection (HWI) in shelter cats. The shaded states are those in which such studies have been completed. One Michigan study, which showed a prevalence of 2%, was an antigen study. (Adapted from Ryan WG, Newcomb KM: Prevalence of feline heartworm disease—a global review. *In* Soll MD, Knight DH [eds]: Proc Heartworm Symposium '95. Batavia, Ill., American Heartworm Society, 1996.)



The use of aspirin has been questioned because vascular changes associated with HWI consume platelets, increasing their turnover rate and effectually diminishing the antithrombotic effects of the drug. Conventional doses of aspirin did not prevent angiographically detected vascular lesions.[22] Doses of aspirin necessary to produce even limited histologic benefit approached the toxic range. Despite this, because therapeutic options are limited, at conventional doses (80 mg orally, every 72 hours), aspirin is generally harmless, inexpensive, and convenient. Because the quoted studies were based on relatively insensitive estimates of platelet function and

pulmonary arterial disease (thereby possibly missing subtle benefits), the author continues to advocate aspirin for cats with HWI. Aspirin is not prescribed with concurrent corticosteroid therapy. Management of other signs of HWD in cats is largely symptomatic.

Figure 207-11 Prevalence (%) of heartworm exposure (positive antibody test) in over 2000 largely asymptomatic cats in 19 states (21 regions). *NNJ,* North New Jersey; *CNJ,* central New Jersey; *LI,* Long Island, NY. (Adapted from Miller MW et al: Prevalence of exposure to *Dirofilaria immitis* in cats from multiple areas of the United States. *In* Soll MD, Knight DH [eds]: Proc Heartworm Symposium '98. Batavia, Ill., American Heartworm Society, 1998; pp 161–166.)



207.6 PROGNOSIS

In the aforementioned study of 50 cats with natural HWI, at least 12 cats died of causes other than HWD. Seven of these and two living cats were considered to have survived HWD (lived ≥1000 days).[8] The median survival for all heartworm-infected cats living beyond the day of diagnosis was 1460 days (4 years; range, 2 to 4015 days), whereas the median survival of all cats (n = 48 with adequate follow-up) was 540 days (1.5 years; range, zero to 4015 days). Survival of 11 cats treated with sodium caparsolate (mean, 1669 days) was not significantly different from that of the 30 managed without adulticide (mean, 1107 days). Likewise, youth (<3 years of age), presence of dyspnea, cough, ELISA-positivity for heartworm antigen, presence of echocardiographically identifiably worms, or gender of the cat did not appear to affect survival.[8] The effect of HWI on survival has been compared with that of other cardiovascular diseases (Figure 207-12).[23]

Table • 207-1 Comparison of Spectra of Macrolides Currently in Use in Cats

DRUG	HW	HOOKWORMS	WHIPWORMS	ROUNDWORMS	TAPEWORMS	FLEAS & EGGS	TICKS	SARCOPTES	EAR MITES

208 CHAPTER • 208 Peripheral Vascular Disease

Philip R. Fox

Jean-Paul Petrie

Ann E. Hohenhaus

Peripheral vascular disease denotes disorders of peripheral vessels including arteries, arterioles, veins, venules, and lymphatics (Box 208-1). Vascular lesions may result from primary vascular pathology or occur secondary to conditions originating in unrelated tissues or organ systems (Box 208-2). Resultant conditions may remain asymptomatic with little or no effect on morbidity and mortality, or they may progress to become life threatening. The development of newer imaging techniques, including improvements in diagnostic ultrasound, has provided accessible methods to clinically characterize these disorders. Vascular abnormalities have been classified according to the type of vessel affected and functional significance of associated lesions (see Boxes 208-1 and 208-2).

208.1 TECHNIQUES USED TO EVALUATE PERIPHERAL VASCULAR DISEASE

208.1.1 Angiography

Angiography is the gold standard for evaluating peripheral vascular disease owing to its superior ability to characterize and visualize normal and abnormal vascular anatomy.[1]

Diagnostic outcome requires careful attention to three important elements: (1) selection of radiopaque contrast agent, (2) technique for vascular delivery of contrast material, and (3) high-quality radiographic imaging.

Factors to be considered when selecting a contrast agent include patient safety, image quality, and cost. The features of safety and efficacy are somewhat related to the ionic composition of these materials. High osmolar ionic compounds include the diatrizoate and iothalamate salts (Conray, Mallinekrodt) (Renografin, Amersham Health). Low osmolar ionic compounds include iohexol (Omnipaque, Amersham Health), iopamidol (IsoVue), and ioversol (Optiray, Mallinekrodt). Low osmolar nonionic compounds include ioxaglate (Hexabrix, Mallinekrodt). Lower osmolar agents, both ionic and nonionic, are generally tolerated best by patients, particularly those sensitive to an increase in intravascular volume or having advanced cardiac disease (high osmolar compounds can generate a greater osmotic load).[2] Nonionic agents also have reduced risk of contrast-related anaphylactoid reactions such as urticaria, flushing, coughing, dyspnea, peripheral edema, and a sudden drop in blood pressure.[3] Contrast related nephrotoxicity is independent of the contrast agent used but can be reduced by maintaining appropriate patient hydration and minimizing the dose of contrast agent used during the imaging study.[4] Low osmolar agents are generally more expensive than high osmolar agents.

Arterial angiography, often performed using carotid or femoral arterial access, can be performed to evaluate normal or abnormal arterial vascular anatomy preoperatively; to assess vessels for occlusive disease including thromboembolism (TE); and to detect or characterize inherited or acquired lesions including peripheral aneurysms, vascular tumors, traumatic injury, and shunts. The specific catheterization technique to be used is guided by consideration of the anatomic location of interest, anticipated lesion, status of patient health, available equipment, and operator experience. After percutaneous or surgical arterial cutdown, a catheter is directed under fluoroscopic guidance to the desired location and contrast agent is injected by hand or by the

use of a mechanical injecting device. Images are acquired using mechanical rapid film changers or digitally. The advantages of digital angiography include rapid rate of acquisition, postprocessing capabilities, and reduced exposure to radiation.[1] Digital subtraction angiography may be used to cancel out portions of an image and thereby improve visualization of structures of interest.

208.1.1.1 Box • 208-1 Peripheral Vascular Diseases

208.1.1.1.1 Diseases of Arteries and Arterioles

Occlusive diseases

- Arterial embolism
- Arterial thrombosis
- Angiitis, vasculitis
- Vasospasm, traumatic, toxic
- Diabetic arteriopathy

Nonocclusive diseases

- Arteriovenous (A-V) fistula
- Arterial aneurysm
- Arterial calcification
- Arteriosclerosis, hyalinosis, amyloidosis
- Atherosclerosis
- Vasculitis

208.1.1.1.2 Diseases of Veins

Phlebectasia

Varicosis

Phlebitis and thrombophlebitis

Venous thrombosis

Venous malformations

208.1.1.1.3 Diseases of Lymphatics

Lymphangitis

Lymphedema

Lymphangiectasia

Lymphatic hypoplasia, aplasia, hyperplasia

Lymphangioma, lymphocysts

Lymphangiosarcoma

208.1.1.1.4 Tumors of Peripheral Blood Vessels

Angioma, hemangioma, hemangiosarcoma

208.1.1.2 Box • 208-2 Causes of Peripheral Lymphatic Disorders

208.1.1.2.1 Lymphangitis, Lymphedema, Lymphadenitis, Lymphadenopathy

Infection

Neoplasia

Reactive hyperplasia

Granuloma

208.1.1.2.2 Lymphedema

Primary developmental abnormality of lymphatics

Hypoplasia

Aplasia

Lymphangiectasia

Hyperplasia

Secondary acquired abnormalities of lymphatics

Surgical excision of lymphatics or lymph nodes

Posttraumatic lymphangiopathy

Neoplastic invasion

Extrinsic compression of lymph vessels or tissue

Acute obstructive lymphadenitis

Chronic sclerosing lymphadenitis/lymphangitis

Lymphatic atrophy with interstitial fibrosis

Radiation therapy

208.1.1.2.3 Lymphocysts

Cystic hygroma, lymphoceles, pseudocyst

208.1.1.2.4 Lymphangiomas

Venous angiography is generally less challenging than arterial angiography, owing to easier access and lower pressures of the venous system. A small intravenous line is placed in a superficial vein distal to the site of the vascular lesion and contrast material is injected. Images are obtained similarly to arteriography. This technique is often selected to detect venous clots (appearing as vascular filling defects) or stenosis. The presence of prolific collateral vasculature can indicate chronic obstruction. Contrast venography of the cranial and caudal vena cava can be performed to assess caval patency that may be associated by a variety of neoplastic, compressive, or thrombotic disorders.

Lymphangiography helps to permit local assessment of the lymphatic system. The technique of indirect lymphangiography relies on the contrast agent, which is infused into tissue, to be selectively absorbed and transported through lymphatic channels.[5] Direct lymphangiography is more challenging (unless lymphangiectases have formed) but provides superior results when successfully performed. Selective lymphatic cannulation requires aseptic cutdown over the lymphatic region of interest. (The identification of lymphangiectases may be facilitated by subcutaneous injection of vital dyes [e.g., 3% Evans blue dye or 11% patent blue violet] into the toe web. By selective resorption of these dyes, the main lymphatic channels

proximal to the metacarpus or metatarsus become grossly outlined.) The lymphatic vessel is then cannulated with a 27-or 30-gauge needle or a special lymphatic cannula.[5] An iodine-containing soluble contrast medium such as sodium and meglumine diatrizoate (Renografin, Hypaque) is injected slowly into the vessel. Because water-soluble contrast media rapidly diffuse through lymphatic walls into surrounding tissues, the radiographic detail is blurred unless radiographs are taken shortly after dye injection. Alternatively, oily iodine-containing contrast agents (Lipiodol) are used, reducing leakage of contrast from the lymphatic vessels. The oily contrast agents are sequestered within the lymphatics and lymph nodes along the draining pathways.[1] Patency of the lymphatic channels can be appreciated in addition to the size of regional lymph nodes. Metastatic disease to the lymph nodes (or granulomas) appears as filling defects within the contrast-filled node. Lymphangiography can also be used to identify the location of lymphatic leakage.[1]

208.1.2 Diagnostic Ultrasound

Ultrasound imaging provides a direct, noninvasive technique for assessing anatomic abnormalities, vascular patency, and function.[6,7] Ultrasound can aid in the diagnosis of peripheral arterial occlusion, central and peripheral arteriovenous (A-V) fistulas, venous thrombosis, aneurysms, traumatic vascular disease, and compression of vascular structures from local disease processes.

Duplex ultrasonography incorporates gray-scale two-dimensional imaging, with pulsed wave (PW) and color flow Doppler techniques. Thrombi, foreign bodies, compression, and abnormal vascular anatomy can be identified with two-dimensional imaging. Color Doppler superimposed on the two-dimensional image can further help define anatomy and identify turbulence associated with vascular malformation and stenotic lesions. Normal arterial flow is laminar with the highest velocity recorded centrally, and the respective color Doppler image has a homogenous appearance. Arterial stenosis increases blood flow velocity across the narrowed lumen with corresponding change in color Doppler signal at and distal to the stenosis. PW Doppler velocity measurements are made along the length of the artery in question and at areas or interest indicated from color flow Doppler interrogation. PW Doppler imaging may help assess the degree (severity) of vascular narrowing by estimating the gradient across the stenosis by the modified Bernoulli equation: gradient (mm Hg) = (maximal velocity)^2 × 4. Moreover, arterial blood flow results in characteristic Doppler waveforms (a rapid forward flow component during systole, transient reversal of flow during early diastole, and a prolonged slow forward flow during late diastole). With mild to moderate vascular stenosis, characteristic changes in the PW Doppler waveform include acceleration of peak systolic velocities and loss of diastolic flow reversal distal to the stenosis. Of course, with complete stenosis, blood flow is interrupted.[8]

208.1.3 Magnetic Resonance Imaging

Magnetic resonance angiography (MRA) is a safe, noninvasive imaging technique that may be useful to evaluate the peripheral arterial system. In human medicine, both contrast and noncontrast MRA methods have been applied for planning interventional procedures (e.g., stent placements) in patients with peripheral vascular disease.[9,10] Unlike other vascular imaging techniques, noncontrast MRA displays blood flow and not the blood vessel itself. Limitations of noncontrast MRA include time of acquisition, variation of blood flow characteristics (e.g., diastolic flow reversal) in diseased vessels, and retrograde filling of arteries during complete occlusion resulting in artifacts and reduction of net forward flow on the image. Contrast-enhanced angiography using a non-nephrotoxic contrast material eliminates many of the previously mentioned limitations. Advantages of contrast-enhanced MRA include shorter acquisition times, high spatial resolution, and high signal-to-noise ratios.[10]

208.2 MECHANISMS OF THROMBOSIS

Hemostasis is a complex process that involves blood vessels, platelets, coagulation proteins, naturally occurring anticoagulants, and platelet inhibitors. Thrombosis results when one or more components of the hemostatic cascade are perturbed, tipping the balance between coagulation and fibrinolysis in favor of coagulation. Physiologic alterations leading to the formation of thrombi have frequently been classified into three main categories: (1) alterations in blood flow, (2) damage to vascular endothelium, and (3) changes in coagulation proteins and platelets, resulting in hypercoagulability.

Normal flow of blood through blood vessels is laminar, with the rapidly flowing red blood cells (RBCs) in the center of the vessel. Platelets and white blood cells (WBCs) are suspended in the blood near the vessel wall. Normal laminar flow can be disrupted by changes in the diameter of the vascular lumen and blood velocity, resulting in simultaneous regions of blood stasis and turbulence (e.g., atherosclerosis). When blood stasis occurs, increased contact occurs between platelets, coagulation factors, and the endothelium, thus promoting coagulation. Turbulent flow also causes a denuding endothelial injury that eliminates the anticoagulant function of the endothelium and promotes thrombus formation.[11]

Because under normal conditions the endothelium plays an important role for anticoagulation, factors that cause endothelial injury or dysfunction promote thrombosis. For example, the presence of atherosclerotic plaques is a well-known risk factor for thrombosis in humans and hypothyroid dogs. In addition, elevated levels of homocytseine (a sulfur-containing amino acid produced by the metabolism of methionine) act as a thrombogenic agent by promoting vascular smooth muscle cell proliferation and inhibition of endothelial cell growth. Hyperhomocysteinemia is a risk factor for thromboembolic disease in humans[12] and possibly, cats.[13,14]

Disorders that result in an imbalance of the hemostatic system toward the development of thrombosis are termed *hypercoagulable*, a physiologic alteration linked to the development of thrombosis. Either increased activity of platelets and coagulation factors or decreased activity of naturally occurring anticoagulants such as antithrombin III can result in hypercoagulability.[11]

When a thrombus becomes dislodged from the site of formation, it moves to a distal site (i.e., embolizes). Clinical consequences are generally related to local or systemic effects associated with resultant end-organ ischemia. Arterial TE can result in many organ systems. Venous thrombi may dislodge, resulting in pulmonary TE, or can result in local disruption of blood flow and venous stasis.

208.2.1 Arterial Thromboembolism

Vascular thrombosis is most readily identified when arteries are affected, and the clinical consequences are generally acute and severe. The aortic trifurcation is one of the most common locations for arterial TE in cats[15] and dogs (Figure 208-1). Atherosclerosis leads to the majority of human thromboembolic disease and is most commonly localized to the carotid, coronary, or cerebral arteries.[16] The differences in cholesterol metabolism in dogs and cats may partially explain the low frequency of atherosclerotic-related arterial TE in veterinary patients compared with humans. Most thrombi are formed in the left heart and embolize distally (see Figure 208-1; Figure 208-2). Thrombi formed in the arterial system where the blood flow rate is high consist primarily of platelets and have been termed *white thrombi*.

208.2.2 Venous Thromboembolism

Thrombi formed in the venous circulation under low blood flow conditions are composed of fibrin and erythrocytes (Figure 208-3) and have been termed *red thrombi*. Venous thrombosis frequently causes fewer clinical abnormalities than arterial thrombosis and consequently is frequently undetected. Deep venous thrombosis, a major risk factor for pulmonary TE in over 90% of cases in humans, is not known to be a risk factor for pulmonary TE in animals. Pulmonary TE occurs in several disease states associated with hypercoagulability. These include nephrotic syndrome, hyperadrenocorticism, immune-mediated hemolytic anemia (IMHA), thrombocytosis, cardiac disease, sepsis, disseminated intravascular coagulation (DIC), heartworm disease, and neoplasia.[17–24] Antithrombin III deficiency may be involved in thrombogenesis as part of a number of these diseases. For example, destruction of RBCs in IMHA releases thrombogenic substances.[24] Antithrombin III inactivates thrombin and other clotting factors, and even a mild reduction in antithrombin III can result in thrombosis or TE. A deficiency of antithrombin III can be secondary to decreased synthesis (e.g., congenital), increased consumption (e.g., DIC), loss of antithrombin from the intravascular compartment (e.g., nephrotic syndrome), and increased protein catabolism (e.g., Cushing's disease). Protein C and protein S are vitamin-K dependent protein factors and major inhibitors of the procoagulant system.[11] Deficiencies of both of these proteins have been associated with clinical thrombotic disorders in humans. A single case report of protein C deficiency has been reported in a thoroughbred colt.[25] The presence of multiple concurrent disorders in patients with TE is common. For example, 47% of cats with necropsy confirmed pulmonary TE had multiple concurrent predisposing disorders.[26]

Figure 208-1 **A,** Gross heart dissected to illustrate the left ventricular outflow tract, from a dog that experienced acute posterior paresis. An extensive pedunculated mass (tumor) is present from the sinus of Valsalva and extending through the ascending aorta. **B,** Distal aorta from this dog containing a saddle embolus.

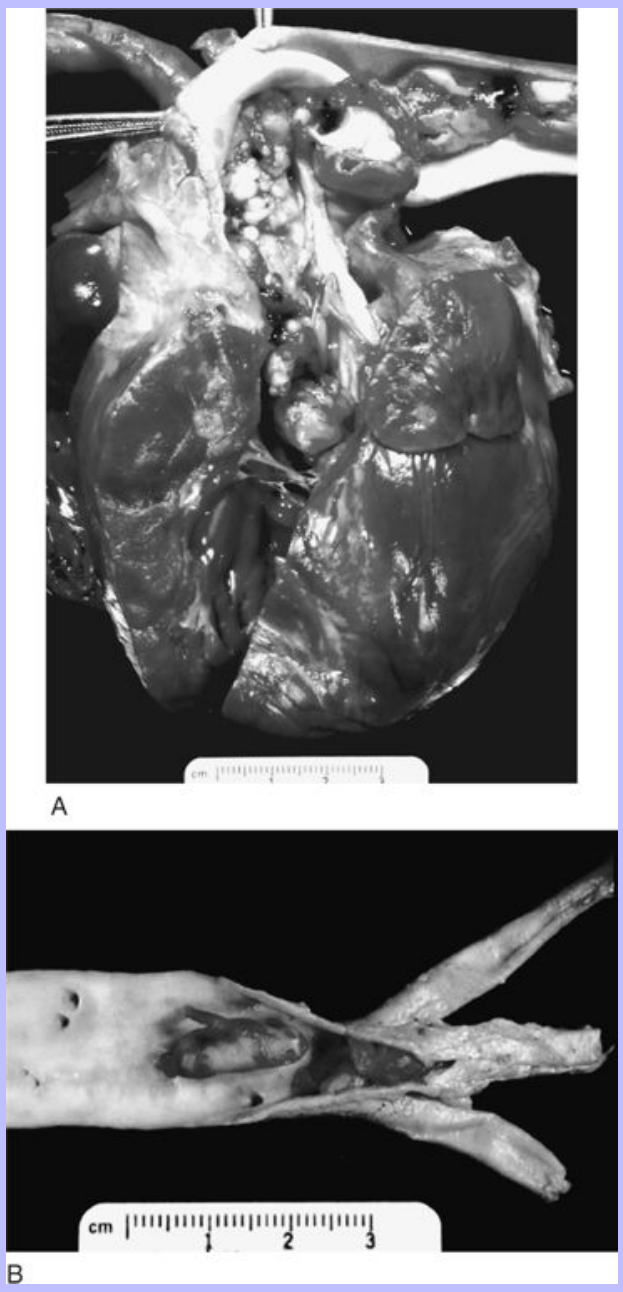

Figure 208-2 Kidney from the dog in Figure 208-1. Extensive, acute hemorrhage is seen that is associated with renal infarction.

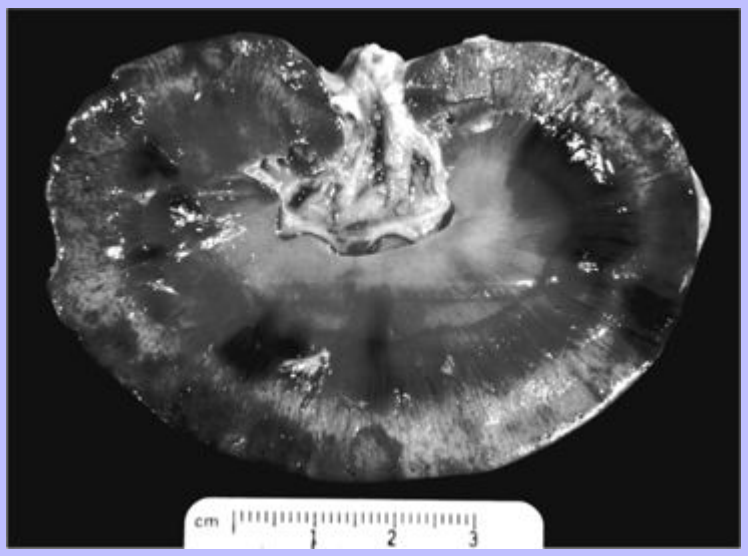

Figure 208-3 Organized thrombus fills the lumen of a vein (*upper left*) in the stomach wall from a dog with disseminated intravascular coagulation (DIC). Gastritis is also evident. A normal artery is present in the lower right.

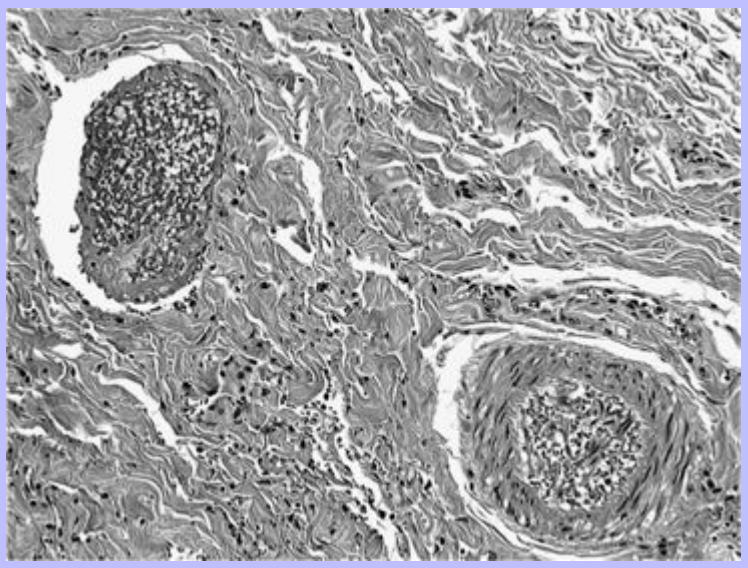

208.3 CLINICAL DISORDERS FREQUENTLY ASSOCIATED WITH THROMBOEMBOLIC DISEASE

208.3.1 Hypercoagulable States

Many systemic and metabolic diseases are associated with an increased risk of arterial or venous thrombosis and TE. Primary hypercoagulable states refer to congenital abnormalities increasing the risk for thrombosis. Primary hypercoagulable states remain poorly characterized and are infrequently recognized in animals.

Secondary hypercoagulable states refer to risk factors that promote the development of thrombosis.[16] Table 208-1 lists causes and predisposing factors of thrombus and TE. Secondary hypercoagulable states resulting in TE have been described in a variety of systemic and metabolic diseases.

208.3.2 Disseminated Intravascular Coagulation

DIC is a specific pathologic process that involves the development of thrombi in the microvasculature and the generalized consumption of platelets and coagulation factors. This results in simultaneous hemorrhage and thrombosis, ischemia, and multiorgan failure. DIC is characterized by overwhelming thrombin and plasmin activation. Various unrelated diseases associated with DIC are unified by unregulated activation of mononuclear cell cytokines initiating simultaneous coagulation and fibrinolysis. Multiple cytokines are believed to be responsible for the initiation of DIC through induction of tissue factor expression on monocytes and endothelial cells.[16] Tumor necrosis factor (TNF)-alpha and interleukin-6 (IL-6) are two of many cytokines involved in the pathogenesis of DIC. Cytokines also inhibit natural anticoagulants including protein C and S complex, tissue factor pathway inhibitor, and antithrombin III. Cytokines affect endothelial integrity, promoting platelet adhesion and resulting in increased levels of plasminogen activator inhibitor-1 (PAI-1) and promote fibrin deposition.[11]

DIC occurs in patients with a wide variety of clinical disorders. Heatstoke, sepsis, pancreatitis, neoplasia, immune-mediated disease, trauma, and toxin exposure are common inciting causes of DIC. The trigger causing DIC in these seemingly unrelated syndromes may be systemic inflammatory response syndrome and the production of proinflammatory cytokines including but not limited to TNF, IL-1, and IL-8.[27] The most important step in treating DIC is elimination of the underlying pathologic condition or triggering mechanisms and the conditions that promote this hypercoagulable state. Anticoagulants have been advocated, although clinical data regarding efficacy are lacking.

208.3.3 Protein-Losing Nephropathy

Protein-losing nephropathy (PLN) results in loss of plasma proteins into the urine through injured glomeruli. The small molecular weight of antithrombin III (65,000 daltons) allows it to pass through the glomerulus similarly to albumin. The resulting hypercoagulable state is most often associated with venous thrombosis and can result in pulmonary TE.[18–22] Arterial (aortic) TE has also been reported in dogs with PLN.[7]

208.3.4 Hyperadrenocorticism

Both spontaneous hyperadrenocorticism and exogenous administration of glucocorticoids have been associated with the development of thromboemboli.[7] The hypercoagulable state in spontaneous

hyperadrenocorticism is characterized by an increase in coagulation factors II, V, VII, IX, X, XII, and fibrinogen, coupled with a decrease in the natural anticoagulant antithrombin III.[28] Thrombin-antithrombin complexes are also increased in dogs with hyperadrenocorticism but with no clinical signs of thrombosis, suggesting subclinical thrombosis. Long-term exogenous administration of glucocorticoids is associated with proteinuria and glomerular changes.[29] Whether or not this ultimately results in loss of antithrombin III and hypercoagulability is unknown. Both arterial and venous TE have been diagnosed in dogs receiving exogenous glucocorticoids.[30]

1148
1149

Table • 208-1 Causes and Predisposing Factors of Thrombosis and Thromboembolism

VASCULAR ENDOTHELIAL DAMAGE	HYPERCOAGULABILITY	ABNORMAL BLOOD FLOW
Arteriosclerosis	Infection/sepsis/abscess	Neoplasia
Atherosclerosis	Neoplasia	Cardiomyopathy
Vasculitis	Hyperadrenocorticism	Congestive heart failure (CHF)
Heartworm disease	Protein losing nephropathy (PLN)	Endocarditis
Catheterization	Protein losing enteropathy (PLE)	Hypovolemia
Injection of irritating substances	Disseminated intravascular coagulation (DIC)	Shock
Neoplasia	Thrombocytosis	Anemia
Vascular incarceration/compression	Platelet hyperreactivity	Polycythemia
Hyperhomocysteinemia	Immune-mediated hemolytic anemia (IMHA)	Dehydration
Feline ischemic encephalopathy (FIE)	Parvovirus infection	Hyperviscosity
Fibrocartilaginous embolism		

208.3.5 Feline Cardiomyopathy

The cause of feline TE is multifactorial and principally accompanies myocardial disease with associated injury to left ventricular or left atrial endothelium. Some affected cats with aortic TE have elevated blood levels of homocysteine when compared with cardiomyopathic cats without TE,[13] and homocysteine metabolism may be abnormal in some felines.[14] Several coagulation abnormalities leading to hypercoagulability have been identified in cats with aortic TE.[31] Platelets from some cardiomyopathic cats have also been shown to be hyperaggregable in response to adenosine phosphate (ADP) in vitro.[32]

208.3.6 Immune-Mediated Hemolytic Anemia

Pulmonary TE is a major complicating factor leading to the high rate of mortality in IMHA. Because of the difficulties in antemortem diagnosis of PTE, most estimates of the number of dogs with IMHA and TE are based on necropsy results and range from 15% to 80%.[33] Use of intravenous catheters, elevated bilirubin concentration, elevated alkaline phosphatase concentration, and decreased albumin have all been associated with development of pulmonary TE.[33] Severe leukocytosis, left shift, and neutrophil toxic change may serve as laboratory markers of systemic thrombosis in some cases.[34] Derangements in routine coagulation tests, prothrombin time (PT), partial thromboplastin time (PPT), and fibrinogen concentration are common in IMHA patients.[24] Thrombocytopenia is also common and severe thrombocytopenia (platelets <50,000/μL) occurs in

approximately 25% of IMHA patients. Fibrin (or fibrinogen) degradation products and D dimer are increased in greater than 50% affected of dogs. DIC is also commonly diagnosed in IMHA.[24]

208.4 THERAPY OF THROMBOEMBOLIC DISEASE

The management of primary diseases resulting in the development of TE is discussed in related chapters throughout this textbook. Therapy of TE should be directed toward the underlying disorder whenever possible. Therapeutic strategies for managing TE include short-term systemic anticoagulation and fibrinolysis followed by long-term antiplatelet or anticoagulant therapy to reduce the risk of rethrombosis.

208.4.1 Supportive Care

General patient care is critical for successful management of thrombosis. Analgesic agents should be considered for acute pain management. Fluid therapy should be administered when indicated to correct acid-base abnormalities and dehydration. Dextrose-containing fluids should be avoided whenever possible because they may cause endothelial damage, further promoting thrombosis. A risk of volume overload exists with heart failure or pulmonary hypertension and fluid therapy must be carefully monitored. Strict cage rest and oxygen therapy are indicated in cases of pulmonary TE or thrombosis associated with congestive heart failure (CHF).

208.4.2 Acute Anticoagulation

Heparin is the mainstay of acute anticoagulation. Anticoagulants prevent additional clots from forming but do not dissolve clots (see thrombolysis). Coumadin therapy for the long-term control of thrombosis is initiated after adequate heparinization has been achieved.

Heparin functions as a cofactor with antithrombin III, and together this complex exerts its effect by neutralizing factor X and thrombin. Heparin is inactivated by gastrointestinal (GI) enzymes when given orally and therefore must be administered by injection. Heparin is administered to prolong the baseline activated partial thromboplastin time (aPTT) to 1.5 to 3.0 times the baseline value. Prolongation of the aPTT or activated coagulation time (ACT) does not correlate well with heparin levels in cats and dogs, and measurement of plasma heparin levels may be more useful in monitoring heparin therapy. Although many different heparin doses have been advocated, little clinical data exist concerning efficacy. Doses of heparin required to achieve adequate heparin levels in cats with TE ranged from 175 U/kg every 6 hours to 475 U/kg every 8 hours, subcutaneously.[35] In normal dogs the dose of heparin required to achieve adequate heparin concentrations was 250 U/kg every 6 hours, subcutaneously.[36] The most common side effect of heparin therapy is hemorrhage. In the event of severe hemorrhage, heparin can be neutralized by protamine sulfate administration.[37]

Low molecular weight (LMW) heparin is being increasingly used.[38] Its anticoagulant effect is limited to blocking the activity of factor X. Because LMW heparin has a lower antithrombin effect than unfractionated heparin, LMW heparin does not markedly influence the PT or aPTT. Measurement of factor X activity has been used to assess the effect of LMW heparin. One advantage of LMW heparin is that it has a lower risk of hemorrhage than conventional heparin therapy. The optimal dose of LMW heparin in dogs and cats with thromboembolic disease remains to be determined.

208.4.3 Chronic Anticoagulation

Warfarin (Coumadin) is a vitamin K antagonist inhibiting the synthesis of vitamin K–dependent clotting proteins (prothrombin and factors VII, IX and X). In addition, warfarin reduces efficacy of the vitamin K–dependent regulatory proteins C and S.[11] Proteins C and S are anticoagulant factors, and their function is the first to be inhibited by warfarin administration. Therefore heparin and warfarin administration are generally overlapped for 2 to 4 days to prevent a transient hypercoagulable state. Some animals appear to do well with just warfarin. Starting doses for warfarin are 0.25 to 0.5 mg every 24 hours in the cat and 0.1 to 0.2 mg/kg every 24 hours in the dog. Due to the high individual patient variability, close monitoring of PT is essential. Early recommendations were to maintain PT 1.5 times the baseline value, and more recent recommendations suggest attaining an international normalized ratio (INR) of 2:3.[39] INR is calculated by the formula $(\text{patient PT/control PT})^{ISI}$. The ISI is a value specific to the tissue thromboplastin that is used in measuring the PT. Coumadin is continued on a long-term basis to prevent recurrent TE. Studies documenting the optimal dose, efficacy, and duration of Coumadin therapy for specific thromboembolic diseases in dogs and cats are unknown.

The use of Coumadin is not without risks. The major risk is fatal hemorrhage, which occurs acutely and unexpectedly. Ideally, pets maintained on Coumadin should live indoors and be well supervised to prevent trauma and to monitor for hemorrhage. Periodic measurement of the PT should be done to ensure adequate dosing. Coumadin interacts with many drugs. The addition of medications to the treatment regimen of a pet on Coumadin should be done cautiously because certain drugs will raise the activity of Coumadin and predispose patients to bleeding. Some of these drugs are phenylbutazone, metronidazole, trimethoprim sulfa, and second-and third-generation cephalosporins. Barbiturates will decrease Coumadin anticoagulant effect. If bleeding complications occur, warfarin therapy is discontinued and administration of vitamin K is recommended.[39]

208.4.4 Antiplatelet Therapy

Antiplatelet drugs have been advocated for long-term management to prevent rethrombosis. These drugs inhibit platelet aggregation and adhesion, preventing the formation of the hemostatic platelet plug. Aspirin inhibits cyclooxygenase, leading to decreased thromboxane A_2 synthesis. This renders platelets nonfunctional by preventing their aggregation.[40,41] Cats lack the enzyme needed to metabolize aspirin (glucuronyl transferase), making them sensitive to aspirin-induced platelet dysfunction. Doses of 0.5 mg/kg every 12 hours in the dog and 25 mg/kg twice weekly in the cat may decrease platelet aggregation.[37] However, rethrombosis generally occurs despite aspirin therapy, although it is not known whether aspirin delays recrudescence. Additional antiplatelet drugs include dipyridamole and ticlopidine. Dipyridamole is thought to inhibit platelet aggregation by inhibition of platelet phosphodiesterase, leading to increased levels of cyclic adenosine monophosphate (cAMP) within platelets. Ticlopidine impairs fibrinogen binding and inhibits platelet aggregation induced by ADP and collagen.[37] The use of these newer compounds has been limited thus far in veterinary medicine.

208.4.5 Thrombolysis

Thrombolytic agents such as streptokinase, urokinase, and tissue plasminogen activator (tPA) are potent activators of fibrinolysis. These agents have been used with variable and often limited success in veterinary medicine.[42–45]

Streptokinase binds plasminogen, and the complex transforms other plasminogen molecules into plasmin. Plasmin then binds to fibrin and causes thrombolysis. Streptokinase binds both free and clot-associated plasminogen. It also degrades factors V, VIII, and prothrombin, resulting in a massive systemic coagulation defect.

Streptokinase has been used to treat aortic thromboembolism (ATE) in cats with varying degrees of success. In one study of 46 cats, 15 were discharged from the hospital after streptokinase therapy with a median survival of 51 days.[45] Reperfusion injury occurred in approximately 35% after thrombolysis, with streptokinase often resulting in fatal hyperkalemia and metabolic acidosis. Eleven of the cats developed clinical hemorrhage after streptokinase therapy. In three cats, hemorrhage was significant enough to require transfusion. Others reported conservative management (treatment of heart failure plus Coumadin or aspirin) of ATE with a hospital discharge rate of 28%, which was similar to cats treated with streptokinase.[15] One recommended dose of streptokinase for dogs and cats with TE is 90,000 U, intravenously administered over 20 to 30 minutes, followed by a maintenance infusion of 45,000 U for 7 to 12 hours. Infusions may be repeated over a total of 3 days.[37]

Recombinant DNA technology produces t-PA, a serine protease. A complex forms between t-PA and fibrin, and that complex preferentially activates thrombus-associated plasminogen-resulting in rapid fibrinolysis.[47] Life-threatening hemorrhage is the number one side effect. The half-life of t-PA in dogs is 2 to 3 minutes; consequently, if bleeding occurs, stopping the infusion will result in the drug clearance from the system in 5 to 10 minutes. Because t-PA causes rapid thrombolysis, the risk of reperfusion syndrome and lethal hyperkalemia is substantial. In one report, 50% of cats with ATE died acutely during t-PA therapy, with death attributed to hyperkalemia, severe anemia, and renal hemorrhage.[46]

208.5 VASCULAR DISEASES

208.5.1 Diseases Of Arteries

208.5.1.1 Occlusive Arterial Diseases

Arterial occlusion refers to the interruption of blood flow within an artery and most commonly results from trauma, thrombi, emboli, arteritis, degenerative lesions such as atherosclerosis, and factors associated with endothelial dysfunction or injury. Arterial thrombosis requires one or more inciting local or systemic conditions: (1) vascular endothelial damage, (2) sluggish blood flow, and (3) changes in blood constituents resulting in a hypercoagulable state.[11] Vascular endothelial injury can be induced by infectious agents (e.g., *Dirofilaria immitis*), prolonged hypotension, hypoxia, acidosis, inflammation, trauma, and immune mechanisms. Compressive lesions, such as from tumors, may promote thrombosis by a reduction in local blood flow and endothelial injury. Thromboemboli usually represent blood clots that have broken free from a site of thrombus formation. Emboli can also consist of tissue particles, fat, gas, bacterial vegetations,

parasites (e.g., heartworms), tumors, or foreign bodies.[48] Entrapped emboli may themselves become thrombogenic. Arterial occlusion can be acute or chronic. Chronic gradual occlusion can occur with mural or extramural hematomas, atherosclerosis, arteriosclerosis, vasculitis, or intimal tears forming valvelike structures.

The potential clinical consequences of arterial occlusion (tissue hypoxemia, ischemia, neuropathy, tissue necrosis) are related to extent and duration of vascular obstruction, and the physiologic consequences of the affected organ or organs. Tissues supplied by the endarteries, which have no connections to collateral vascular beds, undergo greater ischemic injury than organs supplied with collateral circulation. Acute, complete arterial occlusion causes rapid ischemic injury. This is largely due to release of vasoactive substances by the clot, which induces vasoconstriction and reduces collateral circulation. In addition to the acute effects, long-term injury (days or weeks) occurs and includes fibrosis and neuromyopathy.[7]

208.5.1.1.1 Feline systemic thromboembolism

Feline systemic TE is discussed in Chapter 204.

208.5.1.1.2 Canine systemic thrombosis and thromboembolism

Arterial occlusion has been reported in dogs occurring secondary to atherosclerosis, nephrotic syndrome, vegetative endocarditis, neoplastic emboli, dirofilariasis, trauma, and thrombi of left heart origin (see Figure 208-1). The distal aorta, iliac, renal, and femoral arteries are common sites of systemic TE (see Figures 208-1 and 208-2).[7]

208.5.1.1.2.1 History

Acute arterial occlusion is usually indicative of systemic, metabolic, or cardiovascular disease. Clinical recognition and identification of the cause are enhanced by an insightful history, complete physical examination, and appropriate diagnostic tests. Some animals have a history of intermittent claudication, whereas in others, acute paresis or paralysis is the major presenting sign. Acute, complete arterial occlusion may cause posterior paresis, extreme hindlimb pain, and general distress.[49,50] In some cases the animal may have an unsteady gait, lameness, progression to stumbling, weakness, or collapse. Other potential signs include weight loss, exercise intolerance, hindlimb licking or chewing, and hypersensitivity over the lumbosacral region and the hindlimbs. Other signs attributable to systemic or metabolic diseases may sometimes be detected.

208.5.1.1.2.2 Clinical signs and physical examination

The outcome and clinical signs of arterial occlusion depend on (1) size and number of thrombi, (2) degree and duration of vascular occlusion, (3) pathophysiologic consequences of the organ or organs supplied, (4) whether the clot is infected or sterile, (5) whether the event is solitary or repeated, (6) the adequacy of compensatory mechanisms (e.g., collateral vessel recruitment, vasodilatation, clot lysis, restoration of blood flow), (7) the effects of vasoactive chemicals elaborated by the clot on collateral vessels (i.e., vasoconstriction), and (8) related complications (e.g., tissue necrosis, local infection, hyperesthesia). A slowly progressing arteriosclerotic or atherosclerotic stenosis allows time for the development of collateral circulation and may have minimal clinical consequences. A sudden

embolus, however, may not be associated with the development of collateral circulation, and presenting clinical signs may be more severe.[50] Microthrombus formation is common, and rapid clot lysis and abundant collateral circulation usually results in absence of outward clinical signs.

Classic presentation of acute arterial occlusion is described by the seven *P*s: (1) pain, (2) paleness, (3) paresthesia, (4) pulselessness, (5) polar (cold), (6) paresis or paralysis, and (7) prostration.[49] Physical examination may reveal cool distal limbs and swollen muscles. Segmental and pedal reflexes may be depressed. Hypersensitivity over the lumbar spine may exist. A slow onset and progressive peripheral neuropathy after trauma may be associated with ischemia of peripheral nerves. Arterial thrombosis of a front limb may also occur. Clinical signs are usually less severe than those described for posterior limb thrombosis.

In the central nervous system (CNS), arterial occlusion is rarely diagnosed. For signs to be recognizable, several arteries have to be occluded simultaneously, as can occur in severe atherosclerosis or with embolization after arterial catheterization. Cerebrovascular occlusions may lead to sudden disorientation, weakness, anisocoria, and hemiamaurosis. Infarction may follow TE to a localized area of the brain. *Stroke* is a generic term denoting any acute, nonconvulsive, focal neurologic deficit stemming from cerebrovascular disease. The classic presentation includes hemiparesis, but a broad spectrum of neurologic injuries may result. Neurologic signs depend on site, extent, and time course of vascular occlusion. In a series of 17 affected dogs, cerebrovascular disease was associated with coagulopathy, metastatic brain tumor, trauma, sepsis, atherosclerotic thrombus, unknown cause, and vascular malformation.[51] A cerebellar infarction caused by meningeal arterial thrombosis has also been described in a German shepherd dog with acute onset of seizure and neurologic deficits.[52] We have occasionally observed neurologic signs related to stroke in cats associated with severe systemic hypertension. Affected animals usually present acutely blind and show signs of retinal hemorrhage and detachment. Neurovascular disorders may be more common than the literature suggests. Increasing availability of advanced imaging techniques should facilitate the diagnosis of these conditions.

With endocarditis, a heart murmur of mitral or aortic insufficiency may be auscultated. Bacterial embolization from these valves may cause a systemic shower of emboli, which frequently affect abdominal organs, especially the kidneys and small intestines. Complete unilateral or bilateral renal artery occlusion invariably causes severe renal infarction. Affected dogs are depressed and may exhibit an arched back, sublumbar pain, and hematuria.

Acute occlusion of a major mesenteric artery may cause initial gastric hyperactivity, followed by ileus and intestinal infarction. Sudden anorexia, vomiting, bowel evacuation, and abdominal pain may be present. Feces may contain blood. With bowel infarction, bloody diarrhea, severe signs of an acute abdomen, and shock may develop.

208.5.1.1.2.3

Diagnosis

When peripheral arterial thrombosis is suspected, a survey thoracic radiograph is indicated to evaluate cardiac size and shape and to assess for pulmonary changes including edema, thrombosis, or dirofilariasis. Chest and abdominal radiographs should be evaluated for orthopedic lesions, which could result in posterior paresis. In addition, radiographs of the pelvic and hindlimb region may be

indicated to check for masses that could exert pressure on the aorta and for periosteal reactions in the sublumbar area. Doppler echocardiography may be useful for identifying vascular disturbances.[6,7]

Clinical pathology data may help characterize the underlying primary disease. Coagulation profiles are variable. Some cases of glomerulopathies and hypoproteinemia have been associated with reduced levels of antithrombin III.[22] Assessment of protein C and protein S levels should be considered when these tests are available. A clinical pathology data base is also advised to evaluate and detect renal or hepatic disease, dirofilariasis, DIC, and systemic and metabolic disorders. Blood cultures are indicated if endocarditis, bacteremia, or sepsis is suspected.

Confirmation of diagnosis may require proof of a vascular occlusion. This can be accomplished in some cases by physical examination, whereas in others, arteriography or diagnostic ultrasound are required.[1,6,8] The arteriogram can indicate the exact location of the thrombus or illustrate the extent of vascular occlusion and collateral vascular supply (Figures 208-4 and 208-5). Furthermore, radiolucent emboli such as heartworms may be outlined when present as longitudinal filling defects. Contrast angiography and other alternative imaging methods (thermography, perfusion scanning) in human medicine are being replaced by MRA and advanced ultrasound techniques such as intravascular ultrasound.[6,9]

208.5.1.1.2.4

Differential diagnoses

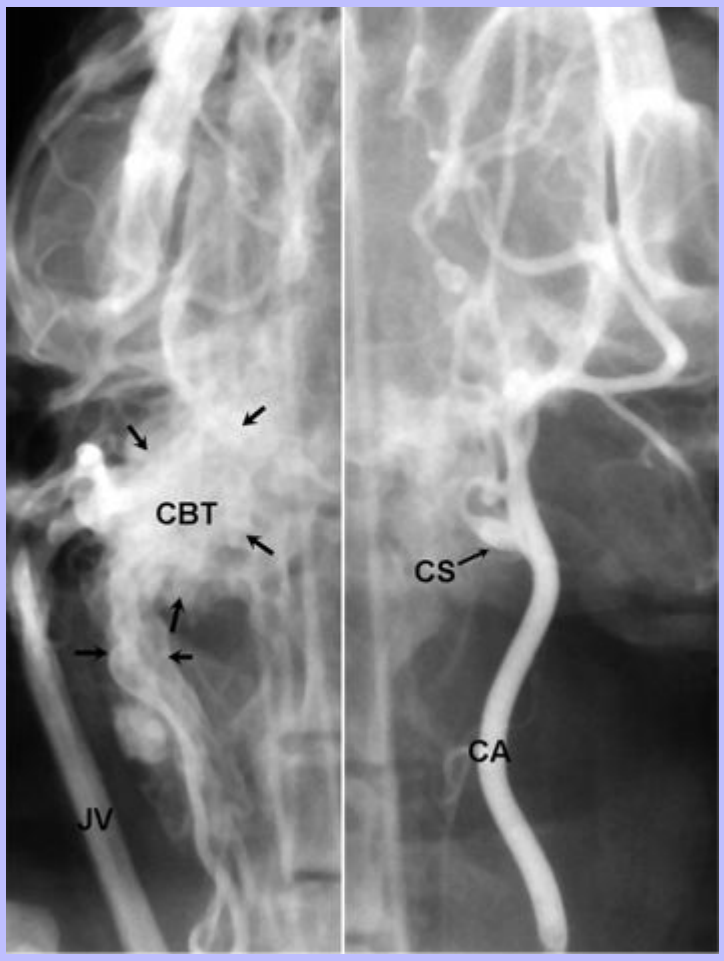
Differential diagnoses include trauma; peripheral neuropathy; spinal, pelvic or vascular tumors; infections; toxoplasmosis; degenerative myelopathy; interventricular disc protrusion; fibrocartilaginous embolic myelopathy; and the cauda equina compression syndrome. Radiographs should be systematically evaluated for signs related to these disorders.

208.5.1.1.2.5

Prognosis

The prognosis depends on the cause, extent, and severity of occlusion, presence or absence of local complications (ischemic neuromyopathy, ulcers), and concurrent embolization to visceral organs. Even in cases with spontaneous recovery, relapses must be expected. Rapid diagnosis and treatment are essential to avoid severe or even irreversible tissue injury.

Figure 208-4 Two ventrodorsal angiograms of a dog with a carotid body tumor. The left panel demonstrates a late arterial-venous phase after injection of contrast medium into the right common carotid artery. A tumor "blush" is seen, with contrast medium opacifying vessels feeding the carotid body tumor (*CBT; arrows*). Venous return is observed via the jugular vein (*JV*). The angiogram in the right panel is a useful comparison and was taken after injection of contrast material into the left common carotid artery (*CA*). Normal flow is observed, and the carotid sinus (*CS*), an area for sensing blood pressure, is evident. (Courtesy of John Bonagura, DVM.)



208.5.2 Feline Ischemic Encephalopathy

Feline ischemic encephalopathy (FIE) results in cerebral ischemic necrosis. FIE occurs in male and female cats of all ages and is more prevalent in the summer months. The cause of FIE is uncertain. Preliminary evidence suggests *Cuterebra* infection as a potential cause in some cases.[53,54]

Clinical pathology is usually unremarkable. Cerebrospinal fluid (CSF) analysis may be normal or have mildly elevated protein levels and a mild to moderate pleocytosis. An increased proportion of large foamy macrophages have been observed in the CSF from 2 to 7 months after the onset of seizures. Suspected diagnosis can be made by T2 weighted MRI. In one study of six cats with FIE, MRI findings included mild to marked asymmetry of the cerebral hemispheres and bilateral asymmetric enlargement of the subarachnoid space.[55]

Gross lesions are usually unilateral and may involve up to 75% of one cerebral or cerebellar hemisphere (or both). Hemispheres may appear atrophic and ridged with wide sulci. Histopathologic findings have included parenchymal atrophy and cystic degeneration, gliosis, and phagocytic macrophage infiltration. Perivascular lymphocytic cuffing of small capillaries and vascular occlusive lesions including thrombosis and vasculitis has been reported. Infarction of the middle cerebral artery represents the most common distribution.

Figure 208-5 Aortogram of a 7-year-old Saint Bernard dog with a saddle thrombus at the aortic trifurcation associated with a chondrosarcoma located near the terminal aorta. The owner had observed four episodes of pain and weakness in the hindlimbs that developed gradually when the dog was taken for a walk. At the beginning of the walk, the dog was normal. If the dog was forced to continue walking after the signs of pain and lameness had appeared, it collapsed. After resting for a few moments, the dog was able to walk again. On clinical examination the femoral pulse was difficult to feel, and the periphery of the hindlimbs was cool. Pain could be elicited when the pelvic area was palpated. Aortography was performed, and a radiograph was taken 4 seconds after the beginning of the injection of contrast medium. On the aortogram the common origin of the internal iliac arteries and the left external iliac artery contain no contrast medium, suggesting that they have been occluded completely. A partial occlusion has reduced the flow of contrast medium into the right external iliac artery. Some collateral blood supply to the hindlimbs probably occurs via the seventh lumbar artery. Anticoagulation therapy was instituted, but it failed to provide relief and the dog underwent euthanasia at the request of the owner.

Clinical signs are typically acute in onset, nonprogressive, and suggestive of unilateral cerebral or brainstem involvement. Seizures are the most common historical or presenting clinical sign. Other clinical signs may include depression, head tilt, anisocoria, circling, seizures, and behavior changes.

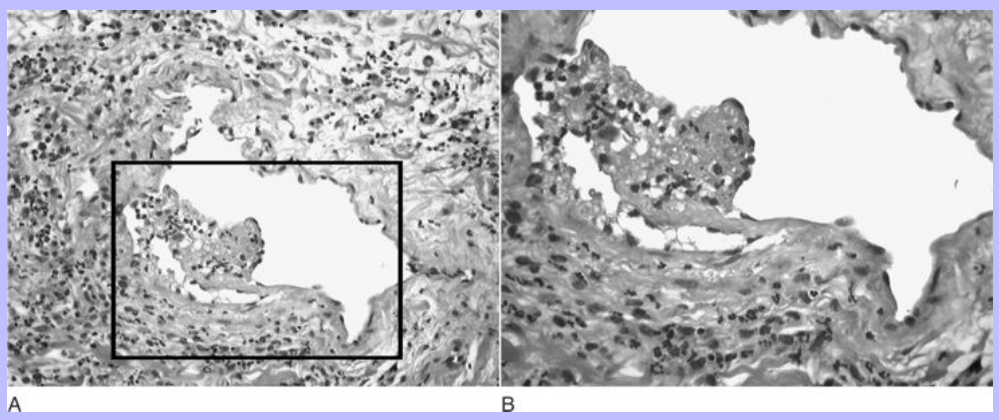
Treatment is limited to supportive care, and the prognosis is generally favorable. Clinical improvement typically occurs over several days to weeks. Multiple episodes can occur. Behavior changes and uncontrollable seizures can persist.[54,55]

208.5.3 Fibrocartilagenous Embolization

Fibrocartilaginous embolization (FCE) is associated with ischemic necrosis of the spinal cord parenchyma. The pathogenic mechanism is not resolved. Spinal cord arteries and veins become occluded with fibrocartilage originating from the nucleus pulposus of the intervertebral disc. Trauma may be a predisposing factor in a large percentage of affected cases. FCE can occur at any age but is most common in adult nonchondrodystrophoid breeds. Young Irish wolfhounds and miniature schnauzers are particularly prone to the disease. FCE has been reported less commonly in cats.[55,56]

1152
1153

Figure 208-6 Vasculitis is indicated by inflammatory cells present within **(A)** and around **(B)** the venous vessel wall. Vascular injury associated with necrosis, degeneration of endothelial and smooth muscle cells, and fibrin deposition is evident. A small intramural thrombus is also present.



Clinical signs of myelopathy vary depending on the location and severity of the spinal cord ischemic injury. Deficits are often asymmetrical, and the clinical signs are not progressive. Affected animals do not typically show evidence of pain, although brief painful periods have been described just prior to the onset of clinical signs.

Diagnosis of FCE is based on excluding other causes of acute myelopathy. Results of plain radiographs are normal. CSF evaluation may be normal or show nonspecific abnormalities including mild protein elevations,

mild pleocytosis, and xanthochromia. Myelography is typically normal, or mild spinal cord swelling is seen. MRI may reveal spinal cord edema on T2 weight images.[55]

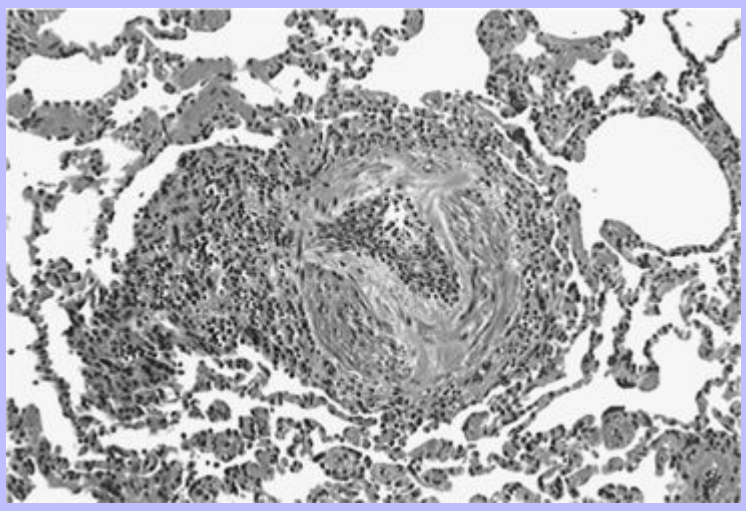
Treatment is primarily supportive care and physical therapy. Evidence for the use of glucocorticoid therapy is lacking. If treatment is attempted, methylprednisolone succinate (MPS) should be given within the first 6 to 8 hours after the onset of neurologic signs. Prognosis for recovery is variable depending on the location and extent of the lesion. Poor prognostic indicators include lower motor neuron (LMN) signs and size of the animal because of the inherent difficulties of performing physical therapy on large breed dogs.[56]

208.5.4 Vasculitis and Angiitis

The terms *vasculitis* and *angiitis* refer to the pathologic syndrome that is characterized by vascular inflammation and necrosis. Although there have been many reported causes of vasculitis, only a few histologic manifestations of the disease have been diagnosed. Vasculitis can occur in toxic, immune-mediated, infectious, inflammatory, and neoplastic disorders. Blood vessels of any type in any organ can be affected, resulting in a wide variety of clinical signs. The nonspecific nature of histologic lesions, coupled with variable clinical presentations, makes the diagnosis of primary vasculitis quite challenging. The clinical consequences of vasculitis depend on the size, number, type, and extent of blood vessels that are affected.[57]

Histologically, vasculitis is characterized by the presence of inflammatory cells within and around blood vessel walls. Vascular injury is associated with necrosis and degeneration of endothelial and smooth muscle cells and fibrin deposition (Figure 208-6). A collection of fibrin, immunoglobulins (Igs), complement, and platelets appears by light microscopy as eosinophilic material within the vessel wall and lumen and is referred to as *fibrinoid*. Eosinophilia secondary to degeneration of collagen and smooth muscle can also be present within the vessel wall.[58] These histopathologic lesions distinguish vasculitis from perivascular inflammation (Figure 208-7). Vasculitides have been classified based on specific inflammatory cell infiltrates that may include neutrophils, lymphocytes, or macrophages.[58,59] As the disease becomes chronic or begins to resolve, predominant cell populations may change. Vasculitis may develop from within a vessel as a result of infectious, immune-mediated or toxic injury or by extension from adjacent areas of inflammation. Infectious agents can injure endothelial cells directly or through the production of endotoxins and exotoxins. The exact mechanism of endothelial injury is not known but involves the formation of oxygen free radicals, local inflammatory mediators, and the recruitment of inflammatory cells.[60] Exposure of subendothelial collagen during endothelial injury results in the activation of Hageman's factor and the subsequent activation of the complement, kinin, and plasmin systems. These lead to increased vascular permeability and inflammation.

Figure 208-7 Section of lung. Perivasculitis is evident as large inflammatory infiltrate surrounding pulmonary arteriole.



Type III hypersensitivity reactions can cause necrotizing vasculitis from the deposition of immune complexes within the vessel walls. Activation of the complement cascade may attract neutrophils, cause immune complex phagocytosis, and result in the release of lysosomal enzymes and oxygen free radicals, thereby leading to further inflammation and necrosis. In the chronic state this reaction becomes diminished, and mononuclear cells replace the neutrophilic inflammation. Immune complex reactions of this type can occur in many disease conditions such as primary immune-mediated disease or be secondary to infectious disease. Emphasis on immune complex activity can only be misleading because immune complexes are rapidly cleared from the circulation.[59,61] In humans the discovery of antineutrophil cytoplasmic autoantibodies (specific for antigens in neutrophil granules and monocyte lysosomes) has allowed further identification of immune-mediated processes in which immune complexes were suspected but not identified. Cell-mediated immunopathogenic mechanisms are initiated in the blood vessel wall. This type of vasculitis is characterized by accumulations of lymphocytes and macrophages within vascular walls. Myocyte necrosis results in fibrinoid degeneration, endothelial hyperplasia, and occasionally thrombosis. A granulomatous type of reaction of the vessel wall can result, particularly in chronic cases. These changes may be accompanied by hemorrhage and ischemic changes in surrounding tissues.[61]

The cause of secondary vasculitides is, by definition, known, and classifications are based accordingly. These conditions usually result from infectious diseases such as feline infectious peritonitis (FIP), canine coronavirus infection, parvovirus infection (rare), Rocky Mountain spotted fever (RMSF), leishmaniasis, and dirofilariasis. They may also occur in drug reactions and in immunopathogenic connective tissue and collagen diseases, such as systemic lupus erythematosus (SLE) and rheumatoid arthritis.[62]

208.5.4.1 Microscopic Necrotizing Vasculitis

Microscopic necrotizing vasculitis (MNV) refers to a large heterogeneous group of clinical syndromes that share similar histologic properties. *Hypersensitivity vasculitis* is often referred to in dermatologic

manifestations and is often clinically distinct from the multisystemic form of necrotizing vasculitis. Termed *juvenile polyarteritis syndrome* (JPS), it has been reported in young beagle dogs.[63,64] Less distinction exists between JPS and those syndromes described as *idiopathic steroid-responsive vasculitides* that can manifest as multisystemic or localized disease.[65,66] Lesions can affect mainly arterioles, capillaries, and venules.

Clinical abnormalities of MNV are often associated with phasic pyrexia, listlessness, and anorexia. In some cases, lymphadenopathy, myalgia, epistaxis, drooling, sneezing, and arthralgia may occur. In addition to the generalized signs, manifestations of specific organ lesions may occur.[67] The most common presenting clinical signs in small animals are dermatologic lesions. Hemorrhagic maculae resembling circular petechiae and ecchymoses are common. Other lesions seen include wheals, urticaria, purpura, nodules, bullae, necrosis, and ulcers. In many cases the skin lesions are associated with pain, pruritus, or both. Less frequently encountered lesions include ulcers at the mucocutaneous junctions or of the mucous membranes, especially located on the head (external ear canal and pinnae, face), bony prominences of the limbs, and the foot pads, as well as pitting edema involving dependent areas such as limbs, ventral trunk, head, and scrotum.[62,63]

Internal organ involvement with MNV frequently goes undiagnosed. This is because clinical signs are vague, simultaneous multiorgan involvement often occurs, or organ manifestations are confused with those of infectious, degenerative, or traumatic conditions (e.g., pneumonia, glomerulonephritis, arthritis, spinal or neuromuscular conditions). The clinicopathologic findings of primary MNV vary according to severity, duration, and specific organ. Lymphopenia, eosinopenia, hypoalbuminemia, hyperglobulinemia, and hyperfibrinogenemia occur commonly. Less consistent findings include leukocytosis with a left shift and toxic neutrophils; leukopenia; neutropenia; monocytosis; a mild normocytic, normochromic anemia; and thrombocytopenia. Serum liver enzymes and triglycerides are often elevated.[57,59]

An idiopathic cutaneous and renal glomerular vasculopathy has been described in kenneled and racing greyhounds, with many characteristics similar to MNV.[68] It is characterized by fibrinoid arteritis, thrombosis, and infarction with deep, slowly healing skin ulcers and peracute renal glomerular necrosis with a predilection for afferent arterioles.

Diagnostic confirmation requires histologic examination of skin, organ, or lymph node biopsies specimen and exclusion of other immune-mediated disease. Special immunologic tests have been recommended to demonstrate a low or high concentration of complement, C3, and elevated levels of circulating immune complexes. The history may be helpful if drug hypersensitivity is suspected.

Primary periarteritis, or polyarteritis, a necrotizing vasculitis affecting small-and medium-sized muscular arteries has been identified in colonies of beagles.[69,70] This polyarteritis occurs in two forms. One form occurs mainly in young beagles, in which arteritis affects major branches of coronary arteries almost exclusively. Clinical signs are usually absent. A second form of polyarteritis is associated with vague multisystemic signs (fever, depression, anorexia, neutrophilia, decreased albumin- to-globulin ratio), a stiff gait, pain on abdominal palpation (beagle pain syndrome), or a combination of these symptoms. The signs are associated with vascular lesions including disseminated, focal, or diffuse intimal thickening and acute fibrinoid necrosis of the media resulting in occlusion and thrombosis.

The differential diagnosis includes pemphigus vulgaris and foliaceus, bullous pemphigoid, SLE; dirofilariasis, specific infectious diseases, chronic neoplasia, and cold hemagglutination disease. The prognosis is usually favorable.

Many therapies have been advocated. Administration of all unnecessary drugs should be discontinued. In many cases immunosuppressive doses of glucocorticoids with or without an antibiotic have been used successfully. Cyclophosphamide may be administered if that fails. Dogs with lesions involving only the skin can be given sulfasalazine (Azulfidine) at an initial dose of 22 mg/lb (49 mg/kg) every 8 hours.[57] Dose frequency can be decreased after lesions improve from three times to twice a day and, later, to once a day. Dogs receiving sulfasalazine should be observed for side effects such as fever, keratoconjunctivitis, and hematologic abnormalities.

208.5.4.2 Polyarteritis Nodosa

Polyarteritis nodosa (PAN) is a rare polysystemic disease associated with a necrotizing vasculitis of unknown cause. The disease affects predominantly segments and bifurcations of small and medium-sized muscular arteries. In humans, PAN is classified among immune-mediated collagen disorders and derives its name from purpural lesions that are palpable in the subcutaneous tissue. In contrast, palpable nodules are not a regular feature of PAN in animals.[71,72] The vascular lesions consist of intimal proliferation, vessel wall degeneration, necrosis, and thrombosis in all stages of development. PAN leads to a loss of vessel wall integrity, petechial and ecchymotic hemorrhages, focal areas of tissue infarction and necrosis, aneurysm formation, nodular swelling, and thickening of the major arteries. Target tissues of canine PAN include the kidneys, skin, mucous membranes, adrenals, meninges, GI tract, connective tissue, and myocardium.[72] The lungs are usually spared.

1154

1155

The clinical presentation includes systemic signs (pyrexia, lethargy, reluctance to walk, vague pain, or weight loss) and a wide spectrum of organ system abnormalities (linear skin ulceration, ulceration of mucous membranes, nasal discharge, spinal pain, and signs of cardiac or renal failure [or both]).[71,72] Clinicopathologic findings may include leukocytosis with a left shift and proteinuria.

The main differential diagnoses are hypersensitivity angiitis and idiopathic polyarteritis. The diagnosis is confirmed by histologic examination of a skin biopsy specimen, and the prognosis is guarded to poor. Treatment includes glucocorticoids, cyclophosphamide, or both.

208.5.4.3 Lymphomatoid Granulomatosis and Miscellaneous Vasculitides

Lymphomatoid granulomatoses and other unclassified vasculitides are characterized by a polymorpholymphocytoid, plasmacytoid, and histiocytoid granulomatous infiltration around blood vessels. Pulmonary nodular lesions of variable size due to lymphomatosis were first described in dogs.[73] Infarction, necrosis, and cavitation occur in some of the masses. The bronchial lymph nodes can be slightly to greatly enlarged, and pulmonary thrombosis is common. The cause of this rare condition is unknown. Occasionally, similar lesions are associated with eosinophilic pneumonitis in occult dirofilariasis, although they can also occur outside of endemic areas of dirofilariasis. An immune-mediated cause is likely because, in some cases, large amounts of IgG and IgM can be demonstrated in plasma cells and macrophages.[74] The differential diagnosis is primary or secondary neoplasia, with which this condition is often confused. Diagnosis is rarely made clinically and requires histologic examination of biopsy material. The prognosis is usually poor. In some patients, multicentric lymphosarcoma has developed at a later date. Surgery or treatment with glucocorticoids and cytotoxic immunosuppressive drugs is only temporarily effective.

208.5.5 Arterial Aneurysm

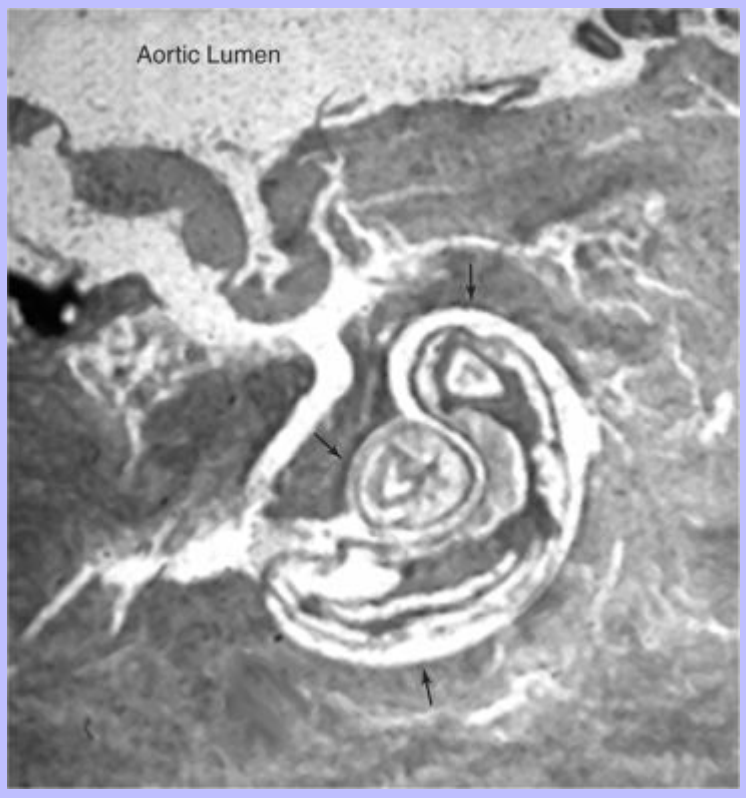
An arterial aneurysm is a circumscribed dilation of an arterial wall or a blood-containing swelling connecting directly with the lumen of an artery. Arterial aneurysms are rare in dogs and cats and only isolated cases have been reported.[75–78] Aneurysms can be categorized based on their shape (saccular or fusiform), cause (atherosclerotic, mycotic, inflammatory, arteritis, traumatic, congenital, dissecting), or their histologic appearance. Two major histologic classes of aneurysms are (1) true aneurysms (aneurysma verum) and (2) false aneurysms (aneurysma spurium).

208.5.5.1 True Aneurysm

A true aneurysm is a vascular dilatation caused by a weakened arterial or venous wall with subsequent widening of the vascular lumen. Histologically, true aneurysms involve the entire arterial wall and contain three microscopic arterial layers. Aneurysms may result from destruction of the media or the elastic fibers of large arteries (or destruction of both) by inflammatory or degenerative processes. Traumatic aneurysms can be true aneurysms or pseudoaneurysms, depending on their cause and histologic appearance. Aneurysms have been found in the aorta of dogs that were caused by migrating larvae of *Spirocerca sanguinolenta* (formerly *S. lupi*)[76] (Figure 208-8). Aneurysms can also result from turbulent blood flow with arteriovenous (AV) fistulas.

Dissecting aneurysm (aortic dissection) involves a hematoma associated with a defect in the aortic intima. Blood within the aortic lumen is forced through the intimal tear into the outer and middle layers of the aortic media, forming a second or false lumen. The dissection can then propagate proximally or distally along the aorta. A report of a dissecting aortic aneurysm was reported in a dog with clinical and histologic findings similar to that reported in humans.[75] Dissecting aortic aneurysm has also been reported in two cats: one with CHF, severe aortic insufficiency and systemic hypertension and a second cat with signs of weakness, lethargy, and cardiogenic shock.[77,78]

Figure 208-8 Photomicrograph of a canine aorta. The intima and media have been disrupted by the presence of the subtropical and tropical parasite *Spirocerca sanguinolenta* (formerly *S. lupi*). The parasite is seen in cross-section (*arrows*). The aortic lumen is at the top of the figure. (Courtesy of John Bonagura, DVM.)



Peripheral aneurysms appear as soft, warm, pulsating bulges. Occasionally, a "machinery" murmur can be auscultated over these areas (see Arteriovenous Fistulas). Clinical signs are frequently absent or vague. If spontaneous vascular rupture occurs, pain, signs of anemia and shock, and pleural or mediastinal effusion may be present. Exsanguination resulting from aneurysmal rupture is possible.

208.5.5.2 Spurious (Pseudo) Aneurysm

Spurious aneurysms, also known as *pseudoaneurysms*, are caused by localized disruption of the native artery. Their histologic appearance includes arterial wall architecture that is formed by fibrous tissue. One cause of spurious aneurysms is a hematoma that communicates with an arterial lumen resulting from venipuncture.[79] Traumatic spurious aneurysms are probably more common than is usually realized. Clinical signs may include lameness, persistent pain, and deep muscular swelling unresponsive to local therapeutic measures, antibiotics, or glucocorticoids. Pitting peripheral edema may be present, and neither blood nor pus can be aspirated from the swelling. The diagnosis of spurious aneurysms may be suspected from

physical examination. Survey radiographs may indicate soft tissue swelling. Diagnostic confirmation has classically relied on arteriography, which illustrates a nodular exudation of contrast medium at the arterial defect. Doppler echocardiography, especially color flow Doppler imaging, aids in identification by depicting blood flow and turbulence. Additional diagnostic tests include computed tomography (CT), radionuclide angiography, and surgical exploration. The differential diagnosis includes chronic infection, obstruction of a deep vein, or abscessation. With a spurious aneurysm, however, pyrexia and neutrophilia are not encountered. The prognosis is favorable if surgical vascular repair can be accomplished.

1155

1156

208.5.6 Arteriosclerosis

Arteriosclerosis is defined as chronic arterial wall remodeling consisting of hardening, loss of elasticity, and luminal narrowing. These changes result from proliferation of connective tissue and hyaline degeneration of media and intima. Proliferation and thickening of the intima with the deposition of ground substances leads to progressive fibrosis and vascular stenosis. Inflammation is not a feature of arteriosclerosis.[80] Arteriosclerotic lesions are commonly detected in old dogs and cats and may comprise part of the normal aging process.[80–82] These changes are typically mild and usually unimportant to health and survival. Thrombosis is rarely a complication of such microscopic lesions, and their functional significance is not known. In other instances, arteriosclerosis may be severe and associated with substantial reduction in intraluminal diameter (often referred to as *small vessel disease*) (Figure 208-9). Lesions of this nature are also common in feline myocardial diseases, particularly hypertrophic cardiomyopathy, and may be detected in canine aortic stenosis as well.[83,84] Arteriosclerotic changes may also occur in aorta and cerebral, renal, spinal, and sinoatrial node artery.[80] Intramural coronary arterial narrowing commonly occurs in association with chronic degenerative valve disease as well. Arterial lesions may have been associated with small regions of myocardial necrosis and fibrosis. Intramural coronary arteriosclerosis was found in 26.4% of old dogs undergoing necropsy.[80] Extensive nonthrombotic, nonatherogenic stenosis of extramural coronary arteries was described in two adult male Labrador retriever dogs with CHF.[85] Disease of extramural arteries is less common. Endothelial aortic plaque formation associated with arteriosclerosis was detected in 77.8% of 58 dogs brought to a small animal clinic in Helsinki for euthanasia.[86] Spontaneous arteriosclerosis, with a predilection for renal vasculature, has been demonstrated in young (<2 years old) greyhounds.[87] The severity of the lesions was correlated with increased renal vascular tortuosity and high shear stress. Clinical consequences of these lesions have not been determined.

Figure 208-9 Arteriosclerosis in pulmonary arterioles. Severe thickening of the arterial intima and media and dramatic reduction of arteriolar lumen is evident. Inflammatory infiltrates are also diffusely present.

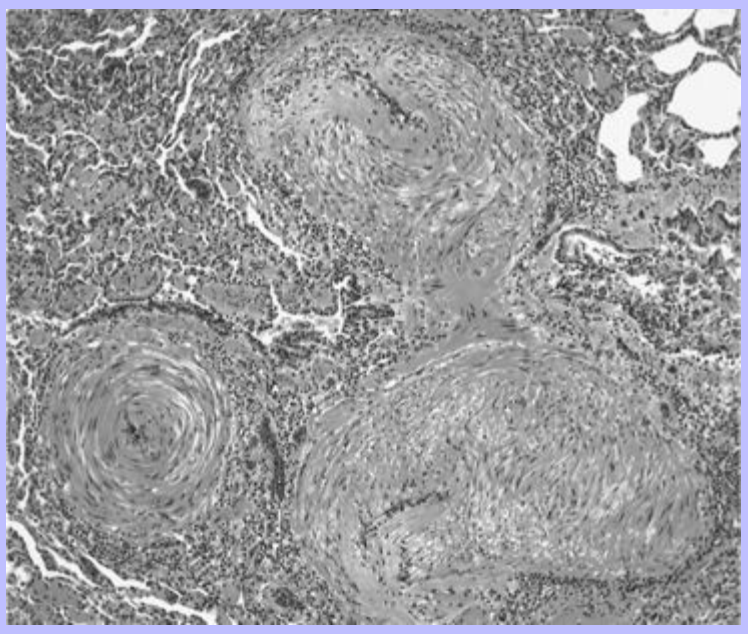


Figure 208-10 Coronary atherosclerosis of extramural coronary arteries in a dog with severe hypercholesterolemia (> 650 mg/dL) caused by hypothyroidism. Epicardial coronary arteries are evident. A larger epicardial branch is labeled *(CA)*. The reader should note numerous light plaques *(P)* within the arteries that represent deposition of lipid. The lower left portion of the figure shows a cut segment of myocardium. The lumina of the subepicardial arteries are also surrounded by a concentric layer of lipid. (Courtesy of John Bonagura, DVM.)

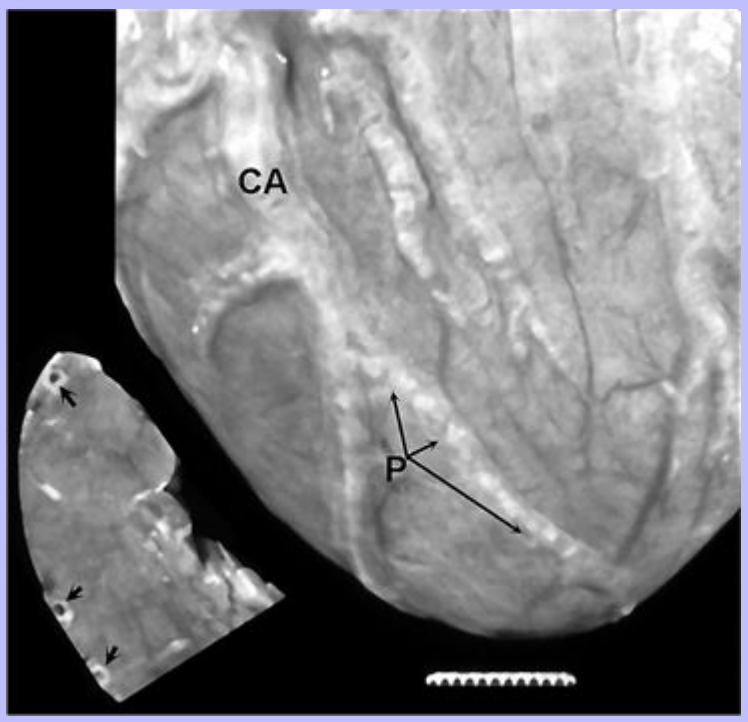


208.6 ATHEROSCLEROSIS

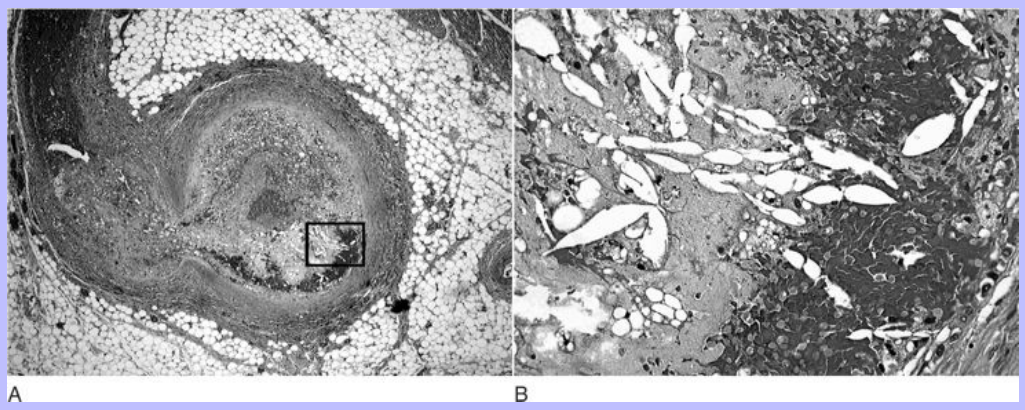
Atherosclerosis denotes inner arterial wall thickening in association with lipid deposition. Affected large coronary arteries often appear grossly thickened, yellow-white, and may have narrowed lumina (Figure 208-10). Histologically, deposits of plaque containing cholesterol, lipoid material, focal calcification, and lipophages thicken the inner sections of arterial wall (intima and inner media; Figure 208-11).[88,89] There can be widespread involvement of arteries from many organs. Unlike the disease in humans, canine atherosclerosis is uncommonly associated with extensive plaque formation, arterial calcification, or thrombosis. Atherosclerosis has not been described in cats.

Atheromas are lipoid arterial plaques and they are rare features of canine atherosclerosis. Atheromas are sometimes referred to as *xanthomatosis*. Atherothrombosis results when a localized atheroma forms on an atherosclerotic plaque, resulting in disruption of blood flow and subsequent ischemia, infarction, or both.[88] Atherothrombosis is most severe in both extramural and intramural coronary arteries, carotid arteries, and renal arteries.

Atherosclerosis has been detected in older dogs as a consequence of the hypercholesterolemia and lipidemia associated with thyroid atrophy. A predisposition for spontaneous atherosclerosis was reported in old, obese dogs with atrophied thyroid glands and hypothyroidism.[88] This observation is in accordance with experiments in which atherosclerosis could be induced in thyroidectomized dogs fed large quantities of cholesterol or cholic acids.[90,91] The spontaneous disease mainly affects male and spayed female dogs. An increased prevalence in miniature schnauzers, Doberman pinchers, and Labrador retrievers has been reported.[88] The distribution and severity of arterial lesions and thyroid atrophy are typically associated with clinical signs of lethargy, anorexia, weakness, dyspnea, collapse, heart failure, vomiting, disorientation, blindness, circling, and coma.[88,92] Recorded ECG abnormalities included atrial fibrillation, notched QRS complexes, and ST segment elevation. Laboratory abnormalities included hypercholesterolemia, lipidemia, low serum triiodothyronine (T_3) and thyroxine (T_4) concentrations, elevated blood urea nitrogen (BUN) (often associated with renal infarction) and liver enzyme concentrations, and high alpha$_2$ and beta fractions in the protein electrophoresis.

1156
1157

Figure 208-11 Atherosclerosis. **A,** Large coronary artery appears grossly thickened and has a narrowed lumen. The inner sections of arterial wall (intima and inner media) are thickened by deposits of plaque containing cholesterol, lipoid material, focal calcification, and lipophages. **B,** Magnified insert from **A**. Atherosclerotic plaque showing clefts of lipid material (*arrow*).



Clinical diagnosis of atherosclerosis is difficult, and the prognosis for dogs with clinical signs related to stenosing atherosclerosis is poor. Potential treatments include thyroid replacement drugs, antihypertensive medication, blood cholesterol–reducing agents, or a low-cholesterol diet. Treatment strategies have not been tested in dogs, and severe lesions are essentially irreversible. Not all dogs with hypothyroidism develop atherosclerosis. Only those with increased levels of very low–density beta lipoproteins tend to be prone to develop atherosclerosis and

plaques. Blood levels of low-density lipoproteins may be increased in these dogs because lipoprotein receptors are reduced and lipoid removal by the tissues is decreased. The elevated lipoprotein concentrations account for arterial lipoid deposits.[91]

Atherosclerosis is strongly suspected as being an inflammatory disease developing in response to injury in the vessel wall in humans. Infiltration of the mononuclear lymphocytes into the intima, local expansion of vascular smooth muscle cells, and accumulation of extracellular matrix is believed to be the pathogenesis of the inflammation. Previously determined risk factors including hyperlipidemia and hypercholesterolemia are believed to enhance leukocyte adhesion to damaged endothelium and reduce local immune response. The role of inflammation in the development of canine atherosclerosis has yet to be determined.[93]

208.6.1 Arteriovenous Fistulas (Arteriovenous Malformations)

A-V fistula is an abnormal communication between an artery and vein bypassing the capillary network. The true incidence is unknown, although A-V fistulas are reported uncommonly in dogs and rarely in cats. Centrally located anomalies may occur between the cardiac chambers (e.g., ventricular septal defect) or between the great vessels (e.g., aorticopulmonary window, patent ductus arteriosus) and are reviewed in Chapter 200 In this section, only peripheral A-V malformations (A-V fistulas) are discussed.

Congenital A-V fistulas are rare and are caused by arrest or misdirection of embryologic vascular differentiation. The persistence of primitive equipotential capillaries and the subsequent failure of the existing anastomotic embryologic channels to differentiate into arteries or veins are responsible for their abnormal communications. Terminology applied to congenital A-V fistulas has been a source of confusion (e.g., hemangioma racemosum, Park-Weber syndrome, hemangioma cavernosum, strawberry birthmark, nevus angiectasis, cirsoid aneurysm, congenital A-V aneurysm).

The most common cause of an acquired A-V fistula is blunt or penetrating trauma.[94] Iatrogenic trauma is often related to venipuncture and accidental perivascular injection of irritating medicaments.[95] Additional causes include neovascularized tumors (carotid body tumor, thyroid tumor, hemangiosarcoma), ruptured aneurysm, mass ligature of arteries and veins, gunshot wounds, and erosion of contiguous vessel walls by infection or arteriosclerosis. Most A-V fistulas involve the extremities, but they can occur anywhere in the body including the neck, spinal cord, body wall, head, brain, abdomen, liver, and lung. They can also occur as a complication of mass ligation of arteries and veins during closed castration.[96–99]

Irrespective of cause and location, A-V fistulas cause similar altered blood flow dynamics. The basic principle is that blood follows the path of least resistance. The A-V malformation is an abnormal connection between a high-pressure arterial system and a low-pressure venous system with a higher capacity. Due to the difference in resistance, blood flows preferentially through the fistula rather than continuing via the artery to the capillary bed. This shunting results in a reduction of flow in the artery distal to the fistula and increased flow in the venous system. In addition to stealing blood from the distal capillary bed, these changes lead to the development of collateral circulation around the fistula. The communicating shunt increases venous pressure, venous blood oxygen saturation, and the diameter and number of anastomotic arteries and veins. Eventually an ectasia of the feeding artery and aneurysmal sacs in the venous area of the A-V communications may develop. Histologic changes occur in affected vessels so that arteries begin to look more like veins (venification) and veins like arteries (arterialization). The rapid runoff of blood through the A-V fistula into the capacitant venous circulation causes turbulence and, potentially, sound (bruit).[100]

Shunted blood flow through a large fistula can be so great that retrograde flow from a distal artery into the fistula occurs. Arterial blood supply to the tissues distal to the A-V fistula may become compromised from competition with the fistula and secondary venous hypertension, resulting in stagnation of venous blood flow in the dilated veins, or even reversal of blood flow in a distal rather than proximal direction. Local edema and ischemia followed by tissue necrosis, ulceration, or organ dysfunction may ensue. In large and mostly centrally located fistulas, the central blood dynamics also become affected. Large flow volumes across the A-V fistula compromise the blood supply to other regions of the body by shifting blood into the capacitance venous circulation. Compensatory responses to increased blood volume (cardiac preload) include elevated heart rate, cardiac contractility, and eccentric cardiac hypertrophy. Augmented cardiac output and gradual expansion of the blood volume partially restore the blood supply to deprived tissues. Eventually, however, the increased venous return and the elevated cardiac workload may induce high-output heart failure.[101]

Clinical history and signs vary according to the location, size, duration, etiopathology, and topography of the fistula. A-V fistulas of the extremities may appear as painless, easily compressible, warm bulges or varicosities (Figure 208-12). Sometimes they are detected incidentally during routine clinical examination. With medium-sized or large fistulas of the extremities, a continuous palpable thrill and pulsation, along with a machinery murmur, can be detected. The leg or region distal to the fistula may be swollen, warmer, or colder than the proximal area (sometimes with severe local ischemia), painful, and affected by pitting edema. Lameness, cyanosis, therapy-resistant toe ulcers, scab formation, or gangrene can occasionally occur distal to the fistula with severe local ischemia. In the dilated superficial veins, a faint pulsation may be felt. In the feeding arteries a *water-hammer* pulse is often present. Animals with high-output heart failure may develop a cardiac murmur of mitral regurgitation and moist lung sounds, indicating pulmonary edema.

When firm pressure is applied proximal to the A-V fistula, or if the feeding artery is compressed, the thrill and bruit disappear and the pulse, and heart rate may drop as a result of diminished venous return and reduced cardiac output. This is referred to as *Branham's bradycardia sign*, and the maneuver is called *Branham's* or *Nicoladoni-Branham's test.* Together with the local thrill or fremitus and the bruit, the Branham's sign is pathognomonic for A-V fistulas.

Other signs have been reported and vary with respect to location and hemodynamic alterations caused by the A-V fistula. An A-V fistula in the orbit was reported to cause exophthalmos.[102] Recurrent bleeding from the mouth was observed in an A-V fistula of the tongue.[98] Restless behavior and lethargy followed by progressive seizures and hemiparesis were reported in a 10-year-old mixed breed dog with a subcortical cerebral A-V malformation.[103] An A-V fistula of the spinal cord at the thoracolumbar junction in a 10-month-old female Australian shepherd dog caused a deteriorating hindlimb ataxia, difficulty in getting up and down, hypersensitivity over the lumbosacral region, and urinary incontinence.[104] Cardiomegaly and pulmonary overcirculation were detected radiographically in a dog with a postsurgical AV fistula, and these changes regressed after the fistula was surgically closed.[97] An A-V fistula was found surgically in the jejunum of an 8-month-old dog with persistent anemia and melena.[105] A-V fistulas in tumors have been recognized as a strong pulsation and fremitus detectable during palpation of the tumor mass.[94] Auscultation of the tumor mass may reveal a machinery-type murmur or bruit.

Figure 208-12 Coon dog with an arteriovenous (A-V) fistula of the ear. The dog was presented for severe bleeding caused by trauma to large distended veins *(inset, arrows)*. A continuous murmur was ausculted over the ear, and Doppler studies demonstrated continuous arterial-to-venous flow. Venous distention is secondary to direct transmission of arterial pressure and marked increases to flow. (Courtesy of S.E. Johnson, DVM, and J. Bonagura, DVM.)

Congenital hepatic A-V fistulas have been reported in young dogs. The hepatic artery connects to the portal vein and causes portal hypertension or reversal of the blood flow in the portal vein.[106,107] There can be a single fistula or multiple fistulas that can be distinctly visualized by abdominal color Doppler ultrasonography

and coeliac arteriography.[108] Clinical signs include lethargy, vomiting, diarrhea, anorexia, weight loss, ascites, polyuria, and neurologic signs related to hepatic encephalopathy.[109]

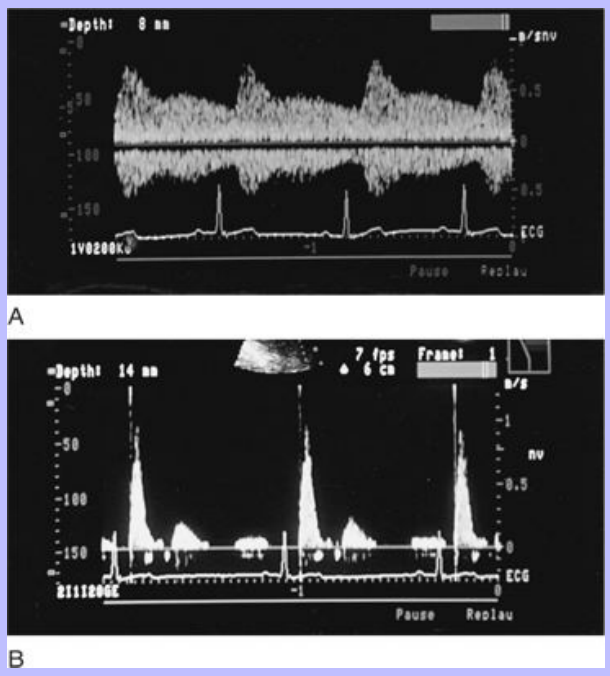
Pulmonary A-V fistulas can lead to respiratory distress and cyanosis. Survey thoracic radiographs of animals with large fistulas may indicate cardiomegaly, a prominent aortic arch, a hypervascular lung field, and an increased interstitial or patchy pulmonary radiodensity, indicating pulmonary congestion or edema, respectively.

Diagnostic ultrasonography, especially color Doppler imaging, has been clinically useful for identifying and localizing A-V fistulas (Figure 208-13).[108,110,111] Findings included the presence of focal intra-arterial flow at the fistula site throughout the cardiac cycle, turbulent pulsatile venous flow at the fistula site, and nonpulsatile venous flow proximal to the fistula. Angiography may be used to define fistula anatomy and size more accurately and to plan management strategies. The absence of a normal capillary phase and premature outlining of the veins are typical arteriographic findings in shunting lesions. The differential diagnoses of A-V fistulas include neoplasms, varices, abscesses, cystic skin lesions, aneurysms, lymphedema, and scarring.

1158

1159

Figure 208-13 Pulsed wave (PW) Doppler recordings from a 5-year-old female golden retriever dog with traumatic A-V fistula. **A,** Doppler interrogation of a large, pulsatile, dilated vessel associated with the right radial artery identified by color flow Doppler at the medial right brachium. The reader should note the continuous flow best seen during diastole. **B,** Pulsed wave (PW) Doppler flows recorded from the normal left radial artery in the same dog.



Management of A-V fistulas has historically required surgical intervention.[112] This usually involves careful ligation of all proximal and distal arteries feeding the fistula, ligation of the draining veins, and complete excision of the A-V collaterals with the venous aneurysmal sacs (so called quadruple ligation). If relapse occurs or if multiple fistulas are present, a wide excision of the involved areas or limb amputation may be the only alternative.

Surgical approaches can often be technically difficult, mutilating, hazardous, and can have a high failure rate with residual clinical symptoms.[113] Consequently, arterial embolization techniques using special embolization wire coils have begun to be used to occlude A-V fistulas, owing to the minimally invasive nature of these procedures.[113,114] In a cat with a forelimb fistula, cyanoacrylate embolization was used to obliterate the fistula followed by en bloc surgical resection of vessels.[115] Transcatheter embolization using vaso-occlusive coils was described in three cats and two dogs with peripheral A-V fistulas.[116]

The prognosis for animals with small A-V fistulas is often good. Morbidity is highest with centrally located A-V fistulas, with fistulas that cause organ dysfunction, with large fistulas that induce a high cardiac output, and with fistulas that cannot be successfully occluded using embolization techniques.

208.6.2 Traumatic and Functional Arterial Disease

Trauma from direct accidental injury or iatrogenic trauma (e.g., surgery or vascular interventional procedures) is a common cause of vascular disease. Direct trauma may result in direct vascular wounds, or it can result in mural contusions leading to delayed thrombosis, necrosis, late hemorrhage, and false aneurysm formation. Vascular wounds can also occur from fractures because adjacent vessels are relatively fixed and vulnerable. Clinical features of traumatic arterial injuries may include diminished or absent pulse, enlarging hematoma, pulsatile arterial bleeding, symptoms of ischemia distal to the wound, injury of anatomically related nerves, and hypotension with major hemorrhage. Compressive forces from local tissue trauma (compartment syndrome) and vascular stenosis may delay or inhibit return to normal function of the affected area. Accurate diagnosis and extent of traumatic vascular injuries can be accomplished by direct examination, arteriography, ultrasound, and magnetic resonance imaging (MRI).[117]

Vasospasm refers to reversible localized or diffuse vasoconstriction of arteries or small blood vessels. If short lived, the ischemia is reversible and permanent damage does not result. However, prolonged vasospasm with ischemia may lead to tissue damage and ulceration. Vasospasm is a common response to blunt and perforating vascular trauma and may also result from perivascular injection of irritating substances. When this occurs, tissue injury and vasospasm can be minimized by local infiltration with procaine hydrochloride or lidocaine. Uncommonly, vasospasm occurs in association with spontaneous arterial rupture (e.g., ruptured cerebral aneurysm, stroke). Angiography is usually required for confirmation. Vasospasm may be elicited by exotoxins. The best-known example is ergotism that produces intense vasospasm of the digits and large vessels by stimulation of the alpha-adrenoceptor. The differential diagnosis of vasospasm includes polycythemia, cold agglutinins, thrombosis, arteriosclerosis, and vasculitis.

208.6.3 Diseases of Veins

Diseases of the venous system frequently cause minor clinical problems, despite the fact that veins are commonly affected by or involved in trauma, TE, edema, local inflammation, and septic processes. Many conditions, however, often go unrecognized. Venous disorders include traumatic injuries, superficial and deep

phlebitis and thrombosis (thrombophlebitis), catheter embolization, aneurysms, venous compression syndromes, varices, and ulcers.

Pulmonary thromboembolism (PTE) is a common and often life-threatening complication associated with a variety of systemic and metabolic diseases. A thrombus formed in the right heart or the peripheral or central venous system can embolize to the pulmonary arterial vasculature. Contributing factors include prolonged immobilization, trauma, surgery, and a range of disorders including IMHA, hyperadrenocorticism, nephrotic syndrome, DIC, sepsis, cardiac disease, amyloidosis, neoplasia, proteins C and S deficiency, and antithrombin III deficiency. PTE is covered in detail in Chapter 218.[21,26]

Varicosis and ulceration are rare in dogs and cats. When detected, they often accompany A-V fistulas. Cutaneous phlebectasia is a benign lesion sometimes erroneously called *telangiectasis*. It is reported almost exclusively in dogs with spontaneous or iatrogenic Cushing's syndrome.[118] Phlebectasia is an abnormal dilatation, extension, or reduplication of veins or capillaries or a combination of these changes.

Venous perforation or *blunt trauma* to veins is usually well tolerated because rapid clotting results in venous occlusion. If when venous occlusion or venous severance is severe, however, resultant edema and cyanosis are usually temporary because of collateral circulation. If all veins draining an area are compromised, marked edema and necrosis can ensue. Blunt trauma has been associated with caudal vena caval obstruction or kinking of the intrathoracic caudal vena cava and ascites.[119]

Venous malformations have been previously referred to as *cavernous hemangiomas*. They can be localized or extensive and appear as cystic dilation of blood vessels. They generally permit only low blood flow, and small lesions are generally asymptomatic. Expansion of the lesion may occur, however, especially after trauma. 1159
Thrombosis may occur due to sluggish blood flow, resulting in local swelling and tenderness. Larger lesions in 1160
dependent areas may enlarge, causing significant vascular dilation. This may result in changes in skin color, ulceration, and hemorrhage. The affected area appears as a warm, soft, compressible mass. No thrills or bruits are present due to the low flow. Pain may result from pressure exerted on deep tissues and nerves.

Figure 208-14 Angiogram of a dog with a cranial vena caval thrombus. The animal developed lymphedema of the neck, face, and front legs 1 week after a transvenous pacemaker lead had been inserted through the jugular vein to facilitate temporary cardiac pacing for complete heart block. Contrast medium was injected into an accessory cephalic vein with the animal positioned in sternal recumbency. Extensive collateral circulation is seen, but filling of the cranial vena cava is not identified. An epicardial electrode is visible in the cardiac apex, and the pulse generator can be seen subcutaneously in the left lateral thorax. (Courtesy of Nancy Morris, DVM.)

Diagnosis is made using history, physical examination, and ultrasound. Venography may be needed to define the lesion. Symptomatic therapy using light, compressive wraps is sometimes helpful for acute management.

Surgical excision of affected vessels is occasionally required, but complete resection is difficult and local recurrence is common.[120]

Thrombosis commonly follows blunt trauma and perforating injuries, particularly with venipuncture or prolonged venous catheterization (Figure 208-14). Phlebitis is a major cause of intimal damage leading to thrombosis. The thrombosis is usually of little local consequence. However, emboli may be carried to the lung and cause PTE. In most animals, blood clots carried to the lung are rapidly lysed and cause no problems. However, when inflammatory diseases, dehydration, or circulatory failure occurs, clot formation may continue in the pulmonary vessels and lead to vascular occlusion, severe dyspnea, pain, and death.[21] In infectious thrombophlebitis, bacterial emboli may be carried to the lungs and cause thromboembolic pneumonia. Spontaneous venous thrombosis is rare, although portal vein thrombosis has been reported. Clinical signs include ascites, peripheral pitting edema, and portosystemic shunting.[121]

Embolization of severed intravascular catheter fragments is an occasional complication of intravenous catheter placement.[122,123] In humans, reported complications of catheter embolization include perforation of cardiac walls, endocarditis, pulmonary embolism, and severe arrhythmias. Therefore it is generally considered prudent to remove catheter fragments. Nonsurgical, transvenous removal of catheter fragments using loop-snare catheters, forceps, and basket catheters have been described. Whenever possible, however, steps should be taken to avoid situations predisposing to catheter fragmentation, including inadequate restraint during catheter placement, withdrawal of catheters through their placement needles during repositioning, failure to properly secure catheter to the patient, and inadvertent severing of catheters during bandage changes.

Phlebitis can occur from a local inflammatory process extending to the veins or can originate from a venous intimal lesion. Common causes of venous intimal lesions are perivenous injection of irritating drugs, infusion of large amounts of fluid, and long-term placement of intravenous catheters. Infusion-related phlebitis occurs in three forms: (1) chemical (injury to vein by irritating drugs), (2) physical (trauma to the intima by catheters, needles, hypertonicity, or particulate matter in infused fluids), and (3) microbial (infected fluids, skin, or catheter tip). Sterile or septic thrombophlebitis may result, usually remains localized, and is characterized by pain, swelling, and exudation (Figure 208-15). Patients with serious illnesses or compromised immune systems, however, may develop sepsis, thromboembolic pneumonia, or endocarditis.

In cases of venous occlusion, clinical signs depend on the anatomic location, extent, and duration of the obstruction. Acute obstruction of centrally located and deep veins causes edema, cyanosis, discomfort, and venous dilatation distal to the obstruction site. Obstruction of the cranial vena cava causes edema in the neck, head, front limbs, and dependent portions of the chest wall (Figure 208-16). Pleural effusion commonly results from central venous obstruction. Clinical disorders of the intrathoracic caudal vena cava have been reported (Figure 208-17).[119] Obstructions of the renal or pelvic area cause edema of the hindlimbs and the scrotum. Clinical signs depend upon collateral vessel reserve and capacity of regional lymphatics. In addition to thrombosis, common causes of venous obstruction include invasive malignant processes and venous compression by abscesses, hematomas, tumors, and lymphadenopathy. A number of tumors have a tendency for venous invasion, including chemodectomas, adrenal tumors, and hemangiosarcomas. Angiography may indicate the occlusive or compressive lesion or highlight increased collateral circulation (or it may do both) (Figure 208-18). Diagnostic ultrasonography can often detect masses or flow disturbances.

The prognosis and therapy of venous obstruction depend on the primary disease. These are discussed in various chapters throughout this book.

208.6.4 Diseases of the Peripheral Lymphatics

The lymphatic system plays a critical role in regulating body fluid volume and immune function. Lymphatics originate within the interstitium as specialized endothelial-lined capillaries transporting fluid, solutes, and macromolecular particles back into the venous system. Fluid, protein, cells, and macromolecular particles from the interstitial space empty into the initial lymphatics composed of a series of small lymphatic capillaries that begin blindly in the tissues. The lymph then flows through a system of lymphatic vessels that progressively increase in diameter. As lymph flows centrally it passes through at least one lymph node before emptying into larger lymphatic trunks.[124] The deep trunks unite to form two major lymphatic vessels: (1) the thoracic and (2) right lymphatic duct. The thoracic duct drains most of the body and returns fluid into the venous system at the brachycephalic vein or the left subclavian vein. The right lymphatic duct drains the right side of the head and neck and right forelimb.

1160
1161

Figure 208-15 Caudal (left) and lateral (right) views of the right rear limb of a young dog with severe edema caused by thrombophlebitis. The problem developed after placement of saphenous vein catheter. The limb is markedly swollen and edema fluid *(arrows)* is leaking through a small ulcer in the skin. Thrombosis of the vein prevents venous drainage and increases lymphatic fluid formation. (Courtesy of John Bonagura, DVM.)

Lymphatic vessels contain many junctions between individual endothelial cells that are connected to the surrounding extracellular matrix by reticular fibres and collagen. These junctions open when tissue hydrostatic pressure becomes elevated and the anchoring filaments stretch, allowing fluid to move into the vessel. As the fluid is cleared from the interstitium, the connecting fibers contract and the junctions between the endothelial cells close. The opening and closing of these junctions allow them to act as inlet valves, preventing the backflow of lymph into the interstitium. The larger vessels of the lymphatic system have progressively fewer open junctions, increasingly muscular walls, and frequent intralymphatic valves that also prevent backflow of lymph. The action of external muscular contraction along with intrinsic contractility of the lymphatic vessels aid in the movement of lymph through the lymphatic system. Lymph is filtered by at least one lymph node before entering the venous circulation. While in the lymph node, the lymph is in contact with the blood circulation and approximately half of the fluid is drained before leaving into the larger lymphatic ducts.[124]

Figure 208-16 Cranial vena cava syndrome associated with a mediastinal mass and cranial vena caval occlusion. Severe peripheral edema of cranial extremities is present.

In addition to its transport function, the lymph system plays a major role in the immunologic responses to infectious agents. It serves as a filtering system to impede the spread of microorganisms and neoplastic cells. The cellular components, in particular the lymphocytes, are indispensable for immunologic reactions and antibody formation.[125]

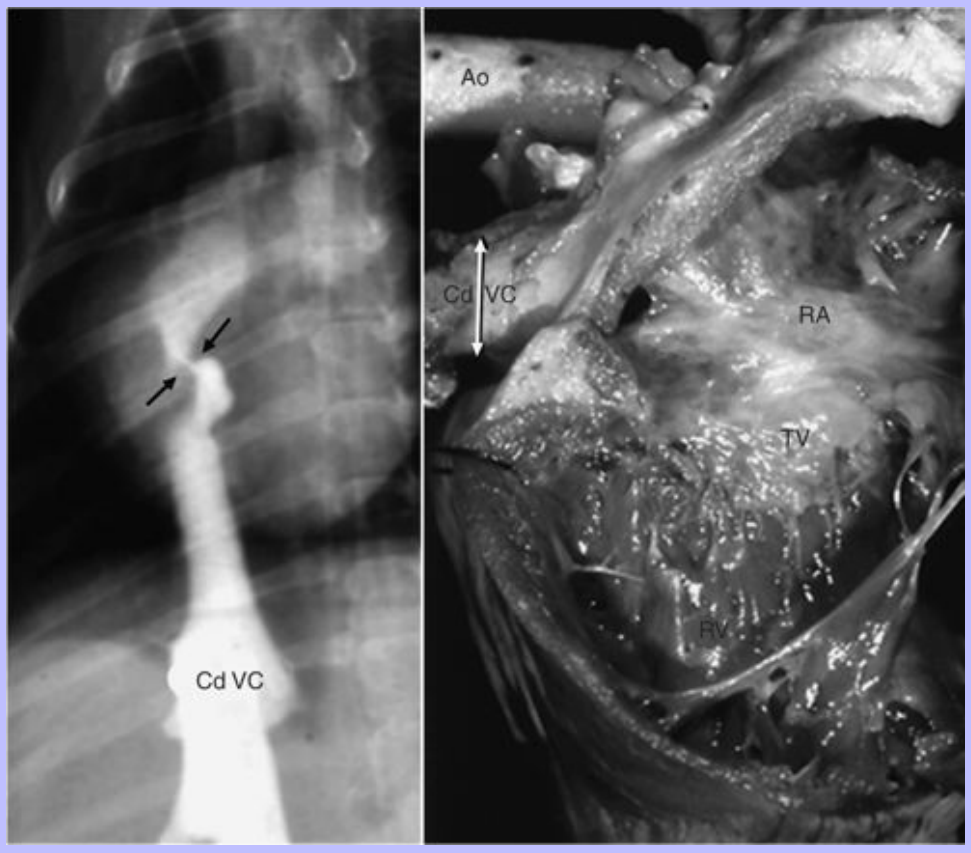
Lymphatic disorders can be subdivided into those of internal organs, such as intestinal lymphangiectasis, and peripheral lymphatic disorders. Several lymphatic diseases have been recognized in animals, including lymphedema, intestinal lymphangiectasia, chylothorax, lymphadenitis, lymphocysts, lymphoma, lymphangioma, and lymphangiosarcoma. Types and causes of peripheral lymphatic disorders are summarized in Box 208-2.

208.6.4.1 Inflammatory Lymphatic Disorders (Lymphangitis and Lymphadenitis)

Lymphangitis and lymphadenitis often occur secondary to local inflammation, particularly involving the skin, mucous membranes, and subcutaneous tissues. Lymphangitis can also result from bacterial or fungal infection or adjacent neoplastic and inflammatory disease. Lymphatics may be affected and occluded as they drain inflammatory agents and their by-products from tissue spaces. In lymph nodes, microorganisms are phagocytized and inactivated or killed by humoral and cellular mechanisms. During this process, lymph nodes may become obstructed, enlarged, warm, and painful. Affected limbs may be locally swollen, and lameness can result. Pyrexia, anorexia, and depression are common, and leukocytosis may be present with acute, severe lymphangitis.

Lymphangitis may become chronic when associated with a granulomatous or static lesion, such as a foreign body, or with unsuccessfully treated acute inflammation. Persistence of inflammatory edema results in mesenchymal cell proliferation, which in turn can cause irreversible thickening of skin and subcutis.

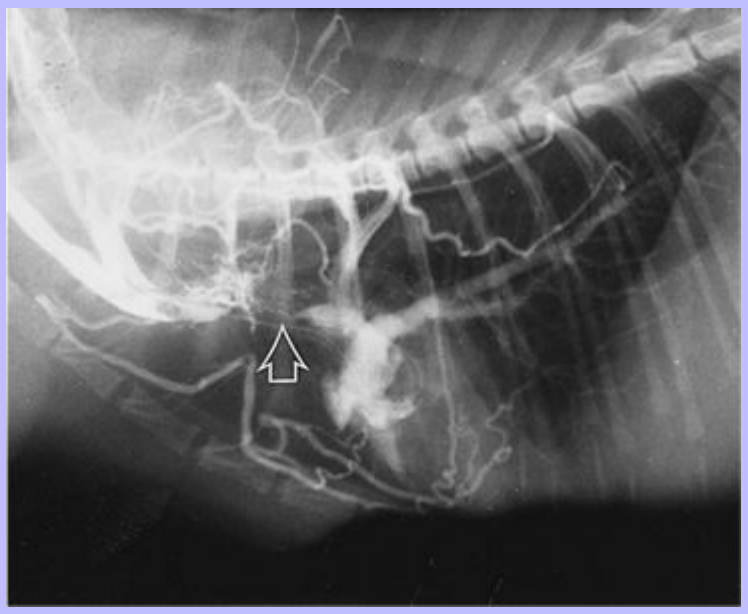
Figure 208-17 Acquired stenosis (fibrosis) of the caudal vena cava in an older dog. The left panel shows an angiogram of the caudal vena cava (*Cd VC*), which demonstrates a severe narrowing of the dye column *(arrows)* at the venous entry into the caudal right atrium. The right panel is a postmortem view of the heart taken from the right lateral perspective. The right atrial and ventricular walls have been retracted to demonstrate the stenotic, caval orifice *(small arrows)*. The reader should compare this opening with the diameter of the caudal vena cava *(to the left, large vertical arrow)*. The right ventricle (*RV*), tricuspid valve (*TV*), right atrium (*RA*), and descending aorta *(Ao)* are shown. (Courtesy of John Bonagura, DVM, and Matthew W. Miller, DVM.)



The prognosis is favorable with early treatment. Therapy consists of moist, warm, local compresses or soaks, which reduce swelling and promote drainage. Aggressive local and systemic antibiotic therapy

usually promotes recovery in animals with fever and anorexia. Bacterial culture and sensitivity testing should be performed if acute lymphangitis fails to respond to treatment and in cases of chronic lymphangitis. Contrast studies and surgical exploration may be indicated if fistulous tracts or abscesses are present or if a foreign body is suspected.

Figure 208-18 Angiogram of a 10-year-old domestic short-haired cat with pleural effusion and edema of the head and neck. Radiocontrast dye was injected into the external jugular vein. Interruption of venous return occurs in the cranial vena cava (*arrow*) caused by compression and obstruction of this vessel by a mediastinal tumor. The reader should note the prominent collateral venous network.



208.6.4.2 Lymphedema

Lymphedema refers to an accumulation of fluid in the interstitial space resulting from abnormal lymphatic drainage.[124] This term should not be used for other forms of edema, such as circulatory edema related to venous obstruction or generalized edema related to hypoproteinemia. Lymphedema may result when capillary filtration exceeds the resorptive capacity of the veins and lymphatics. The protein rich fluid (2 to 5 g/dL) causes a high osmotic gradient and exacerbates fluid accumulation.[125] Numerous classification schemes have been used to categorize lymphedema. Commonly used causative categories of lymphedema include: overload, inadequate collection into lymphatic capillaries, abnormal lymphatic contractility, insufficient lymphatics, lymph node obstruction, and main lymphatic ductal defects.

Traditionally, clinical effort is undertaken to differentiate primary versus secondary lymphedema. *Primary lymphedema* refers to an abnormality of the lymphatic vessels or lymph nodes. *Secondary lymphedema*

refers to disease in the lymphatic vessels or lymph nodes due to a different disease process. Secondary lymphedema can occur as a result of neoplasia, surgery, trauma, parasites, radiation therapy, or infection and is more common than primary lymphedema. Distinguishing between primary and secondary lymphedema is often difficult. A disease process involving a lymph node can result in fibrosis and obstruction with secondary lymphedema developing.

208.6.4.2.1 Primary lymphedema

Primary lymphedema can result from three principle morphologic and functional abnormalities including (1) abnormalities of large vessels including aplasia or hypoplasia of the thoracic duct and cisterna chyli, (2) aplasia of the peripheral lymphatics or congenital valvular incompetence, and (3) lymph node fibrosis or a deficient lymph node size and number.[126]

1162

1163

Lymphedema caused by aplasia, hypoplasia, or dysplasia of proximal lymph channels or popliteal lymph nodes (or dysplasia of both) occurs most often in the hindlimbs of young dogs (Figures 208-19 and 208-20). The edema can be transient, observed only during the juvenile period, or permanent. Mild cases are restricted to the hindlimbs, whereas severe cases may progress to whole body edema.[127–130] Although the condition is frequently bilateral, one limb is often more swollen than the other. A number of cases of suspected congenital lymphedema have been reported.[129–132] Reported breeds include bulldogs, poodles, Old English sheepdogs, and Labrador retrievers, although it is not clear whether these breeds are at increased risk.

The history may identify chronic limb swelling since birth or edema appearing later in life. The swelling represents a pitting edema of varying magnitude that is neither too warm nor cold. The edema is not usually accompanied by lameness or pain unless massive enlargement or cellulitis occurs. Growth and activity are usually normal, but rest and limb massage do not typically reduce the severity of edema. Total plasma protein, serum protein electrophoresis, hemogram, and blood chemistry are generally unremarkable. The diagnosis of primary lymphedema is based on history (age of onset, disease progression, affected limbs, and distribution of edema), and clinical signs. Previous surgery, trauma, or infections should also be noted. Radiographic lymphography may be needed to confirm the diagnosis in subtle cases and is helpful in determining morphology of anomalous lymphatic systems (see Figure 208-20).

The prognosis for resolution of congenital lymphedema is guarded and depends on the cause. Occasionally, dogs that develop hindlimb edema during the neonatal period may improve spontaneously. More frequently, dogs with severe edema of the limbs and trunk succumb during the first few weeks after birth.[127] Chronic lymphatic vessel dilation leads to loss of contractility and permanent lymphatic valvular dysfunction. Metabolic by-products accumulate and lead to collagen deposition and fibrosis. Complications such as abrasions and infection often develop. Dogs with primary lymphedema should not be used for breeding. Test matings of dogs with congenital lymphedema support the hypothesis of autosomal dominant inheritance with variable expression.

Figure 208-19 Marked, nonpainful edema of the left rear limb in a young dog with congenital lymphatic dysplasia. (Courtesy of John Bonagura, DVM.)

Figure 208-20 Lymphangiogram of a young dog with lymphatic dysplasia. After cannulation of a distal lymphatic vessel, contrast medium was infused into the lymphatic system. The reader should note the dilated, tortuous, lymphatic channels *(L)* that end blindly at the stifle *(arrows)*. *T,* Ttibia; *S,* radiopaque surgical sponges. (Courtesy of C. Wendy Myer, DVM, and John Bonagura, DVM.)

208.6.4.2.2

Secondary lymphedema

Persistent lymphedema occurs only after destruction or blockage of a considerable number of major lymph channels (or several sequential lymph nodes with their afferent or efferent lymphatics).[125] Factors that can delay or prevent edema formation include opening of collateral vessels, rerouting of lymph flow through peripheral lymphaticovenous anastomoses and perilymphatic routes of lymph drainage, and increased venous fluid uptake. Secondary lymphedema is often related to a combination of lymphatic and venous obstruction. Inhibited venous return increases lymphatic flow by altering Starling's forces toward increased tissue fluid accumulation. This overloads the lymphatic capillaries and results in the accumulation of fluid in the interstitial space.[133] Distal lymphatics may become more distended, causing loss of valvular competency, stagnation of lymph flow, mural insufficiency, and further accumulation of proteinaceous fluid in subcutaneous tissues. Other common causes include posttraumatic or postsurgical interruption of lymphatics or lymph node excision and blockage of lymph nodes and lymph vessels by compression or invasive neoplasms. Lymphedema resulting from local neoplasia is usually a sign of a widely disseminated and highly invasive malignant process. Several causes of secondary lymphedema have been summarized in Table 208-2.

1163

1164

Clinical signs associated with secondary lymphedema vary depending on the underlying systemic causes. Lymphedema may be localized to the periphery of an extremity (Figure 208-21) or extend proximally to the subcutaneous tissues.[134] The location and severity of obstruction determine the extent of edema formation. For example, sublumbar or intrapelvic obstruction induces bilateral hindlimb edema and edema of the thighs and external genitalia. Mediastinal masses and thrombosis of the cranial vena cava induce bilateral edema of the front limbs and tissue of the ventral thorax, neck, and head. The clinician must palpate all lymph nodes carefully for enlargement and pain. With bilateral hindlimb edema, it is important to perform rectal or abdominal palpation to assess sublumbar lymph nodes. The prostate and anal region or mammary glands and vaginal area should be carefully inspected for neoplasms, which can lead to obstructive intrapelvic processes. Intrapelvic masses should be suspected in all dogs with hindlimb edema and vague signs of sublumbar pain, discomfort during ambulation, or difficulties with defecation or urination. Depending on the type and extent of underlying systemic illness, limb edema may be the only detectable abnormality or may be accompanied by fever, anorexia, and weight loss. Clinicopathologic findings depend on the underlying primary disorder.[135]

Figure 208-21 Pitting edema in a dog with a caudal lumbar mass. The edema was caused by either obstruction of venous return in the rear limbs or obstruction of lymphatic drainage. Tissue fluid was deformed by light digital pressure, resulting in a visible subcutaneous pit in the rear limb (*arrows*). (Courtesy of John Bongura, DVM.)

Diagnosis is based largely on history and clinical examination and is facilitated by diagnostic imaging. Survey radiographs should be taken of suspicious areas, which often include the pelvis or cranial thorax. In a substantial number of cases, soft tissue masses or destructive bony lesions can be detected. Abdominal ultrasonography can provide information about soft tissue masses and readily identifies enlarged lymph nodes and other structures. Lymphography or other imaging techniques may be indicated if the diagnosis remains unclear. Lymphography is often relied upon for definitive diagnosis of lymphatic disorders. In some cases the lymphatics are hypoplastic throughout their course. When aplastic, lymphatics suitable for cannulation and injection of radiocontrast agent may not be found. Failure to outline a lymph node after lymphography is not absolute proof of its absence.[127] Lymphographic features of primary lymphedema include lymph node aplasia and small lymphatics that end blindly or anastomose into collateral vessels around (instead of into) lymph nodes where they would be normally found.

Lymphoscintigraphy is an alternative approach for imaging peripheral lymphatics. This technique requires a gamma-camera system and intradermal injection of high molecular weight–radiolabeled colloids.[136–137] Such equipment and specialized training are not widely available. When compared with conventional lymphography, lymph nodes only appear as hot spots, preventing adequate assessment of nodal structure.

Differential diagnoses for dogs with edema confined to one limb include inflammation, trauma, vascular obstruction, hemorrhage, cellulitis, phlebitis, and A-V fistula. Diagnostic considerations for dogs with edema involving both forelimbs include thrombosis or compression or invasion of the cranial cava by a mediastinal mass. With the latter, edema usually involves the head and neck regions and the limbs. Causes of only bilateral hindlimb edema include obstruction of sublumbar lymph nodes by neoplastic infiltration. If all four limbs are involved, the differential diagnoses should include hypoproteinemia, CHF, renal failure, or portal hypertension. The close association of lymphatic and venous structures can make it difficult to distinguish between lymphatic and venous obstruction, and both can occur at the same time. Ulceration, dermatitis, cyanosis, weeping varices, and fat necrosis are signs of venous obstruction rather than lymph stasis.

Therapy is usually unrewarding. In the early stages of lymphedema, medical management is directed to maintaining the patient's comfort and reducing swelling. Infectious disorders require long-term antimicrobial therapy. Some neoplastic conditions may benefit from chemotherapy or radiation therapy. Long-term heavy bandage application (e.g., Robert Jones splint) may encourage lymphatic flow and reduce subcutaneous lymph accumulation. Local topical skin care and intermittent antibiotic therapy are helpful in reducing cellulitis. With the exception of isolated instances, pharmacologic therapies are generally unrewarding. The benzopyrones (e.g., rutin) are a group of drugs that have been advocated to reduce high-protein lymphedema by stimulating macrophages, promoting proteolysis, and enhancing absorption of protein fragments.[138] Long-term diuretic administration may be contraindicated, because after reduction of interstitial fluid, proteins in the residual interstitial space proteins may promote tissue injury.[135] Surgical options may include (1) procedures to facilitate lymph drainage from affected limbs (lymphangioplasty, bridging procedures, shunts, omental transposition), and (2) procedures to excise abnormal tissue. Surgical excision of the subcutaneous edematous tissue should be staged to decrease devascularization.[135] Short-term administration of anti-inflammatory agents or diuretics, bandaging, and physical therapy may be helpful in cases of traumatic and postsurgical induced lymphedemas.

Figure 208-22 Cat with peripheral edema secondary to lymphatic obstruction by lymphangiosarcoma.

208.7 LYMPHANGIOMA, LYMPHANGIOSARCOMA

Lymphangiomas are benign tumors of lymphatic capillaries and are thought to develop when primitive lymphatic sacs fail to establish venous communication.[139] Lymphangiomas can be classified into three categories based on their histologic appearance: (1) capillary lymphangiomas comprised of a network of capillary-sized lymphatic channels, (2) cavernous lymphangiomas composed of dilated lymphatics that infiltrate the surrounding tissue, and (3) cystic hygromas (unilocular or multilocular, cystic masses lined by a single layer of endothelium supported by a connective tissue stroma and containing a straw-colored, proteinaceous [1.3 to 4.5 gm/dL] fluid).[140] The lesions present as large, fluctuant masses in the subcutaneous, fascial, mediastinal, and retroperitoneal spaces.[141] Lymphangiomas have also been diagnosed on the extremities, metacarpal pads, nasopharynx, axilla, inguinal and mammary region, retroperitoneal space, and skin of dogs.[139,142,143] Clinical signs are related to the size, location, and extent of the lymphangioma. They can exert pressure on surrounding structures and may interfere with muscle function, breathing (compression of the trachea), urination, or intestinal function. Lymph may ooze to the skin surface through single or multiple fistulous tracts. Differential diagnoses include other space-occupying masses such as abscesses, enlarged lymph nodes, neoplasms, and congenital cysts of nonlymphogenic origin. The prognosis can be good after appropriate surgical excision, marsupialization, or radiation therapy.[144] Risk of recurrence is high due to inherent inability to identify distinct boundaries.

Lymphangiosarcoma originates from lymphatic endothelial cells (Figure 208-22).[145] It is a rare malignant tumor in dogs and cats, although it is frequently reported secondary to chronic lymphedema in humans.[146,147] A breed or sex predisposition has not been detected, but medium to large breeds may be at highest risk, and both young and older animals are affected.[145,148] Metastasis occurs commonly in dogs and cats, although an isolated case without metastasis has been reported.[145,149] Clinical signs include pitting edema of the extremities, inguinal region, axilla, and head and neck (see Figure 208-22). In a report of 12 cats with lymphangiosarcoma, nine presented with fast-growing, noncircumscribed subcutaneous masses and the others with a thoracic or abdominal mass. In all cats affected the tumor was invasive, and complete surgical resection was not possible.[149] Associated chylous effusions (pleural, abdominal, subcutaneous) have been reported.[150–153] Pulmonary lymphangiosarcoma was diagnosed in one dog with a chylous effusion.[153] Diagnosis is confirmed by obtaining a biopsy specimen. Histologically, tumors of lymphatic endothelial origin are characterized by a neoplastic proliferation of endothelial cells. Immunocytochemical stains have been used to confirm the diagnosis in dogs. The identification of the factor VIII–related antigen and vimentin indicates the cells are of endothelial origin. The intensity and distribution of the stain has been used to attempt to differentiate lymphangiosarcomas from hemangiosarcomas but is often inaccurate. Newer specific markers to identify lymphatic endothelial cells have been identified in humans and remain to be validated in the canine patient.[153] The prognosis with lymphangiosarcoma is poor, with a high rate of local recurrence and metastasis.

209 CHAPTER • 209 Diseases of the Ear

MaryAnn G. Radlinsky

Diane E. Mason

209.1 GENERAL CONCEPTS

Many different disease processes affect otic health and should be considered when evaluating a dog or cat with possible ear disease. Signalment may implicate certain diseases over others. A complete history begins with general questions about the animal's health (e.g., appetite, sneezing, coughing, vomiting, diarrhea, water consumption) and questions pertaining to primary conditions associated with ear disease. Because the ear is a specialized extension of the integumentary system, a complete dermatologic history should be obtained (i.e., appearance of lesions at the onset of the condition; duration, progression, presence of pain or pruritus; past medical therapy and response to therapy; the presence of other dermatologic problems). A complete physical examination should be performed with special attention paid to the skin to evaluate for hypersensitivities, disorders of keratinization, endocrine disorders, and other dermatologic conditions. A complete neurologic examination may reveal abnormalities associated with the middle ear (e.g., abnormalities of cranial nerves VII and VIII, Horner's syndrome, keratoconjunctivitis sicca, head tilt). Involvement of the inner ear results in other neurologic signs (e.g., head tilt, ataxia, strabismus, abnormal nystagmus), and differentiation from central vestibular disease is extremely important.

Specific examination of the ear includes evaluation of the concave and convex pinnal surfaces, palpation of the ear canals, and otoscopic examination. The ear may need to be cleaned before a thorough examination can be completed. Sedation or anesthesia is occasionally necessary to perform a complete otic exam. This is especially true with chronic conditions of the ear. Abnormalities of the otic exam include pain on palpation of the auricular cartilages, nonpliable cartilage, ossified cartilage, epithelial hyperemia, swelling, erosion, ulceration, exudate accumulation, and hyperemia or lack of transparency of the tympanic membrane. Pain upon opening the mouth is not specific to, but can occur with, ear disease. Other diagnostic tests should include cytologic examination of otic exudate and culture and susceptibility testing based on the cytology and clinical signs of the patient. Skull radiographs, computed tomography (CT), and magnetic resonance imaging (MRI) may be indicated for evaluation of the middle and inner ear. Specific diagnostic tests are available to evaluate tympanic membrane integrity, and one should not assume that the tympanic membrane is intact prior to initiation of medical therapy, including ear cleaning, which may cause immediate exposure of the middle ear to ototoxic substances.

209.2 DISEASES OF THE PINNA

Many different disease conditions can affect the pinna—some are specific to the pinna and others represent distribution of part of a systemic condition (Table 209-1). Following are specific diseases that primarily affect the pinnae (or affect the pinnae as an early manifestation of the disease).

209.3 NONPRURITIC PINNAL ALOPECIA

209.3.1 Canine Pinnal Alopecia

Canine pinnal alopecia is most commonly diagnosed in dachshunds but also occurs in Chihuahuas, Boston terriers, whippets, Yorkshire terriers, and Italian greyhounds.[1,2] The condition usually occurs in dogs over 1 year of age and results in slowly progressive, bilateral pinnal alopecia. Small vellus hairs remain, and complete pinnal alopecia, when it occurs, may not be present until 8 to 9 years of age. The pinnae may become chronically hyperpigmented and thickened. The remainder of the haircoat is usually normal. The condition is benign and requires no specific treatment. Differentiation from other alopecic conditions is by exclusion and histopathologic examination. Miniaturized hair follicles are typically seen on histopathology. Minoxidil, pentoxifylline, melatonin, and milbolerone have anecdotally been reported to induce hair growth in some cases.[2]

209.3.2 Pattern Baldness

Symmetrical alopecia or hypotrichosis of the pinnae, ventrum, and caudal or medial thigh has been recognized in the dachshund and Staffordshire bull terrier.[3] Hair loss begins with the pinnae at 6 to 9 months of age and may progress to complete pinnal alopecia. Total body alopecia with pigmentation may occur with age. Treatment with oral melatonin may cause hair regrowth with this and other pattern baldness syndromes.[2]

209.3.3 Periodic Alopecia of Miniature Poodles and Siamese Cats

Hair loss is usually adult-onset and acute with periodic alopecia of miniature poodles and Siamese cats. Progression of the condition may result in complete, bilateral, pinnal alopecia; however, in cats the alopecia may be patchy or complete.[1,2] The skin appears grossly normal. The pathophysiology of the condition is not known, no treatment has been described, and the hair may regrow over a period of several months.

209.3.4 Congenital Hypotrichosis

A lack of pelage or loss of hair within the first month after birth has been diagnosed in the Belgian shepherd, cocker spaniel, toy poodle, miniature poodle, whippet, German shepherd, Yorkshire terrier, bichon frise, Lhasa apso, Labrador retriever, rottweiler, and basset hound. The condition is seen more commonly in males and usually involves the pinna, temporal region, caudal dorsum, and ventrum. Complete hair loss may occur by 12 to 14 weeks of age. Areas of alopecia may be well delineated from normal skin, and the condition can be diagnosed by finding a marked decrease in the density of hair follicles on skin biopsy of the affected area.[2] A similar condition exists in Birman, Burmese, Devon Rex, and Siamese cats but involves the entire coat, whiskers, claws, and tongue. No treatment exists for this condition; it is heritable, and the client should be discouraged from breeding the animal.[2]

Table • 209-1 Disease Conditions Affecting the Pinna

Nonpruritic Alopecia		
Canine		
Periodic alopecia of miniature poodles	Color dilution alopecia	Pattern baldness
Pinnal alopecia of short-coated breeds	Alopecia areata	Demodicosis
Idiopathic follicular dysplasia	Congenital alopecia	Drug eruption
Congenital hypotrichosis	Dermatophytosis	Hypothyroidism
Estrogen-responsive dermatosis	Ectodermal defects	
Feline		
Idiopathic pinnal alopecia	Dermatophytosis	Demodicosis
Iatrogenic hypothyroidism	Congenital hypotrichosis	Alopecia areata
Iatrogenic hyperadrenocorticism	Hyperthyroidism	
Crusting and Scaling Dermatoses		
Canine		
Fly strike dermatitis	Frostbite	Sarcoptic mange
Proliferative thrombovascular necrosis	Demodicosis	Harvest mites
Zinc-responsive dermatosis	Pemphigus complex	Vasculitis
Idiopathic hyperkeratosis of Boston terriers	Ear margin dermatosis	Sebaceous adenitis
Idiopathic lymphocytic/plasmacytic dermatitis	Lupoid dermatosis	Ear fissures
Idiopathic lichenoid keratosis	Superficial necrolytic dermatitis	Hypothyroidism
Lichenoid psoriaform dermatosis	Dermatomyositis	Pediculosis
Cold agglutinin disease	Systemic lupus erythematosus (SLE)	Leishmania
Feline		
Squamous cell carcinoma	Actinic dermatitis	Notoedric mange
Insect bite hypersensitivity	Frostbite	Vasculitis
Pemphigus complex		
Papular and Nodular Dermatoses		
Canine and feline		
Leoproid granuloma (canine)	Neoplasia	Bacterial pyoderma
Sterile nodular histiocytic granuloma (canine)	Deep mycoses	Leishmania
Eosinophilic folliculitis, furunculosis (canine)	Foreign body	Dermatophytosis
Eosinophilic granuloma (canine)	Tick infestation	Xanthoma (feline)
Pustular, Vesicular, and Bullous Dermatoses		
Canine and feline		
Pemphigus foliaceus	Pemphigus erythematosus	SLE
Epidermolysis bullosa	Drug eruption	Contact or irritant dermatitis
Concave Pinnal Disorders		
Canine and feline		
Atopy	Allergic contact dermatitis	Hypothyroidism
Sex hormone aberrations	Seborrhea	Juvenile cellulitis
Food sensitivity	Idiopathic erythema/edema (canine)	
Auricular Cartilage Disorders		
Canine and Feline		
Aural hematoma	Auricular chondritis	

209.4 CRUSTING AND SCALING DERMATOSES

209.4.1 Scabies and Mange

Erythematous, papular dermatitis of the distal pinnae associated with significant pruritus is an early manifestation of *Sarcoptes scabiei* in dogs. Crust and scale will usually first affect the tip of the pinna or ear

margin. The pinnal-pedal reflex (i.e., rubbing the pinna resulting in a pelvic limb scratch reflex) is often associated with sarcoptic mange but is not pathognomonic for the condition. Concurrent lesions often involve the lateral hocks and elbows and may spread to the rest of the body. The diagnosis is usually made with skin scrapings; however, multiple scrapings may be necessary to achieve the diagnosis.[3] The presence of a single mite, egg, or fecal droppings is diagnostic for the disease. All animals in the household should be treated, and the condition is zoonotic, so owners and handlers should be made aware of the condition. Initial treatment consists of removal of crusts and debris, followed by an acaracidal dip such as lime sulfur, permethrin, organophosphate, or amitraz, which may shorten time to resolution of clinical signs and diminish zoonotic potential. Ivermectin administered subcutaneously, twice at 14-day intervals, or orally three times at 7-day intervals, results in cure. A similar dose schedule exists for milbemcyin. Topical application of selamectin or fipronil may also be curative.[1,2]

1169 1170

Feline mange, caused by *Notoedres cati*, results in alopecia, pruritus, excoriations, and thick crusts of the rostral pinnae and is usually restricted to the ears and head. The extremities and perineum may also be affected due to the sleeping and grooming habits of cats. The parasite may also inhabit dogs, foxes, and rabbits; transient lesions have been reported in humans.[2] The diagnosis is made with skin scrapings, and lime sulfur or amitraz dips are effective treatments. Ivermectin given two or three times subcutaneously is also effective.[2]

209.4.2 Fly Strike Dermatitis

Insect bite dermatitis, primarily caused by the stable fly, *Stomoxys calcitrans*, results in serosanguineous, crusting dermatitis on the ear tips in dogs with erect ears or on the folded edge of the pinna in dogs with pendulous ears. Chronic fly strike dermatitis can become granulomatous in nature. Horse flies (Tabanus species) and deer flies (Chrysops species) may also plague dogs that are housed outdoors, but their bites are usually less reactive than stable flies. The diagnosis is based on an environmental history and response to limiting outdoor exposure. Fly repellents containing permethrin, citronella, or diethyltoluamide (DEET) in petroleum jelly may be used to diminish repeated fly bites. Topical corticosteroid with an antibiotic may hasten the resolution of clinical signs.[1,2] Black flies (Simulium species) may also cause papular dermatitis and alopecia in dogs.

Cats can develop a seasonal hypersensitivity to mosquito bites. Papules, erythema, alopecia, and hypopigmentation occur on the pinnae and face. Pyrexia, lymphadenopathy, and footpad lesions may also occur.

209.4.3 Actinic Dermatitis and Squamous Cell Carcinoma

Damage to the skin by long-term sun exposure occurs most often in white cats, although the condition is also reported in dogs and in cats with pigmented skin. The pinna is most often affected due to its sparse hair covering; the nose, lips, and eyelids may be similarly affected. Waxing and waning ear tip erythema may progress to the development of fine scale and alopecia early in the disease. Erosive, crusted, hemorrhagic lesions and folding of the pinna occur as a precancerous condition, which may ultimately lead to carcinomatous change.[1,2,4] Squamous cell carcinoma is most often diagnosed in older cats (mean age, 12.8 years) with either skin scrapings or biopsy.[5]

Treatment of actinic dermatitis ideally consists of limiting sun exposure between the hours of 10 AM and 4 PM by housing indoors and eliminating sunbathing behavior. Application of sunscreen of SPF 15 or greater may also decrease the effects of solar radiation. β-carotene and canthaxanthin administered orally and the use of

retinoic acids (i.e., isotretinoin, etretinate) have also been reported.[1,2] An initial response to therapy may be seen, but long-term effectiveness has not been thoroughly investigated.[6] Strontium plesiotherapy has been used in the treatment of actinic dermatitis. Failure to respond to medical management is an indication for pinnectomy.

Squamous cell carcinoma is usually locally invasive and slow to metastasize to either local lymph nodes or the lung. Pinnectomy is an effective mode of therapy for severe actinic dermatitis and squamous cell carcinoma. Cryosurgery, radiotherapy, brachytherapy, hyperthermic, and photodynamic therapy have also been used on focal lesions; systemic chemotherapy is not considered effective.

209.4.4 Frostbite

Animals affected by frostbite are usually systemically ill or have recently moved to a cold environment. The ear tips are pale, cyanotic, hypoesthetic, and cool to the touch after exposure. With warming, the tissues become hyperemic and develop scale, crust, and alopecia. The ear tips may curl, necrose, and eventually slough. Initial treatment consists of rewarming with warm water and subsequent symptomatic therapy for scaling and crusting dermatitis. Amputation of necrotic tissue results in improved cosmesis with haired skin and decreases the risk of recurrent freezing, which is more likely in previously frostbitten tissue.

209.4.5 Vasculitis

The underlying cause of vasculitis is often unknown, but the condition occurs subsequent to Type I and Type III hypersensitivity reactions and the deposition of antigen and antibody complex within the vascular wall.[2] The lesions are characterized by erythema, edema, and eventual necrosis and sloughing, leading to a “punched out” or ulcerated appearance to the pinnae. Other affected areas include the lips, tail, pads, and nails. A neutrophilic, eosinophilic, or lymphocytic vasculitis may be evident on histopathology. Proliferative thrombovascular necrosis of the pinnae is a form of vasculitis reported in dogs. Inflammatory vasculitis is not evident in this syndrome and cause is unknown. Conditions such as rickettsial disease, drug eruption, immune-mediated disease, and other underlying systemic conditions should be ruled out. Therapy should be directed at treating the underlying cause. Idiopathic vasculitis cases may respond to immunosuppressive doses of corticosteroids. Other reported treatments include pentoxyphylline, sulfasalazine, or dapsone.[1] Surgical excision of the affected portion of the pinna with wide surgical margins may be indicated if medical management is unsuccessful.[2]

209.4.6 Hyperkeratosis

Crusting and scaling of the pinnae may be caused by idiopathic defects in keratinization, primary disease conditions causing seborrhea, and secondary changes in keratinization due to parasitism. Ear margin dermatosis is common in dachshunds and other breeds with pendulous ears. Seborrheic changes begin at the ear margin and progress to confluence of scale and significant alopecia. Pruritus is variable but may be present in severe cases. The condition is not curable but controllable with keratolytic keratoplastic shampoos (e.g., sulfur-asalicylic acid, benzoyl peroxide or benzoyl peroxide-sulfur, selenium sulfide).[2] Severe cases may require topical or systemic corticosteroid treatment due to inflammation associated with removal of crusts or ear fissure formation.

Sebaceous adenitis is associated with an inflammatory process of the sebaceous glands. Follicular disruption, alopecia, and surface scale initially affect the pinna and may involve the ear canal and trunk.[7] No direct therapy exists for lost sebaceous glands, and supportive care with fatty acids, humectants, and anti-inflammatory corticosteroids can be useful. Retinoids have been used in cases with a granulomatous response to the process.[2]

Other less common disorders can cause hyperkeratosis of the pinna. Idiopathic benign lichenoid keratosis has been diagnosed in four dogs with multiple wartlike papules and hyperkeratotic plaques on the pinnae.[3] Lichenoid psoriaform dermatosis is a rare condition in which erythematous papules and lichenoid plaques appear on the concave surface of the pinna, external ear canal, and ventral head and trunk. Treatment consists of antimicrobial shampoo, systemic antibiotics, and corticosteroids.[2] Lupoid dermatosis is a heritable condition of German shorthaired pointers in which progressive, nonpruritic scale occurs on the pinnae, face, and trunk. No therapy is available for the condition.

1170

1171

209.4.7 Nutritional Dermatoses

Zinc deficiency caused by dietary insufficiency or inability to absorb dietary zinc results in crusting lesions of the pinna, and perioral, periorbital, perianal, and perivulvar sites of dogs. Food allergy can result in steroid-resistant alopecia, crust, scale, hyperpigmentation, and lichenification of the pinnae. Dietary restriction followed by feeding trials is diagnostic of the condition, which may be associated with lesions and pruritus on other parts of the body.

209.5 DERMATOSES CAUSING PAPULES AND NODULES

209.5.1 Tick Infestation

The following ticks may cause local irritation and secondary granuloma formation of the pinna in dogs: American dog tick (*Dermacentor variabilis*), lone star tick (*Amblyomma americanum*), brown dog tick (*Rhipicephalus sanguineus*), and Ixodes species.[3] Of these ticks, Ixodes spp. is least likely to be identified on the pinna or head. Treatment should be aimed at insect removal and prevention of reinfestation.

209.5.2 Neoplastic Lesions

Auricular tumors are more common and more often malignant in cats than dogs. Commonly diagnosed canine pinnal tumors include squamous cell carcinoma, cutaneous histiocytoma, mast cell tumor, sebaceous adenoma, and papilloma. Squamous cell carcinoma, mast cell tumor, basal cell tumor, and fibrosarcoma are commonly diagnosed in cats.

209.5.3 Granulomatous Lesions

Pinnal granulomas may be associated with bacterial infection (Staphylococcus species, *Nocardia*, *Actinomyces*, mycobacteria, atypical mycobacteria), dermatophytosis, deep mycoses, algae, *Leishmania*, and foreign bodies. Canine leproid granuloma occurs in short haired dogs primarily in cool, moist environments. Two millimeter to 5 cm nodules have been described with superficial alopecia and ulceration occurring on the

dorsal pinna and head. Although acid-fast bacilli have been identified on histopathologic examination, cultures are usually negative. Lesions usually resolve spontaneously or respond to surgical excision.[8]

209.6 DERMATOSES CAUSING PUSTULES, VESICLES, AND BULLAE

Autoimmune disorders commonly affect the concave aspect of the pinnae. Lesions are usually symmetrical; vesicles, erosions, and blisters may appear on the pinna prior to the occurrence of generalized disease. Pemphigus complex, systemic lupus erythematosus (SLE), bullous pemphigoid, and epidermolysis bullosa[9] have been associated with pinnal lesions. The diagnosis may be made with cytology and skin biopsy. Differential diagnoses include bacterial infection, drug eruption, and contact hypersensitivity.[2]

209.7 CONCAVE PINNAL DERMATOSES

209.7.1 Atopy

Erythema and hyperplasia of the pinna and upper external ear canal are early signs of atopy. Hyperpigmentation, lichenification, and erythematous ceruminous otitis may result if the condition is allowed to progress.

209.7.2 Allergic Contact Dermatitis

Allergic contact dermatitis is a rare condition described in middle-aged animals due to the long period of induction required for development of delayed hypersensitivity to the offending substance. The condition is often diagnosed secondary to topical medication used to treat otitis externa and may result in pinnal alopecia.

209.7.3 Defects in Keratinization

Systemic conditions such as hypothyroidism, sex hormone aberrations, and seborrhea may affect the concave surface of the pinna. Grease accumulation and hyperkeratotic dermatosis may result.

209.7.4 Juvenile Cellulitis

Juvenile sterile granulomatous dermatitis and lymphadenitis is a rarely diagnosed condition; predisposed breeds include the golden retriever, dachshund, Labrador retriever, and Lhasa apso. Dogs are usually less than 6 months of age when they develop significant mandibular and prescapular lymphadenopathy and edema, exudate, papules, and pustules of the pinna, muzzle, and periocular skin.[1] The diagnosis is based on clinical presentation, culture and susceptibility testing, and skin biopsy. Treatment consists of immunosuppression with corticosteroids, which are tapered over 3 to 4 weeks after remission of clinical signs. Systemic antimicrobial therapy is indicated for the treatment of secondary bacterial pyoderma.

209.8 AURICULAR CARTILAGE DISORDERS

209.8.1 Aural Hematoma

Aural hematomas occur in both dogs and cats secondary to the self-induced trauma of head shaking or scratching. Blood accumulates within the fractured cartilage of the pinna, although swelling is most visible on the concave aspect. Any animal diagnosed with an aural hematoma should undergo a complete evaluation and treatment for otitis externa, because continued head shaking will predispose the animal to enlargement or recurrence of the hematoma. Small hematomas may resolve without therapy; however, second-intention healing may cause deformation of the pinna with a poor cosmetic result. Treatment of the hematoma may consist of corticosteroid injection, evacuation and bandaging, teat cannula drainage, Penrose drain placement, or closed suction drainage.[10] Surgical incision, drainage, curettage, and closure with mattress sutures is preferred because it provides apposition of the cartilage edges and cosmetic results. Sutures remain in place for 21 days to allow adequate cartilage healing. Treatment of the concurrent otitis externa and its underlying cause are vital to the prevention of recurrence.

209.8.2 Auricular Chondritis

Auricular chondritis (*relapsing polychondritis* in cats) is an inflammation and destruction of auricular cartilage usually classified as an immune-mediated disorder. The pinnae are bilaterally swollen and deformed in most cases, although unilateral involvement is possible. Diagnosis is based on biopsy findings of lymphoplasmacytic inflammation with cartilage necrosis, and treatment may be minimal if no significant systemic signs exist. Attempted treatment with immunosuppressive doses of corticosteroids was not successful in cats; dapsone therapy may induce remission.[2]

209.9 DISEASES OF THE EXTERNAL EAR CANAL: OTITIS EXTERNA

209.9.1 Normal Anatomy and Physiology

1171

The external ear canal collects and delivers sound to the tympanic membrane. The ear canal is composed of auricular and annular cartilages that roughly approximate with the vertical and horizontal portions of the canal. The normal dog has a 45-degree angle of the horizontal canal; the angle is approximately 90 degrees in cats. Stratified squamous epithelium with sebaceous glands, ceruminous or apocrine glands, and hair follicles line the canal. Sebaceous glands located in the superficial dermis secrete neutral lipids that assist in maintenance of keratinization, in capturing and removing debris, and in decreasing the humidity of the ear canal. Acid mucopolysaccharides and phospholipids are the main secretions of ceruminous glands located deeper in the dermis. The glandular secretions help to maintain proper humidity and pH in the ear canal, and a normal flora of bacteria and yeast have been identified in the external ear canal of normal dogs and cats.[11] Removal of debris from the deeper portion of the ear canal is achieved in many ways. The ratio of apocrine to sebaceous glands decreases from proximal to distal in the ear canal, resulting in more aqueous cerumen deeper in the canal, and the number of glands and hair follicles also decrease deep in the ear canal. The tympanic membrane is composed of three layers, with epithelial cells migrating away from the center of the tympanum, which aids in the removal of debris and secretions from its surface.

1172

209.9.2 Diagnostic Principles

209.9.2.1 Physical Examination

Complete examination of the pet with otitis includes general physical, dermatologic, otoscopic, and neurologic examinations. An otoscopic examination should be performed slowly and deliberately with dorsal and lateral traction on the pinna, keeping the otoscope centrally located in the canal to avoid placing pressure on the epithelium. Hyperemia, erosions, ulcers, exudate, foreign bodies, stenosis, and masses should be noted. The tympanum should be thin, pale, gray, and translucent, with a visible manubrium of the malleus. The tympanum is usually seen in 75% of dogs with normal ears and in 28% of dogs with otitis.[3] Otoscopy is not sensitive for rupture of the tympanic membrane but can be diagnostic of obvious ruptures.

209.9.2.2 Cytologic Examination

Cytologic examination of exudate within the ear canal is a mandatory part of assessing pets with otitis. Cytology should be done at initial examination and at each re-evaluation, because gross appearance of exudate does not correlate with microscopic character. Material should be collected prior to cleaning the ear canal; specimens collected from the horizontal canal through the otoscope cone may be more representative of the disease process.[3] Mineral oil cytology is the technique most often recommended for identification of parasites. A cerumen sample is mixed with mineral oil on a glass slide prior to microscopic examination. Heat-fixed otic exudate should also be stained with modified Wright's stain (Diff Quik American Scientific McGraw, IL) and Gram stain for evaluation of bacterial pathogens and yeast under oil immersion microscopy (×100). The morphologic type of bacteria, gram-staining characteristics, and presence or absence of inflammatory cells, cerumen, and debris should be noted.

Many clinicians use a scale of 1+ to 4+ in describing numbers of yeast, bacteria, and inflammatory cells to allow evaluation of the progression of the disease process. However, low numbers of bacteria and yeast per high-powered field (hpf) (×40 dry) may be identified in normal ears.[12] Dogs and cats should have two yeast and five bacteria or less per hpf.[12] Yeast numbers 5/hpf or greater in dogs and 12/hpf or greater in cats are abnormal. Bacteria 25/hpf or greater in dogs and 15/hpf in cats are associated with otitis.[12] Persistence of the same pathogens on re-evaluation suggests lack of efficacy or inappropriate therapy, incorrect identification of the primary disease process, or lack of owner compliance with therapy. Any change in the cytologic appearance may suggest reaction to medication or a change in either the type of inflammatory process or secondary pathogens.

209.9.2.3 Culture and Susceptibility Testing

Cultures need not be done if external ear canal cytology is negative for bacteria; it is unlikely that either yeast or bacteria would be present on cultures or would contribute to the disease process in those cases. Culture with susceptibility testing should be considered whenever resistant bacteria may be present or when prolonged or systemic therapy are indicated (e.g., gram-negative bacteria and inflammatory cells identified on cytology, chronic bacterial otitis, suspected otitis media, failure to respond to appropriate medical therapy).[13,14] Cultures should be collected from the tympanic bulla in all suspected cases of otitis media, because horizontal ear canal samples do not correlate with those from the middle ear in over 89% of cases, and cytologic examination of the middle ear may be negative despite the presence of otitis.[15] Because

bacteria may not cross the tympanic membrane, cultures from both sites should provide the highest yield of pathogenic bacteria. Yeast cultures are not routinely performed, because cytology is more sensitive than culture for yeast organisms, which may require specific lipid supplementation of the growth media for some species.[16,17]

209.9.2.4 Radiology, Computed Tomography, and Magnetic Resonance Imaging

Diagnostic imaging may be used to evaluate the patency of the external ear canal and may be necessary to evaluate the integrity of the tympanic bulla. Underlying otitis media should be identified because it perpetuates otitis externa and requires specific therapy separate from that for otitis externa. Evaluating the tympanic membrane to diagnose otitis media, however, can be difficult in cases with significant secondary changes in the external ear canal. Treating otitis externa may decrease secondary changes and allow tympanic visualization at a later date, or imaging may be pursued. Radiographs are not as sensitive as CT or MRI for detecting abnormalities of the tympanic bulla.[18–20] If obstructive external ear disease does not respond to therapy or if the ear canals are palpably fibrotic or ossified, total ear canal excision and bulla osteotomy are required. Imaging of the middle ear is not necessary in those cases, because the middle ear can be evaluated at surgery via bulla osteotomy. Radiographic changes or changes on CT or MRI are valuable in patients with otic neoplasia. Significant changes of the tympanic bulla suggest that complete surgical excision may not be possible. Advanced imaging is also valuable in cases of otitis interna and central vestibular disease.

209.10 PATHOPHYSIOLOGY

Otitis externa describes any inflammatory condition of the external ear canal. The estimated incidence of otitis in dogs and cats ranges from 4% to 20% and 2% to 6.6%, respectively.[1,13] Clinical signs associated with the condition vary, depending on the cause of the otitis. General signs consist of head shaking, scratching, otic pain, and a variable accumulation of cerumen or exudate. The external canal responds to chronic inflammation of the dermis and epidermis with epithelial hyperplasia and hyperkeratosis, sebaceous gland hyperplasia, and ceruminous gland hyperplasia and dilation. These changes are associated with increased cerumen production; however, increased humidity, increased pH, and decreased lipid content of the cerumen predispose the animal to secondary infection. Apocrine gland rupture, sebaceous gland degeneration, ear canal stenosis, and fibrosis or ossification of the canal (or both) usually occur with the end stages of otitis.[21] Because permanent changes of the ear canal can occur with any cause of otitis externa, primary, predisposing, and perpetuating factors should be investigated in all cases of otitis.

1172

1173

209.10.1 Primary Factors

Primary factors are capable of causing otitis in normal ears. Primary factors may not be cured but often are controlled with appropriate therapy.

209.10.2 Hypersensitivities

209.10.2.1 Atopy and food hypersensitivity

Otitis externa is a clinical sign in 50% to 80% of atopic or food-sensitive dogs and may be the sole clinical sign associated with atopy.[22,23] Erythematous ceruminous otitis is most commonly associated with allergic

skin disease.[24] Early clinical signs of bilateral pruritus, concave pinnal erythema, and mild erythematous and ceruminous otitis of the proximal ear canal may progress to significant otitis externa and pinnal hyperpigmentation. The pet can develop end-stage otitis if the primary cause is not identified and treated. Aural pruritus is common to atopy and food hypersensitivity; however, steroid responsiveness is usually only seen with atopy. Atopic dogs also tend to have a slower progression of disease than food-sensitive dogs. Secondary infection with either *Malassezia pachydermatis* or bacterial cocci is common. A definitive diagnosis is based on biopsy, intradermal skin testing, serologic testing, or dietary restriction and subsequent diet trials.

209.10.2.2 Contact hypersensitivity and irritant reaction

Topical otic preparations may cause a delayed hypersensitivity or irritant reaction to the ear canal. A response to initial therapy is followed by progression of disease or change in the character of the otitis with continued therapy. Worsening of clinical signs can occur if the medication is discontinued then readministered. Neomycin, propylene glycol, and dimethyl sulfoxide have been associated with irritant otitis. Reactions are occasionally noted with alcohol, glycerin, povidone-iodine, and concentrations of acetic acid greater than 2%.[3] Contact hypersensitivity or an irritant reaction should be suspected any time otitis externa is exacerbated by therapy or upon changes in the gross or cytologic appearance of the otitis. Both contact hypersensitivity and irritant reaction act as perpetuating factors of otitis externa despite control of the primary factor.

209.10.3 Ectoparasites

Otodectes cynotis is the cause of otitis externa (otocariasis) in up to 50% of cats and 10% of dogs with otitis externa.[3] The infestation in cats may be classified as one of the following: (1) otitis externa, (2) ectopic infestation, or (3) asymptomatic carrier. Signs of otitis include significant pruritus, pinnal erythema and crusting, and accumulation of cerumen in the external ear canal. Gross character of the cerumen is not correlated to the microscopic findings, but is usually dark brown to black in color. Mites may be observed on otoscopic examination; however, mineral oil cytology is recommended, because few mites are required to cause clinical signs. Mites may concurrently inhabit the skin of the head and neck in animals with otitis. True ectoparasite infestation usually results in miliary dermatitis and patchy alopecia in cats. Treatment can include any of the following: carbamates, pyrethrins, rotenone, ivermectin, thiabendazole, or fipronyl.[25] Selamectin has recently been proven safe and effective for treating otocariasis in both dogs and cats.[26,27] The 3-week cycle of the parasite should be considered in treatment planning.

Demodex canis has been associated with mild otitis and excessive cerumen production in dogs with the generalized form of demodicosis. The diagnosis is made with mineral oil cytology; other diagnostics (e.g., biopsy) are less often required. Other parasites such as harvest mites (*Neotrombicula autumnalis and Euotrombicula alfredugesi*) and ticks (*Otobius megnini*) may cause otitis externa. Reinfestation is a common problem due to environmental exposure to these parasites.

209.10.4 Foreign Bodies

Younger dogs, especially hunting or working breeds, are predisposed to otic foreign bodies. The most common foreign body associated with otitis is the grass awn; however, other foreign bodies include dirt, sand, cerumen, exudate mixed with hair, and conglomerates of dried ear medication. All can incite inflammation.

Dogs are usually acutely painful, bilateral foreign bodies are possible, and approximately 20% of otic foreign bodies penetrate the tympanic membrane, leading to otitis media.[3]

209.10.5 Keratinization Defects

Hypothyroidism, male feminizing syndrome, Sertoli cell tumor, hyperestrogenism, and idiopathic seborrhea may be associated with mild otitis externa. Idiopathic seborrhea in cocker spaniels and hereditary defects in cats leading to seborrhea may cause erythematous ceruminous otitis. Changes in the microenvironment of the ear canal lead to secondary purulent otitis.

209.10.6 Idiopathic Inflammatory or Hyperplastic Otitis

Cocker spaniels may be affected by severe, proliferative otitis externa at a young age. Concurrent dermatologic conditions are not necessarily present but should be ruled out for proper management. The cause of the condition is unknown but may be due to a primary glandular disorder.[2]

209.10.7 Other Primary Factors

Immune-mediated disorders such as pemphigus complex may be associated with both pinnal lesions and otitis externa. Pemphigus foliaceus may involve only the ears in some cases, but lesions on other parts of the body are usually present. Drug eruption from systemically administered drugs may also cause both pinnal lesions and otitis externa. Older animals with chronic or recurrent otitis should be evaluated for benign or malignant neoplasia of the skin or adenexal structures of the ear.

209.10.7.1 Predisposing Factors

Predisposing factors make otitis more likely by altering the environment of the external ear canal, thereby making the ear more susceptible to inflammation and secondary infection.

209.10.8 Anatomic Changes

Increased soft tissue within the ear canal, increased compound hair follicles in the canal, and stenotic canals (e.g., Shar Pei, bulldog, chow chow) or chronic changes associated with previous bouts of otitis may be predisposing factors for otitis externa. Dogs with pendulous ears are predisposed to otitis, and otitis is common in breeds of dogs exhibiting increased ceruminous compared with sebaceous gland area (e.g., cocker spaniel, Labrador retriever, springer spaniel).[28] Hair is normally present in the ear canal, and increased numbers of hairs or presence of compound hair follicles have not been correlated to the incidence of otitis in dogs. Routine hair plucking is therefore not recommended and may incite an inflammatory response within the epithelium, perpetuating otitis externa.

209.10.9 External Environment

Increases in temperature and humidity in the environment may be reflected in the ear canal. The incidence of otitis externa is seasonally related to temperature, humidity, and rainfall. A lag period of 1 to 2 months is associated with cases of canine otitis and may vary with geographic location. Positive cultures of the ear canal are more likely during times of increased environmental temperature and humidity.[3]

209.10.9.1 Perpetuating Factors

Perpetuating factors exacerbate the inflammatory process and can maintain the disease after the primary factor has been eliminated. They can induce permanent pathologic changes to the ear canal and are the main reason for treatment failure in otitis externa.

209.10.10 Secondary Bacterial Colonization and Infection

Normal bacterial flora exist in the ear canal of dogs and cats. Staphylococcus species and Streptococcus species are often cultured, *Pseudomonas* is rarely cultured, and *Proteus* was not cultured from the normal canine ear canal.[13] *Malassezia* has also been identified on cytologic examination in normal dogs and cats, and its numbers are significantly increased in erythematous ceruminous otitis.[13] Bacteria and yeast are opportunistic pathogens but can cause significant secondary changes of the ear canal with chronic infection. Increased numbers of bacteria without an inflammatory response may represent colonization, which often responds to topical therapy. The presence of inflammatory cells suggests true infection, and culture and susceptibility is recommended due to resistance patterns of many bacteria. In colonization and infection, cleaning the external ear canal removes exudate, debris, toxins, free fatty acids, and bacteria that perpetuate inflammation and secondary changes of the ear canal.[29]

Staphylococcus species are common in dogs with otitis as are *Pseudomonas aeruginosa*, Proteus species, *Escherichia coli*, Corynebacterium species, and Streptococcus species.[15,30] Acute purulent otitis externa is less common than chronic, but with chronicity and repeated treatment, gram-negative bacteria, such as *Pseudomonas* and *Proteus*, predominate. The associated otitis may have surface erosions or ulcers and copious exudate. Cats may be secondarily infected with *Pasteurella multocida* and less often *Pseudomonas aeruginosa*, Proteus species, or *E. coli*.[1]

209.10.10.1 Malassezia Pachydermatis

Budding yeast has been identified on ear cytology of normal dogs (up to 50%) and cats (up to 17.6%).[17] *Malassezia* are considered part of the normal flora and an opportunist in cases of otitis externa, particularly in cases of erythematous ceruminous otitis. *Malassezia* are lipid-dependent yeast that overgrow in conditions of increased moisture, increased surface lipids, and compromised barrier function of the stratum corneum.[31,32] Enzymes produced by the yeast may allow depolymerization of the interstitial matrix (e.g., hyaluronidase, chondroitin-sulphatase) and cell membranes (e.g., proteinase, phospholipase), increasing tissue invasion and penetration.[32] Cytologic examination is more valuable than culture, because some species of *Malassezia* require specific media supplemented with long-chain fatty acids.[17,31]

209.10.11 Chronic Anatomic Changes

Increased soft tissue volume within the ear canal associated with chronic otic inflammation leads to ear canal stenosis and alters the otic microenvironment. Chronic changes of the epidermis, adenexa, dermis, and cartilage are described in the previous pathophysiology section. The microenvironmental alterations associated with chronic ear canal stenosis and inflammation favor bacterial and yeast proliferation and the retention of

exudate. The changes also hinder proper cleaning and medication of the deeper portions of the external ear canal.

209.10.12 Otitis Media

Untreated infection of the middle ear serves as a source for perpetuating otitis externa. Failure to identify the bacteria, yeast, or byproducts of inflammation in the middle ear may result in recurrent otitis externa and chronic pathologic changes of the middle and external ear.

209.10.13 Treatment Errors, Undertreatment, and Overtreatment

Incorrect treatment of otitis allows bacterial or yeast overgrowth or infection and denies treatment of the primary factor causing otitis. Overapplication of medication or use of occlusive medications increases the humidity of the ear canal, leading to epithelial maceration and inflammation, perpetuating otitis; accumulation of dried medication acts as a foreign body within the ear canal. Undertreatment allows progression of the disease and the development of resistance in the bacteria causing secondary infection.

209.11 GENERAL PRINCIPLES OF MANAGEMENT

The therapeutic plan for otitis externa requires identification of the primary disease process and perpetuating factors. Ideally management is aimed at thoroughly cleaning and drying the ear canal, removing or managing the primary factors, controlling perpetuating factors, administering appropriate topical or systemic therapy (or both), and evaluating response to therapy.

209.11.1 Ear Cleaning

Ear cleaning serves several functions: (1) it removes material that supports or perpetuates infection; (2) it removes bacterial toxins, white blood cells (WBCs), and free fatty acids that stimulate inflammation; (3) it allows complete evaluation of the external ear canal and tympanum; (4) it allows topical therapy to contact all portions of the ear canal; and (5) it removes material that may inactivate topical medications.[3,13] Significantly painful ears may benefit from initial anti-inflammatory therapy to decrease pain and swelling of the ear canal prior to cleaning. Severe cases of otitis externa often require general anesthesia to facilitate complete cleaning and evaluation of the external and middle ear.

Many different solutions are available for removing cerumen, exudate, and debris from the ear canal (Table 209-2). If the tympanic membrane cannot be visualized, only physiologic saline solution or water should be used, because many topical cleaning agents are ototoxic or incite inflammation of the middle ear. An operating otoscope, ear loops, and alligator forceps facilitate manual removal of large amounts of cerumen or debris. Debris is carefully removed under direct visualization, and care is taken deeper in the ear canal (close to the tympanic membrane). Aggressive hair removal is not advised, because inflammation and damage to the epithelium can result in secondary bacterial colonization and infection. Flushing may be performed after large accumulations of cerumen and debris are mechanically removed from the ear canal.

Flushing and evacuation of solution is done under direct visualization through an operating otoscope. A bulb syringe and red rubber catheter system may be used to both flush and evacuate solutions and accumulations from the ear canal. The operator, avoiding drastic pressure changes within the external ear canal that could damage the tympanum, should carefully control suction and manual evacuation of the contents of the bulb

syringe from the ear canal. Other alternatives include tomcat catheters (3.5 F) or flexible, intravenous catheters (14 gauge, Teflon); stiff, narrow catheters should be used cautiously and under direct visualization deep in the external ear canal. Other reservoir systems for delivery or evacuation of solutions include a 12 mL syringe or suction tubing attached to in-house vacuum systems. In-house vacuum systems should be used cautiously and under direct visualization. Care should be taken to avoid trauma to the tympanic membrane until its integrity can be assessed. Initial flushes should be done with physiologic saline solution or water until the integrity of the tympanic membrane is established.

1175

Table • 209-2 Otic Cleaning Solutions

TRADE NAME	ACETIC ACID	BORIC ACID	SALICYLIC ACID	ISOPROPYL ALCOHOL	PROPYLENE GLYCOL	DSS	OTHER
Ace-Otic Cleanser	2%		0.1%				Lactic acid 2.7%
Adams Pan-Otic					X	X	Parachlorometaxylenol, tris EDTA, methylparaben, diazolidinyl urea, popylparaben, octoxynol
Alocetic Ear Rinse	X			X			Nonoxynol-12, methylparaben, alovera gel
Cerulytic Ear Ceruminolytic					X		Benzyl alcohol, butylated hydroxytoluene
Cerumene	X	X					25% Isopropyl myristate
DermaPet Ear/Skin Cleanser for Pets							
Docusate Solution					X	X	
Earmed Boracetic Flush	X	X					Aloe
Earmed Cleansing Solution & Wash					X		50A 40B alcohol, cocamidopropyl phosphatidyl and PE dimonium chloride
Earoxide Ear Cleanser							Carbamide peroxide 6.5%
Epi-Otic Ear Cleanser			X		X	X	Lactic acid, chitosanide
Fresh-Ear	X	X	X	X	X		Lidocaine hydrochloride, glycerin, sodium docusate, lanolin oil
OtiCalm			X				Benzoic acid, malic acid, oil of eucalyptus
Otic Clear	X	X	X	X	X		Glycerin, lidocaine hydrochloride
Oticlean-A Ear Cleaning Lotion	X	X	X	35%	X		Lanolin oil, glycerin
Oti-Clens			X		X		Malic acid, benzoic acid
Otipan Cleansing Solution					X		Hydroxypropyl cellulose, octoxynol
Otocetic Solution	2%	2%					
Wax-O-Sol 25%							Hexamethyltetracosane

Other solutions may aid in the removal of wax in the ear canal. Ceruminolytics are emulsifiers and surfactants that break down ceruminocellular aggregates by causing lysis of squamous cells. A ceruminolytic agent in an alkaline pH may more effectively lyse squamous cells via cell surface protein disruption.[3] Oil-based products soften and loosen debris to aid in their removal but do not cause cell lysis. Water-based ceruminolytics are easier to remove and dry more quickly than oil-based solutions, which are occlusive if they remain in the ear canal. Water-based products include dioctyl sodium sulfosuccinate, calcium sulfosuccinate, and carbamate

peroxide, which has a foaming action with the release of urea and oxygen. Oil-based products include squalene, triethanolamine polypeptide, hexamethyltetracosane, oleate condensate, propylene glycol, glycerin, and mineral oil. In a recent study only the combination of squalene and isopropyl myristate in a liquid petrolatum base had no adverse effects on hearing, the vestibular system, and histopathologic examination.[33] Other agents tested contained glycerin, dioctyl sodium sulfosuccinate (2% or 6.5%), parachlorometaxylenol, carbamide peroxide (6%), propylene glycol, triethanolamine polypeptide oleate condensate (10%), and chlorobutanol (0.5%).[33]

Alcohol-based drying agents added to ceruminolytics include boric acid, benzoic acid, and salicylic acid, which decrease the pH of the ear canal, cause keratolysis, and have a mild anti-microbial effect. Drying the ear canal is important to combat increased humidity, which potentiates infection.

If the tympanum is intact, the ear canal is filled with a ceruminolytic agent for at least 2 minutes and the pinna is cleaned at the same time. The solution is flushed twice with warm water, and the canal inspected. The procedure is repeated until cleaning is complete. Other solutions commonly advocated for ear flushing include dilute chlorhexidine solution (0.05%), dilute povidone-iodine, and acetic acid (2.5%). The first two agents are potentially ototoxic or induce inflammation and should not be used if the tympanum is ruptured. A combination of propylene glycol malic, benzoic, or salicylic acid; 2% acetic acid; or dilute povidone-iodine have been suggested for use in dogs with a ruptured tympanum.[3]

Owners may clean the ears at home with mild preparations of ceruminolytics and drying agents if mild otitis is present without severe accumulation of cerumen or exudate. Aqueous solutions are usually recommended because they are less occlusive and easier to clean from the ear, dog, and home environment.

1175

1176

The ear should be filled with the solution, then massaged for 40 to 60 seconds. The pet should be allowed to shake its head to remove the majority of the solution, and the excess should be wiped from the ear canal and pinna with a tissue. Daily flushing is usually recommended, followed by every other day, weekly, then as needed, depending on the solution. Ear swabs are not recommended for home use, because cerumen and debris may be forced into the horizontal ear canal and impact against the tympanic membrane.

209.11.2 Topical Therapy

Erythematous ceruminous otitis externa is diagnosed 2.7 times more often than acute suppurative otitis according to one report.[24] Yeast ± cocci were identified in those cases, with cocci or rods identified in suppurative otitis.[24] Topical therapy should be based on the cytologic examination to diminish the incidence of inappropriate treatment (Table 209-3). Many preparations combine anti-inflammatories and antimicrobials in an attempt to decrease the inflammation and combat bacterial or yeast overgrowth. All topical medications should be considered supportive, and specific treatment should be aimed at controlling the primary disease process.

Table • 209-3 Topical Medications Used in the Treatment of Ear Disease

GENERIC NAME	TRADE NAME	DOSE	FREQUENCY	DESCRIPTION
Fluocinolone 0.01% DMSO 60%	Synotic	4–6 drops; total dose <17 mL	q12h initially, q48-72h maintenance	Potent corticosteroid anti-inflammatory
Hydrocortisone 1.0%	HB101, Burrows H,	2–12 drops, depending on ear size	q12h initially, q24-48h maintenance	Mild corticosteroid anti-inflammatory
Hydrocortisone 1.0%, lactic acid	Epi-otic HC	5–10 drops	q12h for 5 days	Mild corticosteroid anti-inflammatory, drying agent
Hydrocortisone 0.5%, sulfur 2%, acetic acid 2.5%	Clear X Ear Treatment	2–12 drops, depending on ear size	q12-24h initially, q24-48h maintenance	Mild corticosteroid anti-inflammatory, astringent, germicidal
DSS 6.5%, urea (carbamide peroxide 6%)	Clear X Ear Cleansing Solution	1–2 mL per ear	Once per week to as necessary	Ceruminolytic, lubricating agent
Chlorhexidine 2%	Nolvasan	Dilute 1:40 in water	As necessary	Antibacterial & antifungal activity
Chlorhexidine 1.5%	Nolvasan	Dilute 2% in propylene glycol	q12h	Antibacterial & antifungal activity
Povidone-iodine 10%	Betadine solution	Dilute 1:10–1:50 in water	As necessary	Antibacterial activity
Polyhydroxidine iodine 0.5%	Xenodyne	Dilute 1:1–1:5 in water	As necessary, q12h, once weekly	Antibacterial activity
Acetic acid 5%	White vinegar	Dilute 1:1–1:3 in water	As necessary; q12-24h for *Pseudomonas*	Antibacterial activity, lowers ear canal pH
Neomycin 0.25%, triamcinolone 0.1%, thiabendazole 4%	Tresaderm	2–12 drops depending on ear size	q12h up to 7 days	Antibacterial & antifungal activity, parasiticide (mites), moderate corticosteroid anti-inflammatory
Neomycin 0.25%, triamcinolone 0.1%, nystatin 100,000 U/mL	Panalog	2–12 drops depending on ear size	q12h to once weekly	Antibacterial & antifungal activity, moderate corticosteroid anti-inflammatory
Chloramphenicol 0.42%, prednisone 0.17%, tetracaine 2%, squalene	Liquachlor, Chlora-Otic	2–12 drops depending on ear size	q12h up to 7 days	Antibacterial activity, mild corticosteroid anti-inflammatory
Neomycin 1.75 & polymyxin B 5000 IU/mL, penicillin G procaine 10,000 IU/mL	Forte Topical	2–12 drops depending on ear size	q12h	Antibacterial activity
Gentamicin 0.3%, betamethasone valerate 0.1%	Gentocin Otic Solution, Betagen Otic Solution	2–12 drops depending on ear size	q12h for 7 to 14 days	Antibacterial activity, potent corticosteroid anti-inflammatory
Gentamicin 0.3%, betamethasone 0.1%, clotrimazole 0.1%	Otomax, Obibiotic Ointment	2–12 drops depending on ear size	q12h for 7 days	Antibacterial & antifungal activity, potent corticosteroid anti-inflammatory
Gentamicin 0.3%, betamethasone valerate 0.1%, acetic acid 2.5%	Gentaved Otic Solution	2–12 drops, depending on ear size	q12h for 7 to 14 days	Antibacterial activity, potent corticosteroid anti-inflammatory

Polymixin B 10,000 IU/mL, hydrocortisone 0.5%	Otobiotic	2–12 drops, depending on ear size	q12h	Antibacterial activity, mild corticosteroid anti-inflammatory
Enrofloxacin 0.5%, silver sulfadiazine 1%	Baytril Otic	2–12 drops, depending on ear size	q12h for up to 14 days	Antibacterial activity
Carbaryl 0.5%, neomycin 0.5%, tetracaine	Mitox Liquid	2–12 drops, depending on ear size		Antibacterial activity, parasiticide (mites)
Pyrethrins 0.06%, piperonyl butoxide 0.6%	Ear Mite and Tick Control	5 drops	q12h	Parasiticide (mites)
Pyrethrins 0.05%, squalene 25%	Cerumite	2–12 drops, depending on ear size	q24h for 7 to 10 days	Parasiticide (mites), ceruminolytic
Isopropyl alcohol 90%, boric acid 2%	Panodry	Fill ear canal	As necessary	Drying agent
Acetic acid 2%, aluminum acetate	Otic Domeboro	Fill ear canal	q12-48h	Drying agent, antibacterial activity, lowers ear canal pH
Silver sulfadiazine	Silvadene	Dilute 1:1 with water, 1 g powder in 100 mL water	q12h for 14 days	Antibacterial & antifungal activity
Tris EDTA ±gentamicin 0.03%		2–12 drops, depending on ear size	q12h for 14 days	1 L distilled water, 1.2g Tris EDTA, 1 mL glacial acetic acid; antibacterial activity
Silver nitrate		Use sparingly	As necessary	Cauterization of ulcerative otitis externa
Miconazole 1%; ± topical glucocorticoid (7.5 mL of dexamethasone phosphate [4 mg/mL] to 10 mL of 1% miconazole)	Conofite	2–12 drops, depending on ear size	q12-24h	Antifungal activity
Ivermectin 0.01%	Acarexx	0.5 mL per ear	Once	Parasiticide (mites)
Pyrethrins 0.15%, piperonyl butoxide 1.5%	Many	2–12 drops, depending on ear size	Twice at 7-day interval	Parasiticide (mites)
Pyrethrins 0.05%, piperonyl butoxide 0.5%, squalene 25%	Cerumite	2–12 drops, depending on ear size	q24h for 7 days	Parasiticide (mites), ceruminolytic
Pyrethrins 0.04%, piperonyl butoxide 0.49%, DSS 1.952%, benzocaine 1.952%	Aurimite	10 drops	q12h	
Rotenone 0.12%, cube resins 0.16%	Many	2–12 drops, depending on ear size	Every other day	Parasiticide (mites)

Topical glucocorticoids benefit most cases of otitis externa by decreasing pruritus, exudation, swelling, and proliferative changes of the ear canal. The most potent glucocorticoids available in topical preparations are betamethasone valerate and fluocinolone acetonide. Less potent corticosteroids include triamcinolone acetonide and dexamethasone; the least potent is hydrocortisone. Most dogs benefit from short-term therapy with topical corticosteroids at the initiation of therapy, with concurrent therapy aimed at the primary and other perpetuating factors. Long-term therapy with topical corticosteroids can be deleterious because of systemic absorption of drug. Increased serum liver enzymes and depressed adrenal responsiveness may occur; with prolonged use iatrogenic hyperadrenocorticism is possible. Glucocorticoids alone may be of benefit for short-term therapy in cases of allergic or erythematous ceruminous otitis.

1176 1178

Antimicrobials are important for controlling secondary bacterial or yeast overgrowth or infection. Antimicrobials are indicated in any case with cytologic evidence of bacterial overgrowth or infection, with attention paid to the morphology and gram-staining characteristics of the bacteria. Otic preparations commonly contain aminoglycoside antibiotics. Neomycin is effective against typical otitis bacteria such as *Staphylococcus intermedium*. Gentamicin and polymyxin B are also appropriate initial topical treatments for gram-negative bacterial otitis externa. The significant risk of bone marrow toxicity in people limits the use of chloramphenicol for treating otitis in dogs and cats despite its antibacterial spectrum and availability.

Due to the frequency of resistant gram-negative bacteria such as *Pseudomonas*, other topical preparations have been developed. Enrofloxacin, ophthalmic tobramycin, and topical application of injectable ticarcillin have been used to treat otitis in dogs.[3,34] Their use should be limited to cases of resistant bacteria, and culture and susceptibility testing should be performed prior to application. Other topical agents may be used to supplement treatment of resistant *Pseudomonas*, such as silver sulfadiazine solution and tris EDTA. Tris EDTA can render *Pseudomonas* susceptible to enrofloxacin or cephalosporins by enhancing membrane permeability and altering ribosome stability. Frequent ear cleaning may also assist in the treatment of resistant bacterial otitis; ceruminolytics have antimicrobial properties, and their use in clinical cases has been evaluated.[33,35] Acetic acid in combination with boric acid is effective against both *Pseudomonas* and *Staphylococcus*, depending on concentration and duration of exposure.[36] Ear cleaning removes proinflammatory products, cells, and substances that diminish the effectiveness of topical antibiotics.

Many topical preparations control yeast organisms, which may complicate erythematous ceruminous otitis and suppurative otitis. Common active ingredients include miconazole, clotrimazole, nystatin, and thiabendazole. Preparations containing climbazole, econazole, and ketoconazole have also been evaluated.[37,38] Eighty percent of yeast were susceptible to miconazole and econazole, intermediately resistant to ketoconazole, and 90% were resistant to nystatin and amphotericin B in one in vitro study.[38] Topical ear cleaning agents have some efficacy against *Malassezia* organisms.[35] Other preparations (e.g., chlorhexidine, povidone-iodine, acetic acid) are also effective in the treatment of secondary yeast overgrowth.

Response to topical therapy should be gauged by re-evaluation of physical, cytologic, and otoscopic examinations every 10 to 14 days after the initiation of therapy. Any changes in the results of these examinations should be recorded. Most cases of otitis can be managed topically; failure to respond to therapy should prompt re-evaluation of the diagnosis and treatment.

209.11.3 Systemic Therapy

Systemic glucocorticoid administration may be beneficial in cases of severe, acute inflammation of the ear canal, chronic proliferative changes of the ear canal, and allergic otitis. Anti-inflammatory doses should be limited to 7 to 10 days. Cases of significant thickening or proliferative changes in the external ear canal benefit from systemic antimicrobial therapy. Systemic therapy should be considered if concurrent dermatologic changes of the surrounding skin, pinna, or other regions of the body are present. Long-term administration of appropriate antimicrobials based on culture and susceptibility is required in all cases of otitis media. Systemic therapy for yeast is rarely recommended in animals with otitis alone. One study evaluated oral itraconazole therapy, and in ear samples evaluated on cytology and culture, no change in cytology score was found.[16]

209.12 THERAPY FOR SPECIFIC DISEASES OF THE EXTERNAL EAR CANAL

209.12.1 Ectoparasites

Thorough cleaning of the external ear canal, treatment of all household pets, and whole-body therapy should be considered in the treatment regimen for ear mites. Pets with no clinical signs may be asymptomatic carriers and a reservoir for reinfestation. Otic parasiticides such as pyrethrins, rotenone, amitraz, and carbaryl must be administered every 24 hours throughout the 20-day mite life cycle because they do not kill mite eggs.[13] Thiabendazole eliminates all mite stages, but it must be applied every 12 hours for 14 days. Ivermectin (0.3 to 0.5 mg/kg) may be applied topically once weekly for 5 weeks.[1] Otic administration of medication does not affect mites on adjacent or distant skin locations, and systemic or other total-body parasiticide may be indicated. Alternatively, ivermectin administered subcutaneously (0.2 to 0.3 mg/kg) 2 to 3 times at 10-to 14-day intervals or orally (0.3 mg/kg) every week for four treatments eliminates otic mites and those found elsewhere on the body.[1] Other topicals proven safe and effective for ear mite treatment include selamectin (6 mg/kg) applied to the skin between the shoulder blades and fipronil spray.[25–27] Selamectin administered once in cats and two times, 30 days apart in dogs gave results similar to topical pyrethrin therapy.[26,27]

209.12.2 Idiopathic Inflammatory or Hyperplastic Otitis in Cocker Spaniels

Treatment is aimed at decreasing the secondary ear canal changes associated with this condition. Anti-inflammatory doses of corticosteroids administered orally may be useful. Topical corticosteroid preparations in combination with antimicrobials decrease the soft tissue mass affecting the ear canal but may not be as effective as oral administration. Maintenance therapy may be required both topically and orally; however, low doses of corticosteroids should be used. Re-evaluation should include attention to the potential side effects of corticosteroid therapy. Intermittent treatment of secondary bacterial or yeast overgrowth and infection may be required. Surgery is often indicated due to the severe secondary changes within the ear canal.

209.12.3 Excessive Moisture (Swimmer's Ear)

Other primary disease conditions such as allergic otitis should be ruled out in any dog with erythematous ceruminous otitis. Dogs with frequent exposure to water, however, may require ear cleaning and drying agents to diminish the humidity of the ear canal. Many cleaning and drying agents also posses antimicrobial effects.[35] Products that combine a drying agent and corticosteroid decrease the ear canal humidity and inflammation associated with allergic otitis complicated by swimming. Care should be taken to control primary disease (i.e., allergic otitis), however, and intermittently manage the predisposing factor (i.e., excessive moisture) as necessary. The dog's ears should be cleaned and dried the day of water exposure and for 2 to 5 days after. For continued frequent exposure, maintenance cleaning may be required every other day to twice weekly.

1178

1179

209.12.4 Chronic Bacterial Otitis

Resistant bacteria play an important role in the development of chronic otitis externa. Any dog not responding to initial therapy should be re-evaluated for primary and perpetuating conditions such as allergic disease, foreign body, neoplasia, otitis media, and secondary anatomic changes of the ear canal. Primary disease processes identified in one study included hypothyroidism, atopy, food allergy, and immune-mediated

disease.[34] Infection with Pseudomonas species frequently occurs with repeated treatment of otitis externa, and acquired resistance is common. Culture and susceptibility testing is imperative to guide therapy. Oral antimicrobials combined with topical therapy are used in severe cases with secondary changes of the ear canal. Identification of otitis media is vital to remove the middle ear as a source of otitis externa. Otitis media requires long-term treatment.

Ear cleaning prior to the application of topical medication may increase the efficacy of the agent by decreasing exudate in the ear canal that inactivates antimicrobial drugs such as polymyxin.[2] In cases that fail to respond to first-line drug treatments such as polymyxin or gentamicin, other topical antimicrobial agents should be tried. Ophthalmic tobramycin and injectable amikacin have been described for use as topical antimicrobials in ear disease.[2] The integrity of the tympanic membrane should be known prior to use; the clinician should avoid these medications if the tympanic membrane cannot be proven intact. Enrofloxacin or ticarcillin injectable preparations diluted in saline or water may be applied topically for resistant *Pseudomonas*. Parenteral ticarcillin was used in cases with a ruptured tympanic membrane until healing was observed, at which time topical therapy was instituted; clinical response occurred in 11 of 12 cases.[34] Enrofloxacin and silver sulfadiazine combination is also available in an otic preparation (Baytril Otic, Bayer Shawne Mission, KS).

Other topical therapy may assist in eliminating resistant *Pseudomonas* from the ear canal.

Decreasing the pH of the ear canal with 2% acetic acid is lethal to *Pseudomonas*; diluted vinegar in water (1:1 to 1:3) may be used to flush the ear canal. Acetic acid combined with boric acid is lethal to *Pseudomonas* and *Staphylococcus*, depending on the concentration of each agent.[36] Increasing the concentration of acetic acid may broaden its spectrum of activity but causes irritation of the external and middle ear. Silver sulfadiazine in a 1% solution exceeds the minimum inhibitory concentration of *Pseudomonas* and may be instilled into the ear canal. One gram of silver sulfadiazine powder mixed in 100 mL of water may be used for topical therapy and is also effective against Proteus species, enterococci, and *Staphylococcus intermedium*. Dilute acetic acid (2%) and silver sulfadiazine (1%) have not caused adverse effects in cases with a ruptured tympanic membrane.[1,3,13] Tris EDTA may be applied after thorough ear cleaning to increase the susceptibility of *Pseudomonas* to antimicrobial agents. It must be mixed, pH adjusted, and autoclaved prior to use or is available in an otic preparation (TrizEDTA, DermaPet®, Potomac, MD), which is used to clean the ears prior to instillation of topical antibiotic. Topical antiseptics such as chlorhexidine and povidone-iodine solutions may be helpful, but ototoxicity is an issue, particularly in cases in which the tympanum is ruptured or cannot be evaluated.

Re-evaluation of the pet is important for monitoring response to therapy. Evaluation of the ear canal for progressive secondary changes and cytologic examination will allow alterations in therapy as needed. Significant narrowing of the ear canal is an indication for surgical intervention. Yeast overgrowth may occur with aggressive medical management of bacterial otitis and should be identified to maintain proper medical management.

209.12.5 Refractory or Recurrent Yeast Infection

Malassezia infection is a common perpetuating factor with erythematous ceruminous otitis and alterations in the otic microenvironment. Primary causes of the otitis should be identified and treated. Cytologic examination, not culture, should be relied upon for the diagnosis of yeast infection.[17,31] If a case becomes refractory to therapy, reassessment of the primary condition and perpetuating factors should be done. Miconazole, clotrimazole, cuprimyxin, nystatin, and amphotericin B have all been described for treating

Malassezia otitis. Climbazole had better in vitro activity against isolates of *Malassezia pachydermatis* in one study.[37] Yeast were more susceptible to azole antifungals than polyene antifungals; however, oral ketoconazole, itraconazole, or fluconazole have been recommended for refractory cases.[1,38] Long-term therapy may require topical antibacterial and antifungal combinations.

Ear cleaning may aid in the elimination of yeast organisms by removing cerumen, debris, or exudate and altering the microenvironment of the ear canal. Cleaning with antimicrobial agents such as chlorhexidine, povidone-iodine, and acetic acid may be beneficial; but as always the integrity of the tympanum should be established prior to use. Ear cleaning solutions may also have some efficacy against yeast organisms both in vitro and in clinical cases of otitis.[35,39]

209.12.6 Neoplasia

Chronic otitis externa may be the result of otic neoplasia, or otitis may be a predisposing factor in the development of neoplasia. Cocker spaniels are over-represented for benign and malignant neoplasia and otitis externa.[1,40] Tumors of the skin and adenexal structures of the ear predominate. Benign tumors in dogs include sebaceous gland adenoma, basal cell tumor, polyp, ceruminous gland adenoma, and papilloma. Cats are more frequently diagnosed with malignant neoplasms, but benign conditions include inflammatory polyps, ceruminous gland adenomas, ceruminous gland cysts, and basal cell tumors. Malignant neoplasms in both species include ceruminous gland adenocarcinoma, undifferentiated carcinoma, and squamous cell carcinoma. Ceruminous gland adenocarcinomas are the most frequently diagnosed tumors of the ear canal in dogs and cats; however, one report stated that squamous cell carcinoma occurs with equal incidence in the cat.[40,41]

The biologic behavior of otic tumors cannot be judged by their gross appearance; however, benign masses are usually nodular and pedunculated. Ulceration can be secondary to otitis associated with mass lesions, but malignant masses ulcerate more frequently than benign masses. The tympanic bulla is involved in up to 25% of aural neoplasms, and neurologic signs occur in 10% of dogs and 25% of cats with otic neoplasia.[42] The biologic behavior of malignant neoplasms tends to be local invasion with a low metastatic rate (e.g., 10% in dogs) to draining lymph nodes or lung.

Surgery is the mainstay treatment of otic neoplasia. Conservative excision may be possible for benign lesions, depending on the location of the tumor. Malignancies should be removed by total ear canal ablation and lateral bulla osteotomy. Incomplete excision results in recurrence of the mass and secondary otitis externa. Malignant neoplasia is associated with a median survival time (MST) of more than 58 months in dogs and 11.7 months in cats.[40] Extensive tumor involvement and lack of aggressive management are associated with a poor prognosis in dogs.[40,43] In cats a poor prognosis is associated with neurologic signs, squamous cell carcinoma or undifferentiated carcinoma, vascular or lymphatic invasion, and lack of aggressive therapy.[40,44] Ceruminous gland adenocarcinoma has a median disease free interval of more than 36 months and 42 months in dogs and cats, respectively.[43,44] The MST associated with squamous cell carcinoma and undifferentiated carcinoma in cats is 4 to 6 months.[40]

209.13 ROLE OF SURGERY IN THE MANAGEMENT OF OTITIS EXTERNA

The two most common surgical procedures for the treatment of otitis externa are lateral ear resection and total ear canal ablation. Total ear canal ablation is always combined with a bulla osteotomy to allow complete removal

of all secretory epithelium and exudate associated with the external and middle ear. Care must be taken when choosing a surgical technique for otitis externa.

Lateral ear resection is associated with high failure rates (47% to 80%) with inappropriate patient selection.[45] The procedure should be viewed as an adjunct to medical management, not as a cure. The primary and perpetuating factors associated with otitis externa must be identified and managed or controlled even when surgery is elected. Opening the vertical ear canal improves aeration, decreases humidity, facilitates removal of cerumen or exudate, and improves the distribution of topical medication in the ear canal. Lateral ear resection may be used in cases with mild changes of the vertical ear canal but should be avoided with significant secondary changes of the vertical ear canal or horizontal canal stenosis. Owners should be educated to the continuing need for medical therapy after surgery to avoid further progression of secondary changes of the ear canal. Pets can develop end-stage otitis after lateral ear resection.

Total ear canal ablation is used to treat end-stage otitis and malignant otic neoplasia. Severe secondary changes and proliferative disease are surgically removed with the ear canal en toto. A lateral bulla osteotomy of the tympanic bulla allows complete exploration of the middle ear for the removal of secretory epithelium, exudate, and tumor. The surgery removes the site of chronic inflammation and infection to cure the vast majority of cases of otitis externa and otitis media. Complications of the procedure include facial nerve paresis or paralysis, hemorrhage, para-aural abscessation, otitis interna, Horner's syndrome, pinnal necrosis, continued pinnal dermatitis, and hearing loss. Dogs with obstruction of the ear canal from end-stage otitis or neoplasia may be partially deaf, and postoperatively only osseous conduction of sound remains.

Vertical ear canal resection may be performed in cases of tumors confined to the auricular cartilage or traumatic injury. Significant proliferative disease or changes secondary to otitis externa are rarely confined to the vertical ear canal; concurrent stenosis of the horizontal ear canal usually necessitates total ear canal ablation and lateral bulla osteotomy. The anastomosis between the horizontal ear canal and surrounding skin may undergo stenosis after surgery, necessitating reoperation. Progression of the otitis and tumor recurrence are possible after vertical ear canal resection.

209.14 DISEASES OF THE MIDDLE AND INNER EAR

209.14.1 Normal Anatomy and Physiology

The middle ear consists of the tympanic membrane, three cavities (epitympanic, tympanic, and ventral), and the bony ossicles (malleus, incus, and stapes). The tympanic membrane has two parts: (1) the thin pars tensa that attaches to the manubrium of the malleus and (2), above the pars tensa, the thicker, pars flaccida. The main portion of the middle ear, the ventral tympanic bulla, has two compartments in the cat (ventromedial and dorsolateral). The air-filled bulla is lined with modified respiratory epithelium, which is either squamous or cuboidal and may be ciliated. The four openings in the middle ear are the (1) tympanic opening, (2) the vestibular window, (3) the cochlear window, and (4) the ostium of the auditory tube. The auditory tube is the communication between the middle ear and caudal nasopharynx. The normal flora of the middle ear may be due to this pharyngeal communication, but the role of the auditory tube as a source of bacteria in otitis media is unknown. The tympanic opening is a common source of bacterial infection of the middle ear in dogs with otitis externa. The cochlear and vestibular windows are possible ports of entry for progression of otitis media or ototoxic substances into the inner ear.

Cranial nerve VII, or the facial nerve, the sympathetic innervation of the eye, and the parasympathetic innervation of the lacrimal gland are closely associated with the middle ear. The separation of the facial nerve

from the middle ear is minimal along the rostral aspect of its course through the petrosal bone. The nerve supplies motor fibers to the superficial muscles of the head, the muscles of the external ear, the caudal belly of the digastricus, and the ossicular muscles. The nerve also supplies sensation of the vertical ear canal and concave surface of the pinna.

Postganglionic sympathetic nerve fibers course closely with those of the facial nerve to innervate the smooth muscles of the eye. Preganglionic parasympathetic fibers also pass through the middle ear to innervate the salivary and lacrimal glands.

The inner ear is located within the petrosal bone. The cochlea, vestibule (saccule and utricle), and semicircular canals form the membranous labyrinth, which is encased in bone, called the *bony labyrinth*. The vestibular system functions to maintain the position of the eyes, trunk, and limbs relative to the position of the head, responding to linear and rotational acceleration and tilting. The system consists of the saccule, utriculus, and semicircular canals and communicates with the middle ear via the vestibular window. Fluid within the semicircular canals tends to remain stationary during motion, bending the cilia of the cells in the utricle and saccule, causing depolarization. These stereocilia synapse with the dendrites of the vestibular portion of the eighth cranial nerve and the signal is conducted via cranial nerve VIII to vestibular nuclei in the myelencephalon, the spinal cord, centers in the cerebellum and cerebral cortex, and motor nuclei of cranial nerves III, IV, and VI.[46] The result is coordination of the body, head, and eye movement. Projections to the vomiting centers are responsible for nausea and vomiting associated with vestibular disorders and motion. The cochlear system, involved with the translation of sound, consists of the spiral organ, or organ of Corti, cochlear duct, scala vestibule, and scala tympani. Transmission of sound through the tympanic membrane, ossicles, and cochlear window results in undulation of the basilar membrane of the spiral organ. Cilia bend and cause depolarization and transmission of a signal to cochlear nuclei, caudal colliculi, and cerebral cortex.[46] The cochlear nuclei control reflex regulation of sound via projections to cranial nerves V and VII, which control the muscles of the ossicles. Other projections allow for conscious perception of sound.

209.14.2 Otitis Media

Otitis media may result from extension of otitis externa through the tympanic membrane, aspiration of pharyngeal contents up the auditory tube (e.g., a sequela to upper respiratory tract [URT] infection in cats), or from hematogenous spread. Extension from otitis externa is the most common cause of otitis media, but otitis media may serve as a perpetuating factor for otitis externa. Developmental abnormalities of the external ear canal and pharynx may also result in otitis media due to the accumulation of secretions in the middle ear.[47,48] Neoplasia, inflammatory polyps, and middle ear trauma may be associated with secondary otitis media or result in similar clinical signs.

Cholesteatoma is commonly associated with otitis media and chronic otitis externa. A cholesteatoma is a mass of keratinized squamous cells that accumulate within a structure lined with stratified squamous epithelium. 1180
The lesion is presumed to develop when a pocket of tympanic membrane becomes adhered to inflamed middle ear mucosa. 1181
Significant narrowing of the external ear canal is usually present. Radiographic signs of increased density and bony changes of the tympanic bulla predominate with loss of the air-filled lumen of the external ear canal and concurrent calcification. Treatment is usually limited to total ear canal ablation and lateral bulla osteotomy due to the changes of the external ear canal and mass or accumulation of debris in the tympanic bulla.[49]

The clinical signs associated with middle ear disease often reflect concurrent otitis externa (e.g., head shaking, lethargy, exudate, otic malodor). Significant otic pain, lethargy, inappetence, and pain upon opening the

mouth are more suggestive of middle ear involvement. Neurologic signs may be present due to the course of the facial nerve and sympathetic innervation of the eye. Facial nerve paresis or paralysis result in facial asymmetry (i.e., uneven position of the lip commissures, unequal ear carriage, unilateral ptyalism) and abnormal cranial nerve reflexes on neurologic examination (e.g., menace response, palpebral and corneal reflexes, abnormal ear canal, and concave pinnal sensation). Horner's syndrome, or loss of sympathetic innervation to the eye, can also be complete or partial (i.e., ptosis, miosis, enophthalmia, prolapse of the third eyelid). Otitis interna is usually evidenced by head tilt, abnormal nystagmus, and ataxia and should be differentiated from central vestibular disease based on careful neurologic examination. Otitis interna is not usually associated with ipsilateral hemiparesis or abnormalities in level of consciousness.

Cases of para-aural abscessation usually have concurrent otitis media.[3] The primary cause may be trauma to the external ear canal, severe otitis externa, extension of otic neoplasia, or total ear canal ablation. Signs of middle or external ear disease and soft tissue swelling in the parotid area may be accompanied by draining tracts. A head tilt and pain upon palpation of the area are usually present.

The diagnosis of otitis media is based on a thorough history and physical, neurologic, and otoscopic examinations. A ruptured tympanum strongly suggests otitis media. The pharynx should also be evaluated on physical examination; identification of specific conditions may require general anesthesia due to anatomic location (e.g., inflammatory polyps) or pain associated with examination (e.g., otitis media causing temporomandibular joint (TMJ) pain, severe otitis externa). General anesthesia may also be required to perform a complete otoscopic examination in cases of severe otitis externa in which thorough cleaning of the ear is necessary for therapy and diagnosis (i.e., visualization of the tympanum). Significant otitis externa is commonly associated with otitis media; the tympanic membrane is ruptured in up to 50% of dogs with otitis externa, although 70% of dogs with otitis media had an intact tympanic membrane in one study.[15,50] The tympanic membrane in dogs with otitis externa may be difficult to examine due to secondary changes of the external ear canal, pain associated with otoscopic examination, and accumulation of exudate, cerumen, and debris. Treatment to diminish the severity of otitis externa and general anesthesia may increase the ability to evaluate the tympanum in these cases.

Any case that has significant cerumen, exudate, or debris should undergo careful cleaning of the ear canal to allow evaluation of the integrity and character of the tympanic membrane. The presence of a “false middle ear” occurs when large accumulations of debris lodge against the tympanic membrane, causing it to deviate medially into the middle ear. This makes the external ear canal appear elongated and leads to misdiagnosis of a ruptured tympanic membrane.[3]

Gentle probing of the tympanic membrane with a red rubber catheter under direct visualization may assist in the diagnosis of small tears in the membrane. If the catheter tip is consistently visible, rupture is unlikely. Alternatively, an aliquot of 1 mL of physiologic saline placed in the horizontal canal should remain stationary; disappearance suggests an opening in the tympanum, allowing the fluid to drain into the middle ear.[1] Movement of the fluid may be blocked by large amounts of debris in the middle ear, even in the presence of a tear in the tympanum.

If the tympanic membrane is visible, its character should be recorded in the medical record for comparison upon re-evaluation. Bulging, increased opacity, and hyperemia may be present with otitis media. If otitis media is suspected, radiographs of the bullae may be made. Lateral oblique and open-mouth views are most helpful for evaluating the tympanic bulla, but positioning for comparison of left and right sides is difficult and requires general anesthesia. Ventrodorsal or dorsoventral views allow evaluation of the air-filled lumen and calcification of the external ear canal. Abnormalities of the bulla include increased opacity, sclerosis, and

lysis. Fluid cannot be differentiated from increased soft tissue density (e.g., neoplasia), and absence of radiographic changes does not rule out otitis media. Radiographic changes were absent in 33% of the middle ears in one study of dogs with otitis media confirmed by surgical exploration.[18] Otitis media or neoplasia and otitis interna can cause radiographic evidence of lysis of the petrosal bone.

Other diagnostic tools are available to evaluate patients with otitis media interna. Contrast introduced into the external ear canal followed by radiography, termed *canalography*, is used to diagnose tympanic membrane perforations. The method is useful for acute tympanic membrane rupture and increases the frequency of diagnosing tympanic membrane rupture with concurrent otitis externa and media beyond that of otoscope alone.[51] Advanced imaging with CT and MRI have been studied in normal dogs and dogs with otitis media (Figure 209-1).[18,52] CT is considered superior to MRI for bony changes, whereas MRI is better for detection of soft tissue abnormalities in both dogs and cats.[18,20,52,53]

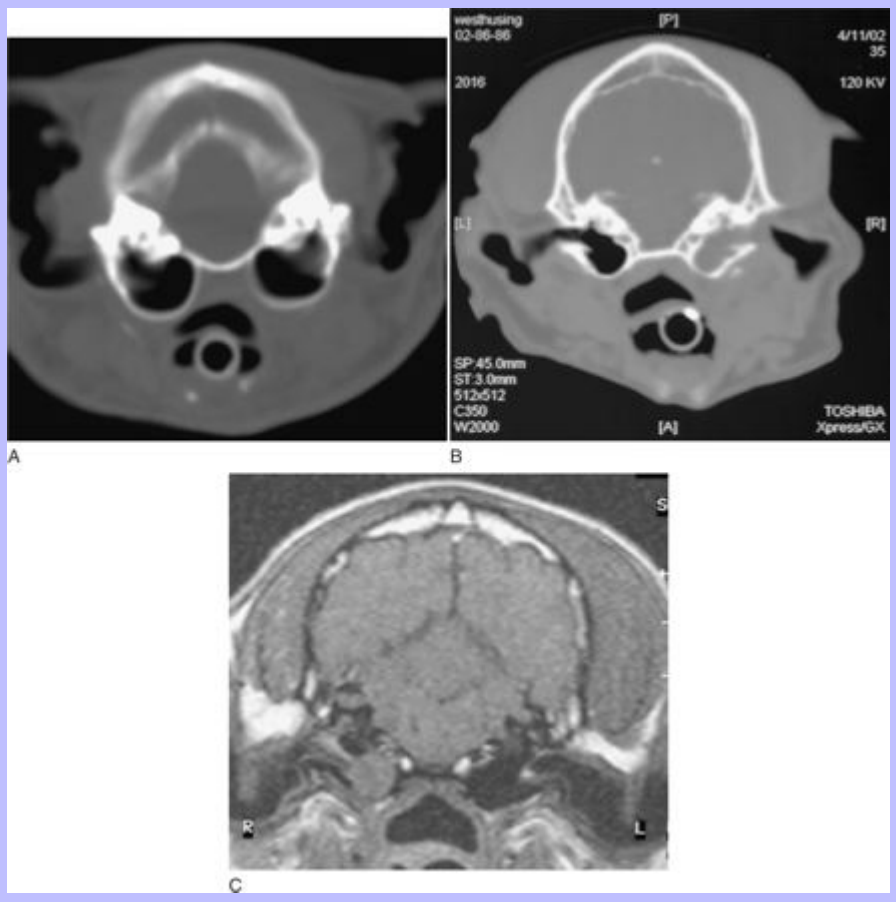
If the tympanic membrane is intact in a dog with otitis media, a myringotomy is performed to obtain samples for culture and susceptibility testing and cytologic examination. Affected dogs are often more comfortable after collection of samples due to decreased pressure in the middle ear after myringotomy. The procedure must be performed with general anesthesia and is usually done after radiography or advanced imaging of the ear. The external ear canal should be thoroughly cleaned and dried prior to myringotomy to avoid contamination with external ear canal debris. Direct otoscopic visualization is used for the procedure. A 20-gauge spinal needle is used to penetrate the tympanic membrane through the caudoventral aspect of the pars tensa. Suction is applied and samples collected—culture and susceptibility takes priority over cytologic examination because cytology is frequently negative, and cultures of the external ear canal do not reflect the middle ear bacteria in the majority of cases.[15] If fluid cannot be aspirated directly from the middle ear, 0.5 to 1 mL of warm, sterile saline can be infused through the needle into the middle ear cavity and aspirated. Alternatively, an open-ended tomcat catheter or small, sterile culture swab may be passed into the middle ear cautiously under otoscopic visualization. Pseudomonas species and *Staphylococcus intermedium* are most commonly isolated, followed by yeast, β-hemolytic *Streptococcus*, Corynebacterium species, Proteus species, and Enterococcus species.[15,54] Surgical exploration is rarely required for the diagnosis of otitis media.

Medical therapy of otitis media should be guided by culture and susceptibility results. The external ear canal is flushed and dried as necessary to treat concurrent otitis externa. Flushing is usually performed under the same general anesthetic episode used for diagnostic testing. If the tympanic membrane is ruptured, the middle ear should be gently lavaged with warm saline. Cytology results, when available, should be used to guide initial therapy. The integrity of the tympanic membrane must be considered when using topical agents to treat concurrent otitis externa: ototoxic medications and vehicles should be avoided if the tympanic membrane is ruptured.

1181

1182

Figure 209-1 Computed tomographic (CT) image of a normal canine ear **(A),** CT image **(B),** and a magnetic resonance image (MRI) **(C)** of a dog with otitis media.



Newly diagnosed cases of otitis media may be started on empiric therapy based on cytology. First-choice antimicrobials include cephalosporins, amoxicillin and clavulonic acid, and fluoroquinolones. Definitive therapy consists of administration of antibiotics based on culture and susceptibility results for a minimum of 4 to 6 weeks. Primary and perpetuating factors of otitis externa should be identified and treated or controlled. Topical medication and flushing of the external ear canal should continue until resolution of clinical signs and normalization of cytology. Gradual improvement of the otitis media is expected within 14 days. The ear canal and tympanic membrane should be evaluated prior to and after discontinuation of therapy. Small tears in the tympanic membrane after myringotomy heal rapidly with appropriate therapy within 2 to 3 weeks.[34,55] However, re-evaluation of the tympanic membrane in dogs with otitis externa media should precede alteration of the topical agents in the therapeutic plan.

Failure to respond to therapy or chronic or recurrent otitis media warrant re-evaluation for surgical intervention. Total ear canal ablation and lateral bulla osteotomy should be considered in cases with severe

secondary changes of the external ear canal and concurrent otitis media. If the external ear canal is not affected, a ventral bulla osteotomy may be performed to remove gross exudate and establish drainage from the middle ear of dogs and cats with chronic or recurrent otitis media. Caution should be taken in considering lateral ear resection and ventral bulla osteotomy in the treatment of concurrent otitis externa and media because lateral ear resection is only an adjunct to medical management of otitis externa.

1182

1183

209.14.3 Neoplasia of the Middle Ear

Neoplasia of the middle ear is rare; most cases represent extension of tumors originating in the external ear canal.

209.14.4 Inflammatory Polyps

Inflammatory polyps are a non-neoplastic admixture of inflammatory and epithelial cells originating in the tympanic bulla in cats. Other sites of origin include the auditory tube and nasopharynx. Macrophages, neutrophils, lymphocytes, plasma cells, and epithelial cells are usually present on histopathologic examination. The cause is unknown, but ascending infection and congenital causes have been suggested.[56] No age or sex predilection exists for the condition, but younger cats are more commonly affected (1 to 5 years of age). Signs can be unilateral or bilateral and depend on the location of the mass lesion. A single polyp can grow into the external ear canal, down the auditory tube into the nasopharynx, or both. Signs of concurrent otitis externa and media are common with polyps limited to the ear, but respiratory stridor, dyspnea, gagging, and dysphagia occur with growth into the pharynx.

Diagnosis is based on otoscopic and pharyngeal examinations. Radiographs of the bulla, nasal cavity, and pharynx may be considered, and CT or MRI can be used to diagnose the site and side of origin of inflammatory polyps.[53,57] Treatment consists of excision by traction or surgical excision via ventral bulla osteotomy.[8,58] Regrowth is a problem in half of the cats treated by traction extraction alone, and Horner's syndrome is common in cats after ventral bulla osteotomy.[8,58]

209.14.5 Otitis Interna

Otitis interna is usually an extension of otitis media or neoplasia of the middle ear. A careful neurologic examination is imperative to the localization of vestibular signs. Clinical signs associated with otitis interna include head tilt, ataxia, horizontal or rotary nystagmus, circling or falling toward the side of the lesion, or ipsilateral nystagmus. The fast phase of nystagmus is usually away from the side of the lesion. Occasionally, animals will become nauseated or vomit. Horner's syndrome or deficits in cranial nerve VII may accompany otitis media interna, but involvement of other cranial nerves, vertical or changing nystagmus, or the presence of conscious proprioceptive deficits or paresis indicate central rather than peripheral vestibular disease. Bilateral peripheral vestibular disease is rare, but the animal will not have a head tilt, nystagmus, or strabismus and may exhibit wide head excursions and a crouched stance or the inability to stand.

The diagnosis of otitis interna is based on history, clinical signs, and physical, neurological, and otoscopic examinations. Advanced imaging may be helpful in distinguishing the anatomic location of the disease process. Treatment with aggressive medical or surgical intervention appropriate to the localization is important in prevention of adjacent brain stem involvement.

209.14.6 Prognosis for Otitis Media and Interna

A fair prognosis can be given if aggressive surgical and medical therapy are possible. Cases with concurrent severe external ear canal changes require total ear canal ablation and lateral bulla osteotomy. Repeated infections after ventral bulla osteotomy or total ear canal ablation and lateral bulla osteotomy may be operated again with resolution of the condition. Resistant organisms, failure to respond to aggressive surgery, and significant osteomyelitis are associated with a poor prognosis. The neurologic signs associated with otitis media and interna may be permanent, but many animals learn to use visual cues and can compensate for vestibular deficits. Facial nerve deficits, Horner's syndrome, and keratoconjunctivitis sicca are often permanent.

209.14.7 Ototoxicity

Ototoxic substances (Table 209-4) damage the cochlear or vestibular systems or both. Otic application of medication can also cause adverse effects through local inflammation of the tympanic membrane or the meatal window (or both), as well as resultant otitis media. Topical medications also cause adverse effects by systemic absorption. Ototoxic substances reach the inner ear after local application and absorption through the cochlear or vestibular windows or hematogenously. The most frequent cause of ototoxicity is the application of an ototoxic substance to the external ear canal in a pet with a ruptured tympanum, which results in distribution to the middle ear. Absorption by the inner ear is increased when inflammation of the cochlear window occurs with otitis media. Hematogenous distribution of ototoxins to the inner ear is inherent in some medications (e.g., aminoglycosides).

The development of ototoxicity also depends on the vehicle of the preparation, chemical composition, drug concentration, concurrent medications, as well as the route, frequency, and duration of administration.[3] Examples of increased risk of ototoxicity depending on the vehicle (e.g., combination of chlorhexidine and detergents) and concurrent medications (e.g., loop diuretics and aminoglycosides) have been described. Minimization of the risk of toxicity should be considered when any potentially toxic substance is administered either topically or systemically. The integrity of the tympanic membrane should be known prior to topical administration of any potentially ototoxic drug, and consequences of each drug should be considered in light of the animal's health and concurrent therapies.

209.14.8 Idiopathic Vestibular and Facial Nerve Diseases

A complete neurologic examination is key to differentiating peripheral from central vestibular disorders. Head tilt, ataxia, horizontal or rotary nystagmus, and cranial nerve VII deficits may be seen with either condition. Central vestibular disease causes paraparesis, conscious proprioceptive deficits, other cranial nerve abnormalities, and vertical or changing nystagmus. Middle ear neoplasia, otitis media interna, idiopathic vestibular syndrome, and congenital vestibular disorders result in peripheral vestibular signs. Congenital vestibular disorders have been described in the German shepherd, Doberman pinscher, English cocker spaniel, Siamese, and Burmese breeds.[59,60] Bilateral congenital vestibular syndrome has been described in beagles and Akitas.[59,60] Clinical signs of head tilt and ataxia in these dogs and cats may be persistent or may improve; animals can be congenitally deaf.

Table • 209-4 Ototoxic Drugs

Aminoglycoside Antibiotics
Neomycin
Dihydrostreptomycin
Gentamicin
Streptomycin
Kanamycin
Tobramycin
Amikacin
Other Antibiotics
Polymixin B & E
Minocycline
Erythromycin
Chloramphenicol
Vancomycin
Loop Diuretics
Furosemide
Bumetanide
Ethacrynic acid
Antiseptics
Chlorhexidine
Iodine & iodophores
Ethanol
Benzalkonium chloride
Benzethonium chloride
Cantrimide
Antineoplastic Agents
Cisplatin

Nitrogen mustard
Miscellaneous
Quinine
Salicylates
Propylene glycol
Detergents
Arsenic
Lead
Mercury

Otitis media interna may be associated with facial paresis or paralysis if cranial nerve VII is affected by the inflammation. Otitis should be ruled out before diagnosing any animal with idiopathic facial nerve paralysis, because otitis requires aggressive management and the idiopathic condition can only be treated symptomatically or with acupuncture.[61]

209.14.9 Deafness

Deafness is classified as inherited or acquired, conductive or sensorineural, and congenital or late onset. Acquired deafness may be either conductive or sensorineural, depending on the etiologic agent, which also affects the time of onset. Conductive deafness results from a lack of presentation of sound to the inner ear, usually secondary to otitis externa media. Sensorineural deafness occurs with abnormalities of the cochlear system, cranial nerve VIII, or auditory pathways and higher brain centers. Inherited deafness, ototoxicity, cochlear nerve degeneration, and presbycusis (age-related deafness) are forms of sensorineural deafness.

209.14.9.1 Diagnostic Principles

Signalment can help to prioritize possible causes of deafness. Certain breeds have a high incidence of inherited deafness, and clinical signs are usually noticed at an early age if the deafness is bilateral. Most other forms of deafness occur as late-onset disorders. The history is important in establishing the nature of the deafness, because certain conditions or treatments may cause deafness (e.g., otitis externa media, ototoxic medications, head trauma, prior infectious diseases). The owner may note behavioral changes in the pet, and complete, bilateral deafness is usually easily identified. Astute owners may notice behavioral changes in puppies at an early age. Inherited deafness usually results in loss of hearing within 3 to 4 weeks of birth due to a degenerative process of the inner ear.[62] The affected pup is often more aggressive than its littermates, because it cannot hear cries of pain during play. The puppy may also be more difficult to rouse and is more vocal than its littermates, especially when they are out of view of the affected pup.

Unilateral deafness is harder to identify, but the owner may report difficulty rousing the pet when it is sleeping in lateral recumbency or difficulty in the pet's ability to orient to the origin of sounds. The physical, otoscopic, and neurologic examinations are important in differentiating peripheral from central disease and establishing whether conductive deafness is possible. The index of suspicion for conductive

deafness is increased in dogs and cats with abnormalities of the external ear canal, tympanum, cranial nerve VII, or sympathetic innervation of the eye.

Abnormalities suggestive of central disease prompt more aggressive diagnostic testing such as advanced imaging and cerebrospinal fluid (CSF) analysis.

Hearing loss can be evaluated with the pet in the examination room. Different sounds can be used in an attempt to observe behavioral reactions to sound. A Preyer's reflex (i.e., movement of the pinna in response to sound) is the minimal expected response.[62] Care should be taken to avoid visual cues and air movement close to the animal's head, which cause an apparent reaction to sound in an affected dog or cat. Unfortunately, pets may be stressed by the hospital environment and may not react to auditory cues even if hearing is normal.

209.14.9.1.1 Impedance audiometry and tympanometry

Impedance audiometry is based on the concept that the intensity of a sound wave is dependent on the size of the cavity in which it is generated and on the compliance of the cavity's containing walls.[3] The external ear canal is occluded for the test, and a sound wave generated. Changes in the pressure within the canal are measured to evaluate the compliance of the tympanic membrane. Accumulation of fluid in the middle ear canal, rupture of the tympanic membrane, immobility of the ossicles, and other causes of conductive deafness alter the results. Normal results in a deaf animal would be supportive of sensorineural deafness.

The acoustic, or stapedial, reflex test is also known as the *acoustic decay test*. A high amplitude sound is used to cause stapedial muscle contraction that protects the structures of the inner ear. This reflex alters tympanic compliance. The afferent (cranial nerve VII) and efferent limbs (cranial nerves V and VII) must be intact for a normal reflex.[1] A normal dog will maintain this reflex for a known period of time, but decay of the reflex occurs in dogs with lesions of cranial nerve VIII.[3] Tympanometry is not commonly performed because it requires specialized equipment adapted from human kits. Ideally the generated sound affects the tympanic membrane perpendicular to its surface. This is difficult to obtain in the dog or cat due to the angle of the ear canal. The results are not sensitive or specific, but they are reliable for the diagnosis of tympanic membrane rupture.[3,63]

209.14.9.1.2 Brain stem auditory evoked response

The brain stem auditory evoked response (BAER), or brain stem auditory evoked potential (BAEP), is an objective measure of hearing. The test identifies the presence or absence of hearing and progressive changes in hearing. Subjective determination of partial hearing loss is possible.[64] Electrodes placed on standard sites of the head record responses to an auditory stimulus generated in one ear. Sound is generated as a series of clicks, and the contralateral ear is excluded by the presentation of *white noise*. The position of electrodes, stimulus intensity, and body temperature can also alter the waves produced.[3] Electrode position is standardized and the sound generated, or stimulus intensity is presented over a range of decibels; the rate of presentation remains constant. The waves generated are subjectively and objectively evaluated. Wave I corresponds to cranial nerve VIII; wave II represents the cochlear nucleus and intracranial, extramedullary portion of cranial nerve VIII. Wave III corresponds to the dorsal nucleus

of the trapezoid body, and waves IV and V originate in the rostral pons and caudal colliculi, respectively.[3]

Wave latencies and amplitudes are used to assess hearing and conduction of impulses through the brain stem, making BAER testing valuable not only in the diagnosis of hearing loss but also for evaluation of brain stem lesions. Most pets do not require sedation or anesthesia for the procedure, which is beneficial because both cause changes in wave latency. Wave latencies and amplitudes vary with the intensity and rate of delivery of the sound.[3] In general, amplitude increases and latency decreases with increasing sound intensity. Interpeak latencies are used to evaluate conduction in the brain stem, which should not change with stimulus intensity.

Conductive deafness reduces the intensity of sound reaching the inner ear. A lack of air-conducted hearing in the presence of bony-conducted hearing is diagnostic of conductive deafness during BAER. The hearing threshold is usually increased when sound is presented through air conduction, but bony-conducted hearing should remain intact. Increased hearing threshold may be accompanied by decreased wave amplitude and increased wave latency in cases of severe otitis externa.[65] Sensorineural deafness alters the appearance of the BAER, depending on the site of the lesion. Alteration of waveforms, increased hearing threshold, or complete abolition of waveforms may be present in animals with sensorineural deafness.

1184

1185

209.14.10 Acquired Late-Onset Conductive Deafness

Conductive deafness is due to lack of transmission of sound through the tympanic membrane and ossicles to the inner ear. Conditions that block sound transmission through the external ear canal, tympanic membrane, or middle ear and ossicles, such as otitis externa, otitis media, and otic neoplasia, cause conductive deafness. Less common causes of conductive deafness include trauma-induced fluid accumulation in the middle ear, atresia of the tympanum or ossicles, fused ossicles, or incomplete development of the external ear canal, which results in fluid accumulation in the middle ear.[62,64,66,67] An increase in hearing threshold, absence of air-conducted hearing, and the presence of bone-conducted hearing on BAER suggest conductive deafness.

The application of a bone-anchored hearing aid was described in one dog with conductive deafness after total ear canal ablation.[68] It maintained bone-conducted hearing and tolerated the hearing aid anchored to the parietal bone. Use of a bone-anchored device was required, because the dog did not have an external ear canal in which to place an earpiece. The hearing aid acted as an amplifier, and the dog seemed to respond to its use.

209.14.11 Acquired Late-Onset Sensorineural Deafness

Presbycusis, or decline in hearing associated with aging, may be due to one of the following: loss of hair cells and degeneration in the organ of Corti, degeneration of spiral ganglion cells or neural fibers of the cochlear nerve, atrophy of the stria vascularis, or changes in the basilar membrane. Because this condition occurs in older dogs and cats from 8 to 17 years of age, animals should be evaluated for concurrent causes of conductive deafness such as chronic otitis externa or media and otic neoplasia. BAER testing may demonstrate normal waveforms in response to high-intensity sound.[69] If conduction is intact at an increased hearing threshold, use of an amplifying hearing aid may be beneficial. Pets may not tolerate occlusive types of ear pieces often used in hearing aids, and training to the ear piece should be done prior to application of the hearing aid.

209.14.11.1

Box • 209-1 Canine Breeds Associated with Inherited Deafness

Akita

American-Canadian shepherd

American cocker spaniel

American Eskimo

American Staffordshire terrier

Australian cattle dog

Australian shepherd

Beagle

Bichon frise

Border collie

Borzoi

Boston terrier

Boxer

Bulldog

Bull terrier

Catahoula leopard dog

Chihuahua

Chow chow

Collie

Dachshund

Dalmatian

Doberman pincer

Dogo Argentino

English cocker spaniel

English setter

Foxhound

Fox terrier

French bulldog

German shepherd

Great Dane

Great Pyrenees

Greyhound

Ibizan hound

Italian greyhound

Jack Russell terrier

Kuvasz

Labrador retriever

Maltese

Miniature pincer

Miniature poodle mongrel

Norwegian dunkerhound

Nova Scotia duck tolling retriever

Old English sheepdog

Papillion

Pit bull terrier

Pointer

Poodle (toy & miniature)

Puli

Rhodesian ridgeback

Rottweiler

Saint Bernard

Schnauzer

Scottish terrier

Sealyham terrier

Shetland sheepdog

Shropshire terrier

Soft-coated Wheaton terrier

Springer spaniel

Sussex spaniel

Tibetan spaniel

Tibetan terrier

Walker American foxhound

West Highland white terrier

Yorkshire terrier

Ototoxic substances, chronic exposure to loud noise, hypothyroidism, trauma, and bony neoplasia can also cause acquired late-onset deafness in dogs and cats. Ototoxicity can result in abolition of waveforms or an increase in hearing threshold on BAER.[3] BAER testing can be used to re-evaluate patients for return of function after withdrawal of medication after exposure to ototoxic medication.

209.14.12 Congenital Sensorineural Deafness

Inherited sensorineural deafness usually results in complete loss of hearing in the affected ear by 5 weeks of age. Many breeds can be affected with the condition (Box 209-1). The condition has been linked to coat color in many breeds of dogs and white cats. The condition is common in white cats, and mode of inheritance is thought to be autosomal dominant with incomplete penetrance.[70] The condition is most common in white cats with blue irides. The correlation of white coat, blue eyes, and deafness is not perfect, but cats with two blue irides have a greater risk of deafness than cats with one blue iris, which have a greater risk of deafness than cats without blue irides.[70] Total hearing loss occurs more often in long-haired white cats.[70] The condition is common in certain breeds of dogs, such as dalmatians, which have a nearly 30% incidence of deafness (combining unilateral and bilateral deafness).

1185

1186

The trait is associated with the dominant merle or dapple gene in collies, Shetland sheepdogs, Great Danes, and dachshunds. The incidence of deafness tends to increase with increasing amount of white in the coat, and dogs homozygous for the merle gene are usually deaf and may be solid white, blind, or sterile.[62] The piebald or extreme piebald gene is associated with deafness in dalmatians, bull terriers, Great Pyrenees, Sealyham

terriers, greyhounds, bulldogs, and beagles. Inheritance is thought to be autosomal recessive, but the trait may be polygenic.[64]

Heterochromia irides and lack of retinal pigment are associated with white color in dogs and cats. Hearing loss may be associated with absence of pigment in the cochlear stria vascularis. Diminished blood supply and disorders of endolymph production, with changes in the chemical or mechanical properties of endolymph, lead to degeneration of the organ of Corti secondary to stria vascularis atrophy. Loss of hair cells and abnormalities of the cochlear duct, Reissner membrane, tectorial membrane, and internal spiral sulcus are typical of cochleosaccular type of end-organ degeneration seen in these cases.[3,64,66,70,71]

Clinical signs of deafness may be recognized in puppies as young as 3 weeks of age by astute owners; definitive diagnosis of uni-or bilateral deafness is usually made by BAER testing at 5 to 6 weeks of age when the auditory system is completely developed and cochlear degeneration, if present, is complete.

209.14.12.1 Congenital Acquired Sensorineural Deafness

Exposure to bacteria, ototoxic drugs, low oxygen tension, and trauma in utero or during the perinatal period rarely causes deafness in young animals.

210 CHAPTER • 210 Diseases of the Nose and Nasal Sinuses

Anjop J. Venker-van Haagen

210.1 FUNCTIONAL CONSIDERATIONS

210.1.1 Functional Anatomy

The nose has four main functions: (1) to provide a portal through which air can flow to reach the alveoli, (2) to modify or regulate the flow of air, (3) to facilitate water and heat exchange (e.g., to condition the inspired air), and (4) to pass inspired air over the olfactory epithelium—the sheet of neurons and supporting cells that lines the nasal cavities. Speculation exists regarding the functions of the nasal sinuses. It seems plausible that the frontal sinuses protect the rostral portions of the brain from frontal trauma.

The apical portion of the nose, consisting of hairless integument and the nostrils, is called the *nasal plane*. It is supported by cartilage, which also supports the portion of the nose between the nasal plane and the bony portion. The levator nasolabial and levator labii superior muscles can move the cartilaginous parts. Dilation of the nostrils changes the pattern of flow of inspired air. The nostrils are dilated when increased airflow is needed, as in dyspnea, and to aid sampling of interesting odors.

The bony case of the nose is the facial portion of the respiratory passageway. The nasal cavity, comprised of bony and cartilaginous parts, extends from the nostrils to the choanae, being divided into right and left halves by the nasal septum. Each half of the nasal cavity has a respiratory and an olfactory region. The nasal conchae—slightly ossified scrolls covered by nasal mucosa—fill the nasal cavities. Together with the nasal glands, the nasal mucosa has a role in *conditioning* the inspired air. During normal inspiration, the respiratory and olfactory air currents are concurrent. When the dog or cat wants to sample environmental odors, the nostrils are dilated and forced inspiration occurs in which a greater volume of inspired air takes a more dorsal course around the ethmoturbinates, where the olfactory receptors are most numerous.[1]

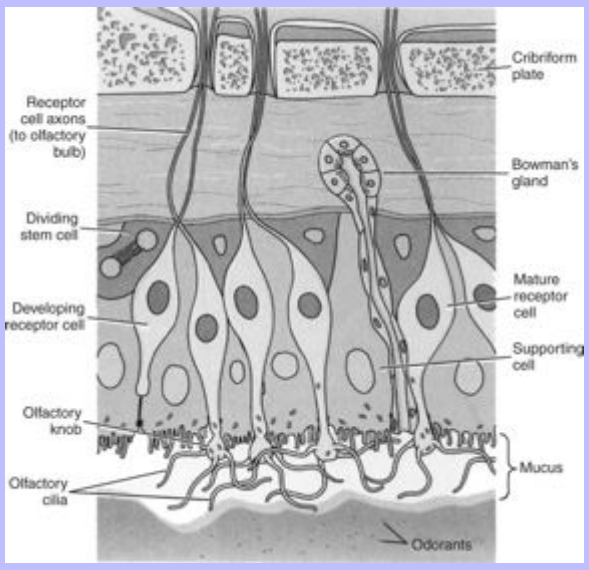
210.1.2 Regulation and Conditioning of the Inspiratory and Expiratory Airflow

The respiratory airflow through the nasal cavity is regulated by the ventilatory control systems. The nose represents an important part of the resistance of the airway and thereby influences gas exchange in the alveoli. The resistance has to be overcome by greater negative pressure in the thorax during inspiration, which leads to better expanding and filling of the alveoli by the inspired air and a greater venous blood flow in the lungs. In humans, a prolonged increase in nasal resistance due to severe obstruction can lead to cor pulmonale, cardiomegaly, and pulmonary edema.[2] In dogs, pulmonary edema is known to develop in laryngeal obstruction. Pulmonary edema may occur by a similar mechanism when severe obstruction of nasal airflow exists. The most common consequence of increased resistance is, however, mouth breathing.

Heating, or cooling of inspired and expired air as it passes through the nose is largely accomplished by radiation from the mucosal blood vessels. The flow of blood is from posterior to anterior, opposite to the flow of the inspired air. Humidification occurs by evaporation from the blanket of mucus covering the mucosa and the serous fluid from the nasal glands. The nasal blood flow and the activity of the nasal glands are regulated by the autonomic nervous system. The autonomic innervation of the nose consists of parasympathetic and sympathetic nerve fibers, joined together in the vidian nerve. The conditioning of the inspired air by the nose

is an important function for protection of the alveoli. Even under extremely dry or cold conditions, the bronchi receive air warmed to body temperature with a humidity of around 98%.

Figure 210-1 Diagram of the olfactory epithelium showing the major cell types and the projection of the olfactory receptor neurons to the bulb (see discussion of Olfaction in text). Bowman's glands produce mucus, and supporting cells help to detoxify chemicals that come in contact with the epithelium. (Courtesy Neuroscience. Sunderland, MA, Sinauer Associates, Inc., 1997, p. 267)



210.1.3 Mucosal Cleaning

The pseudostratified respiratory mucosa in the nose consists of ciliated, intermediate, basal, and goblet cells. They rest on a well-defined basement membrane supported by a deep, loose lamina propria containing small blood vessels, venous plexus, and ducts of mucous and serous glands, sensory nerves, and blood cells. The tall ciliated cell is the predominant type, and it extends from the basement membrane to the luminal surface, where cilia admixed with microvilli are found. The cilia actively move the overlying blanket of mucus by a to-and-fro movement, called the *ciliary beat*. A more forceful forward movement and a less forceful recovery beat occurs. The forward movement transports the mucus blanket toward the pharyngeal end of the esophagus. The two-layer mucous blanket is sticky, tenacious, and adhesive. The outer layer is more viscid than the deeper, periciliary layer. Insoluble particles, allergens, and bacteria caught on the outer layer are thus carried to the esophagus. Soluble material reaches the periciliary layer and is absorbed.[3]

Sneezing starts with a rapid inspiration followed by an involuntary, sudden, violent, and audible expulsion of air through the nose and mouth. The reflex occurs after stimulation of sensory receptors in the nasal mucosa. It is the ultimate cleaning procedure for the nasal cavity in dogs and cats.

210.1.4 Olfaction

Three sensory systems are dedicated to the detection of chemicals in the environment: (1) olfaction, (2) taste, and (3) the trigeminal chemosensory system.[4] Olfactory information can influence feeding behavior, social interaction, and reproduction. A dog's sense of smell, together with its personality and intelligence, functions as a nose for humans in many circumstances.

The transduction of olfactory information occurs in the nasal olfactory epithelium, the sheet of neurons and supporting cells that lines the caudolateral wall, the ethmoidal conchae, and the dorsal part of the nasal septum.[5,6] The olfactory receptor neuron is a bipolar neuron that gives rise on its basal surface to an unmyelinated axon that carries the olfactory information to the brain. At its apex the receptor neuron has a single process that expands into a knoblike protrusion from which several microvilli, or olfactory cilia, extend into the thick layer of mucus that lines the nasal cavity and controls the ionic milieu of the olfactory cilia (Figure 210-1).

Generation of receptor potentials in response to odors takes place in the cilia of receptor neurons. The axons of the olfactory receptor cells form the olfactory nerves that pass through the cribriform plate directly to the olfactory bulb, on the anteroventral aspect of the ipsilateral forebrain. Olfactory information is passed to the amygdala and primary olfactory cortex. Further pathways for processing olfactory information include the thalamus, hypothalamus, entorhinal cortex, and hippocampus.[7]

210.2 HISTORY, CLINICAL SIGNS, AND PHYSICAL EXAMINATION

210.2.1 History and Clinical Signs

The medical history in nasal disease often includes clear statements of specific problems, because the signs of nasal disease—discharge, sneezing, bleeding—are obvious to the owner. Additional questions should be asked about the animal's general condition, appetite, drinking, activity, and endurance, and about changes in its habits. These questions and a general clinical examination are indicated because some systemic diseases cause nasal discharge (distemper, viral rhinotracheitis) or epistaxis (bleeding disorders), whereas some nasal diseases (such as advanced aspergillosis) can cause general malaise, and dyspnea can occur in obstructive nasal disease.

If nasal discharge is the predominant sign, the following questions should help determine whether it is from the left, the right, or both nostrils. If a nasal discharge is present, it should be characterized (watery, mucoid, pus, blood) and its frequency noted. Discharge occurring only during sneezing indicates a less productive mucosal disease than does continuous discharge. Occasional nasal bleeding is less alarming than frequent and profuse nasal bleeding, which can be fatal.

Sneezing, like coughing, is a reflex associated with protection of the mucosa. Particles, foreign bodies, inflammation of the mucosa, or abnormal turbulence in the nasal cavity associated with local drying of the mucosa can stimulate the sensory receptors in the mucosa. Continuous sneezing can cause irritation of the mucosa, leading to more sneezing and sometimes epistaxis.

Pain in the nose may only become obvious when the animal begins to react adversely to the owner's customary petting. A dog with pain in the nose may object to having a collar or the loop of a leash drawn over its head,

even though this is usually associated with the pleasure of a walk. Questions to obtain information about nasal pain should be adapted to the living conditions of the dog or cat.

A nasal stridor is a soft, rustling or sniffing sound that is synchronous with inspiration, expiration, or both. Narrowing of the nasal passageway, which increases the velocity of the airflow, causes the sound.

Dyspnea may be caused by nasal obstruction in cats and dogs, both of which tend to avoid mouth breathing even in this situation, almost to the point of suffocation. Apparently, avoiding the consequent bypassing of the nasal function of air cleansing and conditioning has a high priority.

210.2.2 Physical Examination

After the shape of the nose as a whole is evaluated, the clinician should listen to the animal's respiration for nasal stridor. Under quiet conditions, the clinician should listen close to the dog's (and especially the cat's) nose while gently closing its mouth. If stridor is noted and the clinician suspects it is caused by nostrils that are too narrow, moving the nasal alae laterally can change the tone of the stridor. Symmetry of the airstream can be examined by watching the movement of a small fluff of cotton held in front of each nostril. At the same time, the odor of the expired air can be noted. The area around the nostrils should be inspected for nasal discharge or crusts and the nasal plane for epithelial crusts (which could be caused by pathologic dryness), epithelial lesions, and depigmentation. The ventral wall of the nasal passages, which also forms the roof of the mouth, should be inspected through the opened mouth. The teeth, especially the canine teeth, should be inspected at the same time, because dental abnormalities can cause disorders of the nose.[8] More in-depth inspections belong to special diagnostic procedures and require anesthesia.

210.3 SPECIAL DIAGNOSTIC PROCEDURES

210.3.1 Radiography

The standard radiographic examination of the skull consists of a lateral and a dorsoventral projection. These radiographs may provide all the information that is needed, or they may serve as a part of the *survey* examination. These standard projections are usually of limited value in examination of the nose and nasal sinuses, and special projections, such as craniocaudal radiographs, open-mouth projections, or radiographs with intraoral film, are required.

Radiography of the skull demands the most stringent and careful radiographic technique. Any unintended obliquity in positioning will hinder evaluation of the radiographs. Deep sedation or general anesthesia is mandatory. When the diameter of the skull exceeds 10 to 12 cm, a grid must be used to diminish the unfavorable effect of scattered radiation on radiographic quality. A grid is not used when part of the skull is radiographed in open-mouth projections or when radiographs are made with intraoral film. Both nonscreen film in a lightproof envelope for intraoral application and screen film in a cassette with intensifying screens should be available. Nonscreen films require a much longer exposure time but produce radiographs with greater detail.

Radiographs provide a complete overview of the anatomy, with high spatial resolution. However, superimposition of structures on the film may make it difficult and sometimes impossible to distinguish a particular detail, especially when structures differ only slightly in density.

210.3.2 Computed Tomography

Like conventional radiography, computed tomography (CT) is based on differences in attenuation of an x-ray beam in different parts of the body. With the x-ray beam collimated to a narrow fan shape, the x-ray tube revolves around the object during exposure and the beam is altered as it penetrates the object. An array of sensitive detectors on the opposite side of the object quantitates the x-rays passing through, thereby determining the x-ray attenuation in different parts of the object, in all projections. Computer analysis of this collection of attenuation measurements results in a cross-sectional image of the object. This product is then displayed on a monitor with high spatial resolution and higher contrast resolution than can be provided by conventional radiographs. An intravenously administered radiographic contrast agent should help to define normal from abnormal tissue and facilitate the recognition of blood vessels. Because the images represent "slices" of the object, they do not suffer from superimposition, but they also do not provide a survey view.

Positioning of the animal is just as important in CT as in conventional radiography. The position of the object within the gantry will determine the scan plane. Support is perpendicular to the opening of the gantry and perpendicular to the scan plane. Therefore CT of the body is always axial, perpendicular to the long axis of the body, with some adjustment possible through angulation of the gantry relative to the dog or cat. Other scan planes can be achieved if the object can be positioned differently relative to the gantry opening. This is important, because interfaces between organs or structures can only be imaged satisfactorily when they are perpendicular to the scan plane. The head in particular can be easily examined in different scan planes. Transverse (coronal) scans of the head are made with the animal in prone or supine position and the head extended. Dorsal (axial) scans are made with the animal in supine position and the nose pointing upward. Sagittal scans are made with the animal in lateral recumbency and the head raised on a support.

210.3.3 Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is based on the magnetic properties of atomic nuclei that have an odd number of protons. Because protons are in a continuous state of rotation, called the *nuclear spin*, and have an electrical charge, they may be thought of as tiny magnets. The hydrogen nucleus consists of a single proton, and hydrogen is abundant in living tissues; therefore hydrogen is eminently suitable for MRI.

In the body the magnetic forces of protons point in all directions, canceling each other out. When the body is placed in a strong, homogeneous magnetic field (in clinical imaging, usually between 0.15 and 1.5 Tesla [1 Tesla being 10,000 times the strength of the earth's magnetic field]), the protons are forced into positions parallel to the axis of this magnetic field, not only spinning around their own axes but also around the axis of the magnetic field, like a child's spinning top. The frequency of this *precession* is called the Larmour frequency, and it depends on the strength of the external magnetic field.

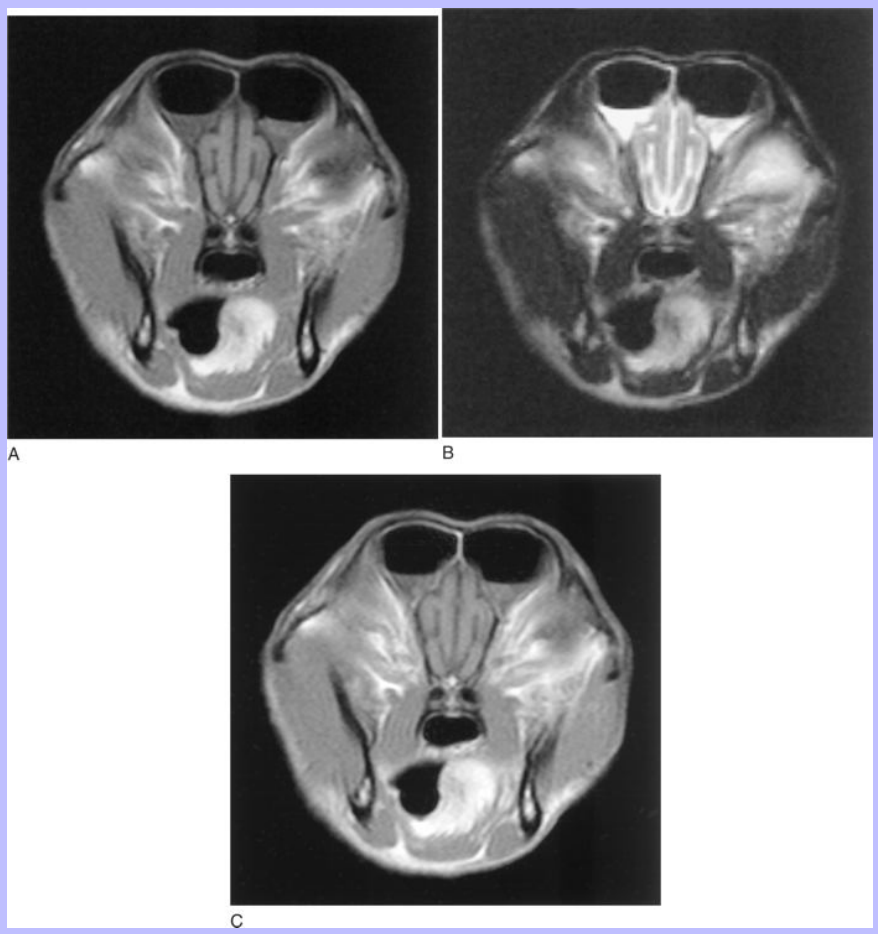
1188

1189

Using radio waves of the same frequency as the precession frequency, the protons can be made to resonate: they will precess around the axis of the external magnetic field at a larger angle, and all protons will be in phase. When the radio frequency wave is switched off, pulse relaxation occurs through two phenomena: (1) the protons realign in the magnetic field (T1 relaxation), and (2) they go out of phase (T2 relaxation). During the process of relaxation, the protons emit weak radio signals; it is these signals that are used to create the images. The images may be dominated by the concentration of protons (proton density), by T1 relaxation (T1-weighted images), or by T2 relaxation (T2-weighted images).

By using gradient coils to create small variations in the x, y, or z direction of the external magnetic field, certain scan planes and slices can be selected in which the precession of protons has exactly the right frequency to be susceptible to the radio wave pulses. Images can then be made in different scan planes without having to reposition the patient. These images are influenced by the concentration of hydrogen nuclei in the part of the body being examined, by the chemical nature of the environment the nuclei are in, and by the interactions between nuclei. MRI provides detailed anatomic images with soft tissue contrast that is superior to that of CT. The soft tissue contrast may be further enhanced by the intravenous administration of a contrast medium that is a paramagnetic substance (usually gadolinium). Its predominant effect is to shorten T1, so the regions that take it up are bright on T1-weighted images (Figure 210-2).

Figure 210-2 Transverse magnetic resonance image (MRI) showing fluid in the frontal sinuses of a dog. The fluid is dark on a T1-weighted image **(A)** and bright on a T2-weighted image **(B)**. After the intravenous administration of contrast medium, the T1-weighted image **(C)** reveals enhancement of the well-vascularized mucosa of the frontal sinus but not of the fluid.



210.3.4 Rhinoscopy

Rhinoscopy is a relatively simple procedure in dogs and cats. It requires anesthesia and tracheal intubation to prevent air circulation through the nasal cavities. Most veterinarians prefer to perform the examination with the dog or cat in sternal recumbency, in a sphinxlike posture. A firm pillow is placed between the head and the front legs so that the head is stabilized but not fixed. The rhinoscopic examination is preceded by a careful inspection of the oral cavity and the pharynx.

A simple otoscope can be used for visualization. It should be of good quality, having a strong light source and dark specula, to illuminate the rostral part of the nasal cavity. The nostril is approached from the lateral side at an angle of 45 degrees to the vertical surface of the nasal plane. The tip of the speculum is placed near the lateral limit of the nostril and is then introduced by slowly turning the otoscope until its line of vision is parallel to the nasal cavity. This movement is necessary to push the nasal ala, which obstructs the opening, into a lateral position.

Once the otoscope is introduced, visibility is often poor. Nasal disease often causes discharge and the tip of the speculum can become blocked by mucus. The lens of the otoscope can be slid slightly to one side, allowing the introduction of a small suction cannula while vision through the lens is maintained. The mucus is removed under visual control, and the rostral part of the nasal cavity is then examined.

The use of an otoscope is often preferable for diagnosis and removal of foreign bodies that have entered the nasal cavity via the nostril. A forceps (called a *foreign body forceps*) developed for use through an otoscope under visual guidance can be found in catalogs for human otoscopic instruments.

An endoscope is needed for complete examination of the nasal cavity. The basic equipment includes a light source, a flexible fiber-optic cable, and a small diameter endoscope. The author and colleagues prefer the 25-degree vision rigid endoscope that is 2.7 mm in diameter and about 15 cm long. The best instruments have a wide-angle lens, which is important for orientation and facilitates the examination. This scope is adequate for most cats and dogs. For small cats, a 1.2 mm diameter rigid scope is needed. In most cats and dogs the 2.7 mm scope can be introduced, and alongside it a suction cannula (size 6) or a foreign body or biopsy forceps can be passed.

The light source for rhinoscopy can be a single-outlet model, but a combined light source and electronic flash generator is necessary to obtain photographic images. The camera should be adapted to the telescope and the timing of the flash. For teaching purposes a chip camera and a video recorder are great assets. Additional equipment for rhinoscopy includes several suction cannulas (size 6), a vacuum source, a selection of biopsy forceps, and a small dropper bottle of 0.1% adrenaline solution to stop profuse bleeding (no more than 1 or 2 drops should be used at a time).

The anatomic borders that guide the inspection of the nasal cavity are the nostril rostrally, the nasal septum medially, the roof of the nasal cavity dorsally, and the bottom of the nasal cavity ventrally. The cribriform plate is part of the caudal boundary, the other part being the ventrally positioned opening to the nasal pharynx, the choanae. The endoscopic procedure aims at bringing the greater part of the nasal cavity into view. The procedure is limited by the choanae, if not by the pathologic process. Careful maneuvering and repositioning of the endoscope should result in a reliable impression of the normal and pathologic structures in the nasal cavity.

The main indications for rhinoscopy are a history of unilateral nasal discharge, the known or probable entrance of a foreign body, obstructive disease indicating tumor with no conclusive radiographic findings, and severe rhinitis with a suspicion of aspergillosis. In all other cases of chronic nasal disease with no significant findings by radiography, rhinoscopy might be helpful but is not always conclusive.

The inspection of the nasopharynx and choanae can be accomplished with a flexible endoscope having a diameter of 4 mm and being capable of 180-degree retrospective vision, introduced via the mouth and then around the soft palate. This instrument not only provides visualization of the lesions but also affords the opportunity to biopsy.

210.3.5 Olfactory Tests

No simple method exists to study olfaction in dogs. The sense of smell should be tested by activation of the olfactory receptor neurons and activation of the brain. The activation of the brain is recorded by electroencephalographic olfactometry analysis. Some authors have reported results in dogs with supposed normal olfactory function and in those that have lost the sense of smell.[9–11]

210.4 CONGENITAL DISEASES

Congenital malformation of the nasal plane is a common finding in brachycephalic breeds. The cartilage supporting the nasal plane is soft; thus the alae collapse, closing the nares. Corrective surgery is a simple procedure and consists of removing a cone-shaped piece of the ala and suturing the sides of the incision together in such a way that the nasal opening is enlarged.[12]

In dogs and cats, variable congenital lesions of the nasal plane or more extensive clefts can be repaired surgically. The success of surgery is largely dependant on the available tissue around the cleft. Oronasal and oropharyngeal clefts cause rhinitis and should be considered for surgical repair. Euthanasia may be justified if repair is not possible and nasal discharge and dysphagia are causing recurrent fever and pain. Nasal dermoid sinus cysts have been reported in dogs.[13] This cyst is recognized as a fistula in the midline of the bridge of the nose, producing intermittent discharge. Exploration of the fistula may reveal skin and hair as far down as the nasal septum. This abnormally located tissue must be completely removed before the skin incision is closed. A congenital cerebrospinal fluid (CSF) fistula, causing rhinorrhea, was reported in a cat. It was closed successfully.[14]

The frontal sinuses are variable in size and sometimes even absent. Their absence is not associated with clinical signs. Congenital ciliary dysfunction has been documented in dogs of various breeds. Primary ciliary dyskinesia is a disorder in which ciliary function is ineffective and uncoordinated, resulting in rhinitis, bronchitis, bronchiectasis, and bronchopneumonia. When associated with situs inversus, the clinical syndrome is known as *Kartagener's syndrome*. The initial signs (nasal discharge and coughing) usually begin at an early age, from days to 5 weeks of age. However, some dogs have remained asymptomatic for months. Complications are caused by colonization of the mucosa and the conchae by *Pasteurella multocida* and *Bordetella bronchiseptica*, which can cause hypoplastic conchae via bone resorption.

Mucociliary clearance in the dog's nasal cavity can be measured by placing a small drop of ^{99m}Tc macroaggregated albumin deep in the cavity, via a catheter, beyond the non-ciliated rostral half. The velocity of mucus clearance ranges from 7 to 20 mm/min.[15] The test is not affected by anesthesia. However, not all normal

dogs have a clearance rate within the reference range, and inflammation can change the velocity of the ciliary beat. To avoid spurious values, the test should be repeated and performed bilaterally.

Functional analysis of cilia in vitro is performed by examining transverse sections in electron micrographs after glutaraldehyde-osmium fixation. Major ultrastructural lesions in cilia of dogs with primary ciliary dyskinesia include lack of outer dynein arms, an abnormal microtubular pattern, and an electron-dense core in the basal body.[15] The prognosis is guarded. Affected dogs that develop severe recurrent bronchopneumonia usually die of sepsis. Continuous treatment with broad-spectrum antibiotics may enable such dogs to survive longer. Therefore cultures should be repeated to maintain correct antibiotic treatment based on sensitivity testing. A worthwhile review of treatment and long-term survival in dogs is available.[15]

1190

1191

210.5 INFLAMMATORY DISEASES

210.5.1 Viral Rhinitis

Viral rhinitis is a prominent disease in cats. The initial clinical signs are paroxysmal sneezing, conjunctivitis, and serous ocular and nasal discharge. About 5 days after the onset of sneezing, the nasal discharge becomes mucopurulent and there may be ocular complications. The condition usually persists for 2 to 3 weeks. Feline herpesvirus-1 (FHV-1) and feline calicivirus (FCV) are the most prevalent and virulent respiratory pathogens of cats and account for at least 80% to 90% of their infectious upper respiratory tract (URT) infections.[16,17] The introduction of modified-live virus (MLV) vaccine against these two viruses has substantially decreased mortality and morbidity but has not eliminated the diseases. Immunization against these viruses protects the cat from development of severe disease but not from infection.[18]

Because these viruses can spread rapidly among kittens and the prevalence of chronically infected virus carriers is high, elimination of the disease is not feasible. It is estimated that 80% of cats recovering from acute infection become chronic carriers. The predominant route of infection is by direct cat-to-cat contact.[19] The chronic carrier state may develop subsequent to infection with either FHV or FCV and also occurs in vaccinated cats. Although cats carrying FHV do not necessarily shed virulent virus continuously, they should be considered infectious when they are sneezing and have nasal discharge. Calicivirus carriers shed virulent virus continuously from the oropharynx. They may have no clinical signs or mild nasal discharge, gingival ulceration, and periodontitis.

Viral rhinitis is a prominent clinical sign of canine distemper (Figure 210-3). Vaccination has reduced the occurrence of the disease to sporadic cases in countries where stray dogs are limited and veterinary care adequate. Herpes infection in newborn puppies is characterized by profuse mucopurulent nasal discharge. The diagnosis is usually made at autopsy.

Figure 210-3 A 5-month-old Samoyed with distemper and bilateral mucopurulent discharge. Viral rhinitis is a prominent clinical sign of canine distemper.

210.5.2 Bacterial Rhinitis

Primary bacterial rhinitis is uncommon in both dogs and cats. Bacterial rhinitis develops as a sequela to viral rhinitis in cats, can be caused by foreign bodies in both dogs and cats, and occurs secondary to many other disorders due to disruption of normal mucociliary mucosal integrity.

210.5.3 Mycotic Rhinitis

Mycotic diseases involving the nasal cavity, the frontal sinuses, and the nasal plane occur in both dogs and cats. In dogs the most prevalent mycosis in the nasal cavity and frontal sinuses is caused by *Aspergillus* spp. The fungus is also found rarely in the nasal cavity in cats. C*ryptococcus neoformans* is a more common cause of mycotic nasal disease in cats and in certain geographic areas is quite common; nasal infections also occur in dogs. *Alternaria* spp. may infest the nasal plane in cats, causing proliferation of the skin and thereby dyspnea.

Aspergillus spp. are considered to be opportunists, producing infections in man and animals, especially when resistance to infection is reduced or when large numbers of spores are present. Spores of *Aspergillus fumigates* are present on household plants, on furniture made of plant material, around bird cages, and simply in house dust.[20]

In dogs, *Aspergillus* spp. plaques are usually found in the caudal part of the nasal cavity or in the frontal sinus. They are presumed to represent primary infections. The toxins produced by the fungus cause atrophy of the conchae in the areas of the fungus plaques and severe destruction of the mucosa and underlying structures in the entire nasal cavity and frontal sinus. There may be bone resorption and periostitis on the frontal bones, and

atrophy and resorption of the internal surface of the frontal bone may open the way to the brain. The disease may spread bilaterally, destroying all internal and external bony structures, as well as the orbit, the nasal septum, and the nasal plane. *A. fumigatus* was identified in 25 of 27 of dogs (involving the sinus and related structures).[20] Disseminated aspergillosis caused by *A. terreus*, not originating from the airways, has also been reported.[21] *Aspergillus* spp. can be associated with longstanding traumatic changes in the mucosa, caused by persisting foreign bodies in the nasal cavity or oronasal fistulas. These infections are presumed to be secondary to the trauma.

Clinical signs of aspergillosis in the nose and frontal sinus are dominated by profuse mucopurulent nasal discharge and nasal pain. Depigmentation of the nasal plane below the nostril from which discharge appears is a characteristic sign (Figure 210-4). Intermittent hemorrhagic discharge occurs and profuse nasal bleeding is not unusual. When only the frontal sinus is infected, hemorrhagic discharge or profuse bleeding from the nose may be the only sign. The nasal infection is often unilateral initially, becoming bilateral later. Aspergillosis is often not suspected in its initial stage, and histories of nasal discharge present for months are common. No apparent correlation exists between the duration of the initial nasal discharge and the severity or progression of signs by the time of diagnosis. Other factors, such as the number of infecting spores and the resistance of the host, may play a role. Depression is a prominent sign when the frontal sinus is infected.

1191 1192

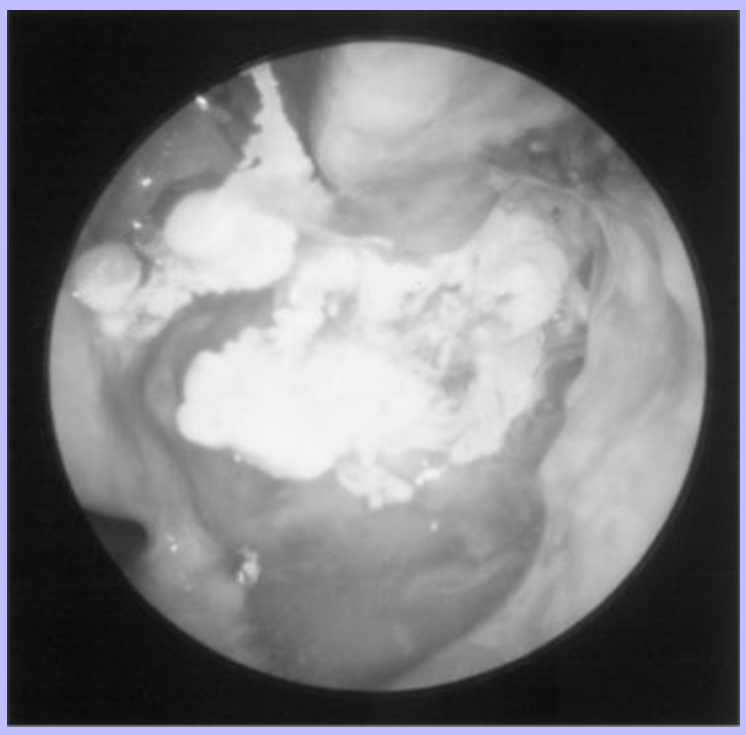
Figure 210-4 Depigmentation of the nasal plane below the nostril from which discharge appears in a dog with nasal aspergillosis in the right nasal cavity.

The diagnosis of aspergillosis as the cause of rhinitis is made by the finding of fungal plaques or positive fungal culture results. Recognition of the fungus plaque is facilitated by the atrophy of the conchae around it, which reduces the normal obstruction to rhinoscopic vision in the caudal part of the nasal cavity (Figure 210-5). The extent of the destruction in the nasal cavities and the frontal sinuses is well demonstrated by radiography, CT, or MRI, but the diagnosis depends on finding the fungus (Figure 210-6). When the fungus is in the frontal sinus alone, radiographs usually demonstrate irregular soft tissue densities in the frontal sinus, thickening of the wall of the sinus, and sometimes reaction of the periosteum. A CT scan may reveal the severity of further bony involvement. A 3 to 4 mm diameter trephined opening in the frontal bone on the side

of the affected sinus can reveal the fungus as thick, grayish-yellow material, sometimes with greenish lumps. This material should be removed and cultured. Cultures from nasal discharge are often negative because the fungus is usually located in the caudal part of the nasal cavity and is not shed in the nasal discharge. A serologic test is available for detecting antibodies to *Aspergillus* spp. in serum.

Treatment of sinonasal aspergillosis is topical or systemic. Topical treatment is usually with enilconazole or clotrimazole. The choice between these two drugs is arbitrary, because there has been no satisfactory clinical trial to compare them. The ongoing discussion is how to apply the suspensions and how long the treatment should be given. The basic idea is to flush the frontal sinus and the nasal cavity (e.g., via tubes introduced through trephine holes). The author's clinical experience (in about 120 cases; an average of 10 per year) indicates that administration of 10 cc of a 10% suspension of enilconazole per tube twice daily for 14 days is sufficient. It is unpleasant for the dog because enilconazole has a bitter taste that most dogs dislike intensely. A retrospective study of cases treated in our clinic (unpublished data) revealed success in about 95% in over 100 cases. Hence 90% success can be expected. A less unpleasant systemic treatment would be much preferred, but the success rates and observed toxicities of other methods are not yet encouraging. Details on clotrimazole therapy have been published.[17]

Figure 210-5 Aspergillus plaque. A rhinoscopic view in the caudal part of the nasal cavity.



Cryptococcosis is found as a cause of rhinitis in dogs and cats. The clinical signs are obstructive rhinitis and mucopurulent discharge. In cats, crusts sometimes occur on the nasal plane and the bridge of the nose. Some cats develop mucopurulent conjunctivitis. In fresh material from the nose placed on a slide and stained with

India ink, *Cryptococcus* spp. organisms are recognized as thick, encapsulated, round to oval yeasts. They can be cultured on Sabouraud's agar.

Ketoconazole, itraconazole, or fluconazole can be used for therapy, which should be continued for 8 weeks. *Alternaria* spp. are found to cause granulomatous infections with crusts on the nasal plane in cats. Antimycotic treatment may be disappointing and removal of the nasal plane, as in nasal plane squamous cell carcinoma, can be a satisfactory solution.[22]

210.5.4 Neurogenic Rhinitis

The clinical signs of neurogenic rhinitis in dogs are dryness of the nasal plane on one or both sides, sometimes with crusts, and slight mucopurulent nasal discharge. The most frequent clinical signs are dryness of one side of the nasal plane together with ipsilateral keratoconjunctivitis sicca and mucopurulent conjunctivitis. The cause of the disorder is loss of parasympathetic innervation and when keratitis sicca is present, the dysfunction also affects the lacrimal, palatine, and nasal glands.[23] In dogs with this disorder, ipsilateral otitis media can be suspected if reddening of the tympanic membrane is noted. The lesion in the parasympathetic nerves may be caused by otitis media, because the parasympathetic nerves are carried in the chorda tympani and pass freely through the middle ear. In all cases, treatment of the otitis media with broad-spectrum antibiotics resolved all problems.

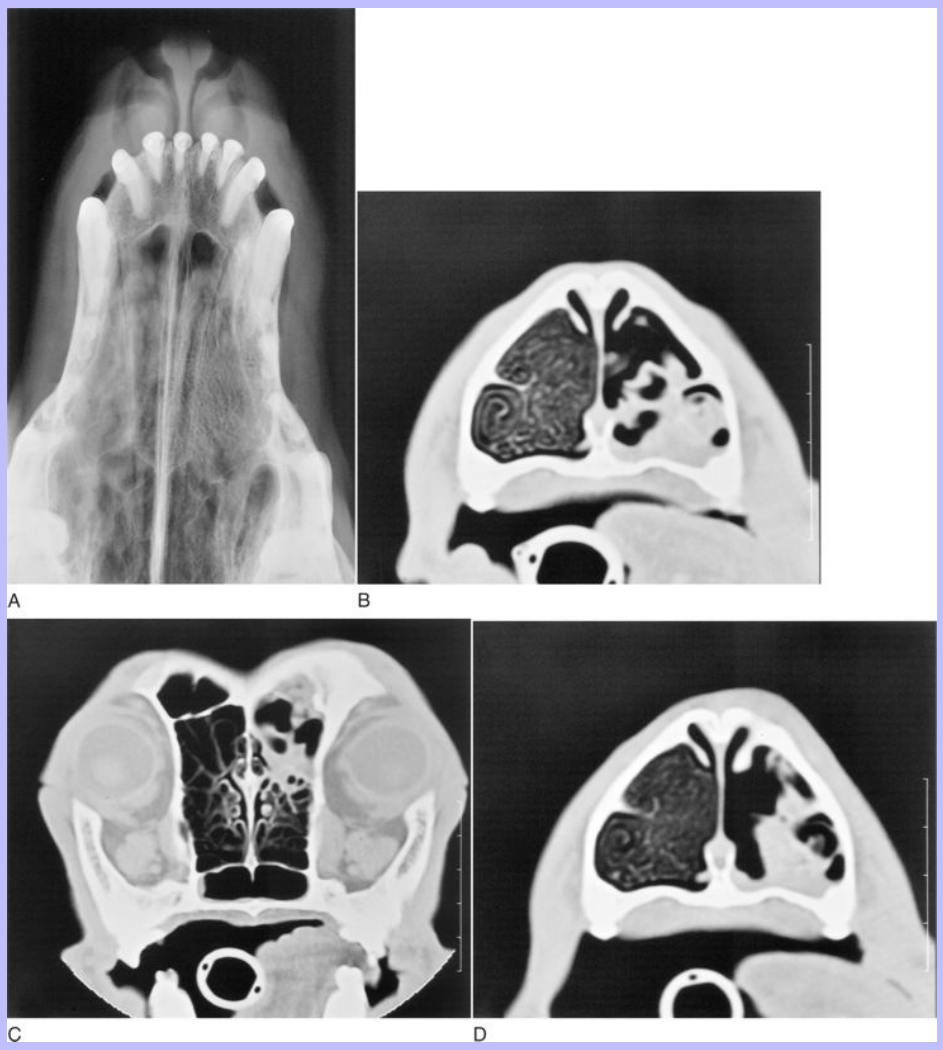
Diagnosis of neurogenic rhinitis is more difficult when it is bilateral. The Schirmer tear test should be helpful, but no values have been reported. Clinical examination and exclusion of other causes may lead to presumption of a possible neurogenic cause. Massaging nonperfumed moistening cream into the nasal plane eight times daily and administering four drops of artificial tears into the nasal cavity four times daily will resolve the clinical signs if the diagnosis is correct. This treatment will be required lifelong, because no known specific treatment for the parasympathetic nerve dysfunction exists.

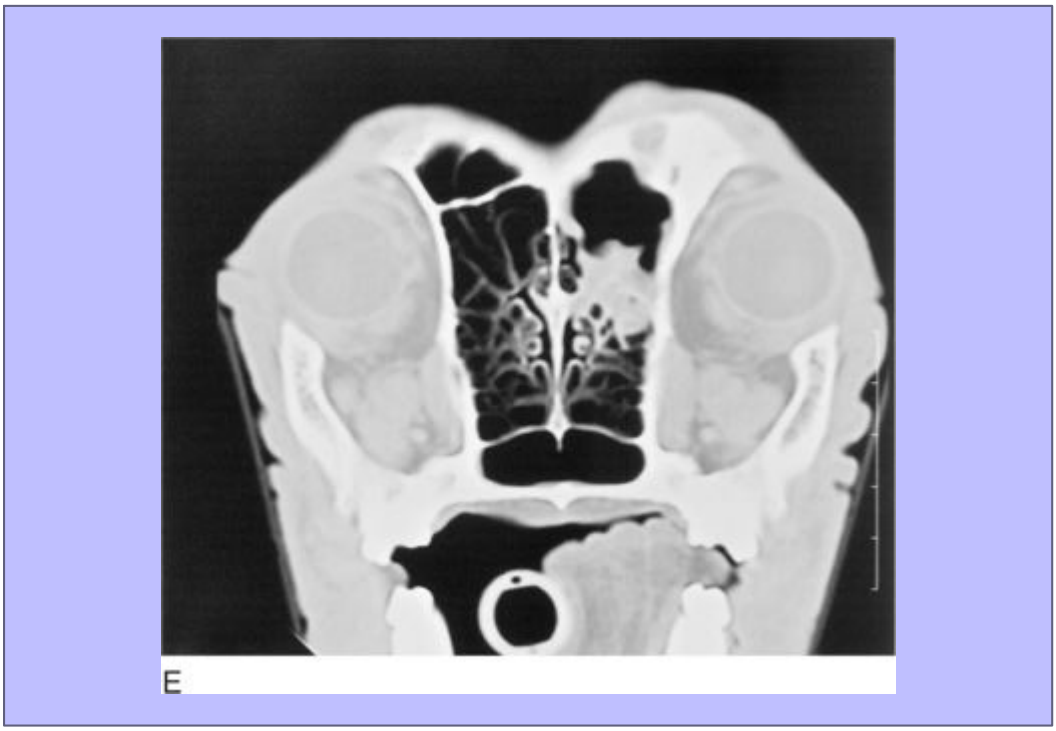
210.5.5 Specific Rhinitis

Polyps occur in the nasal cavity in both dogs and cats. They consist of focal accumulation of edema fluid, hyperplasia of the submucosal connective tissue, and a variable inflammatory infiltrate of eosinophils, plasma cells, and lymphocytes. Hence they are not neoplastic but inflammatory polyps.[24] They are found in the nasal cavity of cats with signs of obstructive rhinitis. Bilateral obstruction may be caused by bilateral polyps or a unilateral polyp that extends into the nasopharynx.

Diagnosis is usually made by rhinoscopy. The polyp is seen as a red mass in the nasal cavity, and biopsy reveals it to be inflammatory tissue. Removal is difficult, usually requiring removal of all structures in the nasal cavity through a small opening in the nasal bone. This damages the olfactory epithelium, and recognition of food is disturbed. When one nasal cavity is freed of polyps, the cat regains its sense of smell with help from the intact side. Bilateral surgery should be avoided and, when necessary, only performed after the cat seems to be fully recovered from the first operation.

Figure 210-6 **A,** Dorsoventral radiograph (intraoral nonscreen film) of the nasal cavity of a Great Dane with aspergillosis of the left nasal cavity and frontal sinus. **B** to **E,** Transverse 5 mm thick computed tomography (CT) images of the nose and frontal sinuses of the same dog before **(B** and **C)** and 6 weeks after **(D** and **E)** successful treatment. The reader should note the remnants of the trephined openings in the nasal and frontal bones. No obvious differences exist between CT images before and after treatment. The extent of the destruction in the nasal cavities and the frontal sinuses is well shown by radiography and CT, but the diagnosis depends on demonstrating the fungus.





Polyps in the nasal cavity are rare in dogs. They are diagnosed by rhinoscopy and biopsy, which reveals inflammatory tissue. They are usually unilateral. Rhinotomy via the nasal bone and removal of all conchae and the polypous tissue relieves the obstruction. Histologic examination will reveal whether the structure is a polyp or an unexpected neoplasm. In dogs, polyps usually recur after 1 or 2 years, but in cats recurrence is rare. 1193 1194

In young dogs and cats, foreign bodies such as grass and other plant material are common. Owners may know when the material entered the nasal cavity, usually via the nostril. Being plant material, the foreign body has the density of soft tissue and is usually not visualized on radiographs. Rhinoscopy in search of a foreign body needs patience and the use of suction, under visual control, to remove mucopurulent exudate before the foreign material is exposed and can be removed. Grass can enter the nasal cavity while a cat is chewing on it, as cats often do. Out of a ball of mucus and grass in the pharynx, a sprig of grass can enter the nasal cavity via the nasopharynx. It can be found by rhinoscopy and removed under visual control via the nostril.

Nasal allergic rhinitis is presumed to occur, but confirmation of the diagnosis has not yet been convincing, partly because IgE-based rhinitis, as occurs in human, has yet to be demonstrated.

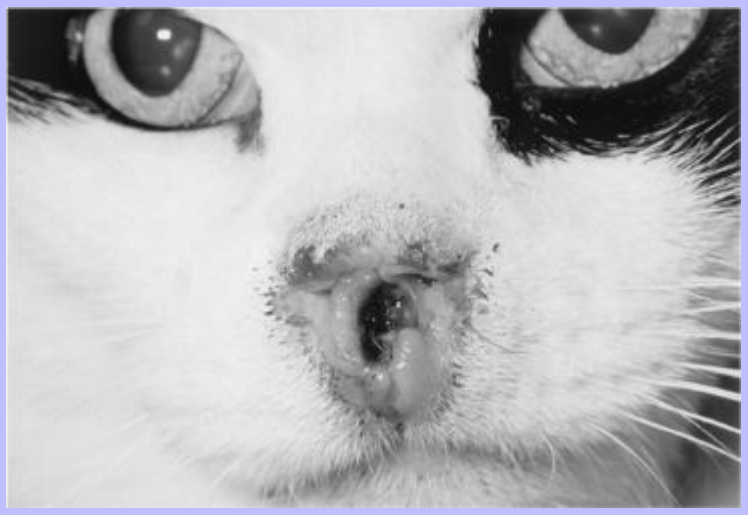
210.6 TUMORS OF THE NASAL PLANE, NASAL CAVITY, AND FRONTAL SINUS

210.6.1 Tumors of the Nasal Plane

Squamous cell carcinoma of the nasal plane is found in cats in most countries of the world (Figure 210-7). The diagnosis should be made by biopsy, but the diagnosis is often delayed because initial biopsies may only reveal inflammation. When the tumor grows and destruction of tissue is in progress, total removal of the process is justified, provided that the removed tissue is submitted for histologic examination. In the

differential diagnosis of processes causing proliferation of the tissue of the nasal plane, with crusts and destruction, infection by *Alternaria* spp. and eosinophilic granuloma should be included. Both are easily identified in biopsy material. Surgical removal of the neoplastic nasal plane in cats has been instructively described.[25] One firm incision will allow histologic confirmation of a tumor-free cut surface. Squamous cell carcinoma of the nasal plane sometimes occurs in dogs. The cosmetic results of removal of the nasal plane are less satisfactory in dogs than in cats. In both, the best results are obtained when tumor growth does not yet extend around the nasal plane. Other tumors of the nasal plane are fibroma and fibrosarcoma, which grow initially beneath the epithelium and do not ulcerate primarily. Surgical removal in an early stage is possible without too much cosmetic damage.

Figure 210-7 Squamous cell carcinoma of the nasal plane of a cat. Biopsy is required to differentiate tumor from inflammatory tissue.



210.6.2 Tumors of the Nasal Cavity

Tumors occur in the nasal cavity of dogs and cats of all ages, but most often in pets over 5 years of age. Almost all are malignant. They invade the surrounding tissue but rarely metastasize before the dog or cat is euthanized. The most frequent tumors are squamous cell carcinoma and adenocarcinoma; less frequent are chondrosarcoma, osteosarcoma, and lymphosarcoma.

The clinical signs include sneezing, hemorrhagic discharge, and mucopurulent discharge. In most cases, unilateral obstruction of the nasal cavity is recognized because of nasal stridor. No evidence of pain is observed, and the dog or cat becomes dyspneic only when the mouth is closed, which means when sleeping. As long as the tumor is unilateral, the dyspnea is moderate. When the tumor obstructs both nasal cavities, dyspnea during sleep becomes a serious hindrance, causing the animal to awaken repeatedly during the night and often be very depressed in the morning. When no therapy is offered beyond permanent tracheostomy, which is rarely accepted by the owner, recurrent nasal bleeding and dyspnea are the usual reasons for euthanasia, in both dogs and cats. Cats, however, often stop eating, which may provide a humane end point and a reason for euthanasia.

Radiographs should be obtained with the dog or cat under anesthesia. Tumor is suspected when increased density is found in one or both nasal cavities, with loss of normal maxillary and ethmoidal conchae.[26] The extension of the tumor should be considered when estimating the animal's life expectancy, but this is usually decided by the owner's interpretation of the quality of the animal's life. In all cases in which the radiographic diagnosis is uncertain, rhinoscopy is the next diagnostic procedure. Under rhinoscopic visualization the tumors vary greatly in shape and firmness, and their color ranges from gray to deep red. Biopsies are always taken for histologic confirmation of the diagnosis. If no therapy is planned, neither CT nor MRI is indicated. Radiation therapy could be considered, and details have been described.[27]

210.6.3 Tumors of the Frontal Sinus

Tumors in the frontal sinus develop within a bony case. The frontal sinus does not have a specific function; therefore development of the tumor will be noticed only when unilateral nasal bleeding is recurrent or when the enlarging tumor causes pressure atrophy of the frontal bone and becomes apparent as a swelling arising in the frontal sinus. 1194 1195

In the diagnostic investigation of recurrent nasal bleeding, radiographs will be made of the nasal cavity and the frontal sinus, and a radiographic density in the frontal sinus will be noticed. The differential diagnosis of such a density in combination with a radiographically normal ipsilateral nasal cavity includes aspergillosis, tumor, and accumulation of mucus associated with obstruction of the nasofrontal duct. Because the frontal sinus is separated from the brain by only a thin layer of bone, additional diagnostic imaging by CT or MRI is valuable. When a swelling arising in the frontal sinus is recognized by physical examination, the same procedure of taking radiographs followed by CT or MRI is indicated. With these imaging tools, extent of the lesion and differentiation of the contents of the frontal sinus may be determined. Tumor in the frontal sinus can be recognized by CT or MRI with an intravenously administered contrast medium. Vital tissue will be enhanced by the contrast medium, whereas debris will not. It must then be determined by CT or MRI whether the bony case of the frontal sinus is intact, especially whether the orbit or the brain is invaded, and whether the contralateral frontal sinus is included in the process.

When these procedures indicate that the tumor can be removed, a surgical approach via the frontal bone is indicated. At the end of the surgical procedure it is important to examine the patency of the nasofrontal duct and to relieve any obstruction. Like tumors in the nasal cavity, most tumors in the frontal sinus are malignant, and complete surgical removal is unlikely. Biopsy of the tumor through a small trephined opening in the frontal bone should be considered as an intermediate step.

210.7 TRAUMA TO THE FRONTAL SINUS AND THE NOSE

210.7.1 Trauma to the Frontal Sinus

Blunt or sharp objects can cause traumatic injury to the frontal sinus. The frontal bone in dogs and cats is relatively thick and provides good protection, so a fracture of it implies that a heavy blow to the head has occurred. The pet should therefore be given a thorough clinical examination for (1) signs of shock such as tachycardia, hypotension (prolonged capillary refill time, weak pulse), rapid respiration, dilation of the pupils, hypothermia, muscle weakness, restlessness, and depression or even coma[28] and (2) other fractures or wounds. Frontal bone fractures do not require immediate attention unless brain damage is suspected. In the absence of signs of brain damage, and when other traumatic injuries have been attended to, the nature and extent of the

frontal bone fracture should be examined by radiography, CT, or both (Figure 210-8). Prolonged anesthesia is needed; thus these procedures are usually delayed for 24 hours or more.

When bone fragments are seen to be present in the frontal sinus they should be removed. Like any foreign body, small bone fragments are likely to become sequestered. Surgery should be performed with full attention to aseptic procedures. Before attempting reconstruction of the frontal bone, it is important to examine the patency of the nasofrontal duct and to relieve any obstruction. Airtight suturing of the subcutis, including periosteum, followed by routine skin closure prevents the development of subcutaneous emphysema. Administration of broad-spectrum antibiotics for 3 weeks and strict limitation of activity during this period (keeping a cat confined to the house) will prevent complications.

Figure 210-8 Transverse 5 mm thick computed tomography (CT) image through the frontal sinuses of a Labrador retriever with fractures of the right frontal sinus caused by being struck by a car. CT allows accurate assessment of the nature and extent of the fractures and identification of loose fragments in the frontal sinus. Bone fragments seen in the frontal sinus should be removed.

210.7.2 Trauma to the Nose

Trauma to the nose is characterized by massive bleeding, which adds to the other effects of the impact in promoting shock. A thorough examination for signs of this is indicated (see Trauma to the Frontal Sinus). Fractures and wounds should be noted, but priority must usually be given to the treatment of hypovolemic shock.

When the dog or cat is sufficiently stable, the larger vessels should be ligated and skin sutures should be placed as needed. Skin sutures, sometimes supported by subcutaneous sutures, may be sufficient to remodel the outer form of the nose. Fractures of the choanae are best left alone, because they are unlikely to ever result in obstruction. Severe traumatic damage to the nose almost always causes temporary obstruction, making tracheotomy necessary. Adequate oxygenation aids in avoiding general malaise and loss of appetite. Liquid or soft food facilitates eating. In dogs the tracheal cannula is often left in place for 10 days or longer. In cats that have difficulties with long-term tracheostomy, a small intranasal catheter may be placed and connected to the oxygen supply. Use of this method, however, depends on the pathway through the wounded nose. In the author's experience, the nose is functionally adequate in 2 to 3 weeks. If needed, more corrective surgery could be attempted after 6 weeks.

210.8 EPISTAXIS

Epistaxis (i.e., nasal bleeding) is often spontaneous and transient, and it is apparently due to a local cause. When it is recurrent or profuse, with considerable loss of blood, diagnostic investigation is indicated. The several causes of epistaxis should be considered in planning diagnostic procedures. Recurring epistaxis occurs in both dogs and cats, but profuse nasal bleeding occurs mostly in dogs. Recurring epistaxis in dogs and cats can be caused by ulcerative rhinitis, mycotic rhinitis, and tumor in the nasal cavity. Profuse nasal bleeding in dogs is most often caused by aspergillosis in the nasal cavity or frontal sinus, or it is caused by tumor in the nasal cavity and frontal sinus. Epistaxis can also be the sole sign of defects in primary hemostasis (platelet plug formation) or secondary hemostasis (coagulation cascade).[29] Lesions in the nasal mucosa leading to epistaxis can also occur with systemic diseases such as leishmaniasis and amyloidosis.

1195 1196

Epistaxis caused by local disease in the nasal cavity or frontal sinus is approached (as are all nasal diseases) by a general and specific examination for nasal disease, as described earlier in this chapter. When the bleeding has occurred recently, radiographic examination should preferably be delayed for at least 48 hours because clotted blood can be misinterpreted as a mass in the nasal cavity. Rhinoscopy should also be delayed for at least 48 hours after the bleeding has stopped, because the presence of blood clots hinders inspection and could lead to misinterpretation of findings.

In the meantime, profuse nasal bleeding should be stopped. It is best to sedate the animal (phenobarbital [2 mg/kg] is advised, because it does not affect blood pressure). After considerable blood loss, sedation that causes hypotension could lead to shock in association with hypovolemia and should therefore be avoided. Sedation will help stop bleeding.

Nasal tamponade is only acceptable for a short period and under anesthesia. For less profuse bleeding, nasal drops of 0.1% adrenaline are helpful. The use of adrenaline should, however, be restricted. Overdose could cause death due to vasoconstriction of the arteries supplying the brain. The administration of three drops in one of the nasal cavities in dogs and one drop in cats, repeated up to three times per 24 hours, is acceptable and effective when used during the bleeding. It should not be used in an attempt to prevent nasal bleeding. When examination

of the nasal cavity and the frontal sinus reveals no cause for the bleeding, further investigation of primary diseases causing hemostasis is indicated.

211 CHAPTER • 211 Diseases of the Throat

Nolie K. Parnell

211.1 GENERAL ANATOMY AND PHYSIOLOGY

The throat is an important, but mostly ignored, communal area of both the gastrointestinal (GI) and respiratory tracts. Anatomically it is divided into the pharynx and larynx. The pharynx is further divided into the nasopharynx, the oropharynx, and the laryngopharynx. The nasopharynx is located dorsal to the soft palate, between the choanae and the intrapharyngeal opening. It is a functional space that allows the nasal cavity to communicate with the larynx. The oropharynx is ventral to the soft palate and extends from the palatoglossal arches rostrally to the base of the epiglottis caudally. The intrapharyngeal opening and the rostral border of the esophagus create the boundaries of the laryngopharynx, the most caudal part of the pharynx.[1] The laryngopharynx functions as an intersection to both the respiratory and digestive tracts. The larynx consists of three unpaired cartilages (epiglottis, cricoid, and thyroid) and one pair of arytenoid cartilages. The glottis (or cranial opening of the larynx) is composed of the corniculate and cuneiform process of the arytenoid cartilages and the epiglottis. Minor anatomic differences exist between feline and canine larynx.[2] Cats lack the interarytenoid cartilage found in dogs and instead have an interarytenoid ligament in its place. Cats also lack a vestibular ligament. Due to this deficiency the feline arytenoid cartilage is connected to the ventral aspect of the larynx by the vocal ligament. Another important anatomic difference is cats lack the laryngeal ventricles that are found between the vestibular and vocal folds in the dog. No dramatic differences exist between feline and canine innervation and muscles of the larynx.

Swallowing, or deglutition, is a complex reflex action that coordinates many structures. Cranial nerves, the swallowing center in the reticular formation of the brain stem, the muscles of mastication, tongue, soft palate, pharynx, larynx, and esophagus are all involved in what appears to be a simple act of allowing transport of material from the mouth to the stomach.[3] As a lesser recognized function, swallowing also allows saliva and debris to be removed from the pharynx. Deglutition begins as a voluntary act but during its execution becomes a reflex. Deglutition is traditionally described as having three phases: (1) oral, (2) pharyngeal, and (3) esophageal. The oral phase begins when mastication is complete. The tongue then moves the food bolus that is organized at the base of the tongue to a position that is on midline between the tongue and the hard palate. Motor fibers to the tongue are supplied by cranial nerve XII. Sensory fibers from the oral cavity and motor fibers to the masticatory muscles and soft palate originate from cranial nerve V. The oral phase is voluntary, but when the food bolus is pushed into the pharynx, receptors are stimulated that initiate the involuntary, or reflex, component of deglutition. Sensory receptors are found in the pharynx, palate, and epiglottis. Impulses from these receptors are transmitted along the glossopharyngeal nerve, recurrent laryngeal branch of the vagus nerve, and the maxillary branch of the trigeminal nerve to the swallowing center in the medulla (located in the floor of the fourth ventricle). The efferent arm of the reflex involves the motor nuclei of cranial nerves V, VII, IX, X, and XII.[4–6] These nerves supply the muscles of mastication, tongue, palate, pharynx, larynx, and esophagus. During the pharyngeal phase the goal is to pass food from the oropharynx into the esophagus and to prevent food from being aspirated into the trachea or moved into the nasopharynx. This is accomplished by elevation of the soft palate and the palatopharyngeal folds moving inward as the vocal cords are pulled together and the larynx is elevated against the epiglottis. The final act during the pharyngeal stage of swallowing occurs when the cricopharyngeal muscle relaxes, the upper esophageal sphincter opens, the bolus moves into the esophagus, the sphincter closes, and the pharyngeal muscles relax. The cricopharyngeal muscle is innervated by the pharyngoesophageal nerve, which is formed by cranial nerves IX and X.[1] The final stage of deglutition, the esophageal stage, transports the

bolus from the esophagus, through the gastroesophageal sphincter, and into the stomach. The esophagus is innervated by the vagus nerve.

The larynx has three functions: (1) to act as a conduit for air, (2) to protect the lower airway from aspiration during deglutition, and (3) vocalization. The glottis remains partially open when an animal is at rest. When greater airflow is needed, the glottis is widened by abduction of the arytenoid cartilages and vocal folds (via cricoarytenoid muscles) during inspiration (and the same structures adduct during expiration). The cricoarytenoid muscles are innervated by the caudal laryngeal nerves, which are derived from the recurrent laryngeal nerves. The recurrent laryngeal nerve innervates all the muscles of the larynx except the cricothyroid muscles that are supplied by the cranial laryngeal nerves.[7] During deglutition the larynx is pulled cranially by the geniohyoideus and mylohyoideus muscles. This allows the epiglottis to close over the larynx, protecting the lower airways. The adductor muscles close the glottis concurrently. This creates an additional defense against aspiration.

211.2 HISTORY AND PHYSICAL EXAMINATION

Animals with diseases of the throat can have a variety of historical complaints. Pharyngeal diseases can be confusing because historical findings can be related to swallowing difficulties or the upper respiratory tract (URT). Historical findings secondary to laryngeal dysfunction are usually related to either inability to regulate airflow and protect the airway, or they are related to changes in vocalization. Respiratory sounds can be extremely useful in localizing the disease, whether it is pharyngeal or laryngeal, but they are not helpful if one tries to attribute a specific respiratory sound to a specific condition. Coughing, dyspnea, and nasal discharge are common clinical complaints. Stertor, a snoring sound heard on inspiration, is usually due to an intermittent obstruction such as an elongated soft palate. Stridor, an inspiratory high-pitch wheeze, is most commonly associated with laryngeal lesions. Stridor is created by air turbulence through a narrowed laryngeal opening. Any changes in vocalization would suggest a laryngeal disorder. Reverse sneezing, which is described as short periods of forceful inspiratory nasal effort with the head pulled back, indicates irritation to the dorsal nasopharyngeal mucosa.[8] Dysphagia cases can be confusing because ineffective swallowing may not be obvious to the owner and may not be the primary historical complaint. Other signs such as coughing, gagging, regurgitation, and nasal discharge may be reported in animals with either oropharyngeal dysphagia or other diseases of the throat.

A complete physical examination (including a neurologic examination) is important when evaluating animals with pharyngeal or laryngeal disease because dysfunction may be indicative of systemic disease (i.e., myopathy, neuropathy) or there may be secondary complications from the disorder (e.g., aspiration pneumonia). If laryngeal disease is suspected, the larynx should be palpated for pain or structural abnormalities. The area over the larynx should be ausculted for abnormal sounds secondary to turbulence. Part of this complete physical examination may include exercising the patient, because occasionally manifestation of the disease only occurs after physical exertion. Many animals will have dyspnea, and a thorough physical examination may not be possible until the animal is stable. Significant airway compromise may be overlooked. It is important to assess the degree of respiratory compromise by evaluating the patient's attitude, posture, mucous membrane color, and both respiratory rate and pattern. Precluding the emergency situation, once the general examination is complete one may concentrate on examining the oral cavity. It is extremely difficult, if not impossible, to adequately evaluate the larynx and pharyngeal areas without heavy sedation or general anesthesia. In most cases it is easier for the examiner, and safer for the animal, if tracheal intubation is performed. A standard method of evaluating the oral cavity should be established so that one does not miss an important abnormality. The larynx is evaluated both for structural problems and functional abnormalities; the pharynx is evaluated for physical abnormalities. Pharyngeal function cannot be evaluated when the patient is sedated; rather, video fluoroscopy is recommended when critically assessing pharyngeal function.

211.3 DIAGNOSIS

211.3.1 Diagnostic Imaging

Lateral and ventrodorsal radiographic views of both the skull and cervical areas are indicated. Radiopaque foreign bodies can be identified that may be missed on laryngoscopy and pharyngoscopy (e.g., sewing needle embedded in soft tissues). Radiographs are also useful in identifying bony changes associated with chronic inflammation or neoplasia, identifying clues of unreported trauma (e.g., subcutaneous emphysema), and occasionally soft tissue masses. Suggestion of a soft tissue mass is confirmed by direct visualization and histopathology. Thoracic radiographs are also indicated. Symptoms of lower respiratory disease may be masked when a patient has concurrent, and more severe, upper respiratory symptoms. Evaluation for aspiration pneumonia, metastases, or suggestion of a motility disorder (i.e., megaesophagus) is possible.

Ultrasonography and computed tomography (CT) are noninvasive modalities to evaluate the pharynx and larynx. Ultrasonography can identify soft tissue masses, help guide fine needle aspiration, and evaluate laryngeal function.[9,10] The presence of air in these areas can limit the usefulness of this modality in establishing a definitive diagnosis. CT may be used to fully evaluate involvement of neoplasia or middle-ear disease if a nasopharyngeal polyp is suspected.[11]

Videofluoroscopy is essential for any case of dysphagia. A barium swallow allows the act of swallowing to be recorded and studied for abnormalities. The patient should be recorded attempting to swallow barium to mimic liquids and then should be given a meal (canned food mixed with barium) to be recorded. Videofluoroscopy is superior to radiography because it allows all phases of deglutition to be evaluated instead of recording one moment (intermittent moments) of the event. Unfortunately videofluoroscopy is limited to referral centers only.

211.3.2 Pharyngoscopy and Laryngoscopy

Laryngoscopy and pharyngoscopy allow assessment of both structural abnormalities and function of the larynx. A flexible endoscope is used for these procedures because visualization of the nasopharynx requires retroflexion. Occasionally a foreign body will be found just caudal to the larynx and may be retrieved endoscopically. The patient is placed in sternal recumbency and anesthetized with either propofol or sodium thiopental. Once anesthetized, gauze is passed under the maxilla behind the canine teeth. The gauze is used to elevate the head, so external compression of the neck is avoided. Flexible endoscopy is ideal to evaluate the nasopharynx. If that is not possible, the caudal pharynx can be evaluated using a dental mirror and a snook hook. This will be sufficient in evaluating most nasopharyngeal polyps, masses, or caudal foreign bodies. It will not allow diagnosis of more rostral diseases such as nasopharyngeal stenosis. Laryngeal function is usually evaluated first by assessing the motion of the arytenoid cartilages. The traditional approach involves titrating anesthesia that allows both visualization of the arytenoid cartilages and deep spontaneous breaths to occur. In a normal animal the arytenoid cartilages will abduct symmetrically with each inspiration and close on expiration. The frustration with this technique is multiple. Maintaining the correct level of anesthesia is difficult (i.e., the animal is too awake to allow adequate visualization of the arytenoid cartilages or anesthetized so that the patient will not spontaneously breathe); shallow breathing can limit adequate assessment; and concerns about the effect of anesthesia on laryngeal function are legitimate concerns when performing the traditional laryngeal examination. The recently introduced technique attempts to eliminate the effects of anesthesia from the examination. Patients are premedicated with acepromazine maleate and

butorphanol tartrate and induced with propofol. Doxapram hydrochloride (2.2 mg/kg intravenously) is used to increase laryngeal motion and minimize or eliminate the effects of anesthesia.[12]

211.3.3 Miscellaneous

Hematology and biochemical profiles should be performed on patients with pharyngeal and laryngeal dysfunction, but they will rarely confirm the definitive diagnosis. Occasionally virus isolation (feline calicivirus [FCV]) and PCR (feline herpes-1 virus [FHV-1], *Chlamydia* spp., and *Mycoplasma* spp.) are indicated in the diagnostic workup. Culture and sensitivity of tissue or secretions can provide valuable information during the diagnostic workup. Cytology and histopathology are also essential for critically evaluating infiltrative disease or mass lesions.

211.4 DISEASES OF THE PHARYNX

211.4.1 Nasopharyngeal Polyps

Nasopharyngeal polyps are histopathologically benign, pedunculated masses consisting mostly of fibrovascular tissue and variable severity of inflammatory cells.[13] It is the most common nasopharyngeal disease of younger cats and accounts for almost one third of all feline nasopharyngeal diseases.[14] No sex or breed predilection exists; although nasopharyngeal polyps are most commonly found in younger cats (mean range 0.4 months to 6.1 years), this disease should also be included in the differential diagnosis for older cats.[14–17] Nasopharyngeal polyps are believed to originate from the middle ear or auditory tube and then expand into the nasopharynx and external auditory canal.[18] It is unknown why nasopharyngeal polyps occur, but it does not seem likely that the polyps are a manifestation of chronic viral (FCV or FHV) infections.[17] Clinical signs are variable but include nasal discharge, sneeze, stertor, and phonation changes. Definitive diagnosis is made by direct visualization of the nasopharyngeal mass and histopathology. Quite often, nasopharyngeal polyps can be discovered with digital palpation of the soft palate. Diagnostic imaging (skull radiographs and CT) is not necessary for the diagnosis but can provide valuable information toward the extent of the mass and possible middle ear involvement. Treatment depends on clinical presentation and extent of disease. If evidence of concurrent middle ear involvement is seen, a ventral bulla osteotomy is indicated. If the disease appears to be limited to the nasopharynx, then traction avulsion to remove the polyp at its stalk is usually attempted. The high rate of reoccurrence with this disease (33%) has led to the suggestion that ventral bulla osteotomy should be performed on all cats with nasopharyngeal polyps.[16] Nasopharyngeal polyps are considered a disease of cats, but a case of a nasopharyngeal polyp in a dog has been reported.[19]

211.4.2 Nasopharyngeal Stenosis

Nasopharyngeal stenosis is primarily a disease of cats but has been reported in a dog.[20,21] It is a rare disease that is characterized by scar tissue that forms a membrane or “webbing” above the soft palate and obstructs airflow through the nasopharynx. Cats are believed to develop nasopharyngeal stenosis as a consequence of healing from injuries to the area (infectious, traumatic). Cats with the nasopharyngeal stenosis have chronic histories of stertorous breathing and open-mouth breathing.[20,22] Diagnosis is made using flexible endoscopy to evaluate the nasopharynx and visualizing a pinhole-sized orifice where the caudal nares should be seen (Figures 211-1 and 211-2). Treatment of nasopharyngeal stenosis involves surgical resection of the lesion, but

the prognosis should remain guarded because the webbing may reoccur.[21,23] Balloon dilation of the stenotic area has been proposed as a successful alternative to surgery.[22,24]

211.4.3 Pharyngeal Foreign Bodies

Foreign bodies can occur in both dogs and cats and creates both acute and chronic pharyngeal disease.[25–27] Grass awns, fish hooks, and bones are all possible, but wood sticks are the most common penetrating foreign bodies.[25,27] Medium and large breed dogs are affected more often with oropharyngeal penetrating injuries, presumptively because of their stick-chewing or retrieving behavior. Clinical signs of acute disease include pawing at the mouth or face, hypersalivation, oral pain and malodor, dysphagia, and dyspnea. Cervical or facial swellings combined with intermittently draining tracts were more commonly seen with chronic pharyngeal foreign bodies. Pharyngeal and retropharyngeal abscessation is a common complication secondary to bones, grass awns, sticks, pins, or needles. Dogs with pharyngeal or retropharyngeal abscesses will exhibit anorexia, pharyngeal pain, swelling, and will be febrile.[1] Although rare, osteomyelitis and quadriparesis are possible complications to penetrating stick foreign bodies.[28,29] In contrast, nasopharyngeal foreign bodies are more likely to create inflammation and nasal discharge. Migration of nasopharyngeal foreign bodies does not occur. Diagnosis of pharyngeal foreign bodies is difficult and frequently frustrating. Radiographs are helpful if the foreign body is radiopaque; however, if it is radiolucent the foreign body will remain elusive. Endoscopy is helpful in locating a foreign body, and if the foreign body penetrated the pharynx, endoscopy can localize the traumatized area. Aggressive search and retrieval of penetrating pharyngeal foreign bodies is important early in the course of the problem. If the foreign body is not successfully removed in its entirety during the acute stage, the prognosis decreases dramatically.[25]

211.4.4 Pharyngeal Mucoceles

A mucocele is a collection of saliva from a damaged salivary gland or duct. Synonyms include sialocele, ranula, or salivary cyst. Mucoceles are not true cysts because they are lined with granulation tissue and not the characteristic epithelial tissue.[30] The cause of mucoceles is unknown, although traumatic causes such as dog bites and choke collars have been purposed. Pharyngeal mucoceles are the least common type of mucocele, with sublingual and cervical being more common. Regardless, pharyngeal mucoceles are clinically important because most animals with pharyngeal mucoceles present in respiratory distress. Dogs are more affected than cats, and miniature poodles appear to be at increased risk of developing pharyngeal mucoceles.[31,32] Due to the patient's respiratory compromise, it is important to establish a patent airway either via tracheal intubation or tracheostomy prior to examination. Diagnosis requires visualization of soft, nonpainful, fluctuant mass in the pharynx. Fine needle aspirate of the mass will reveal a thick, tenacious fluid that is characteristic of saliva. Drainage of fluid is important in the acute management of pharyngeal mucoceles, but surgical correction via marsupialization and resection of the associated salivary glands will need to be pursued at a later date.[31]

Figure 211-1 Normal nasopharynx.

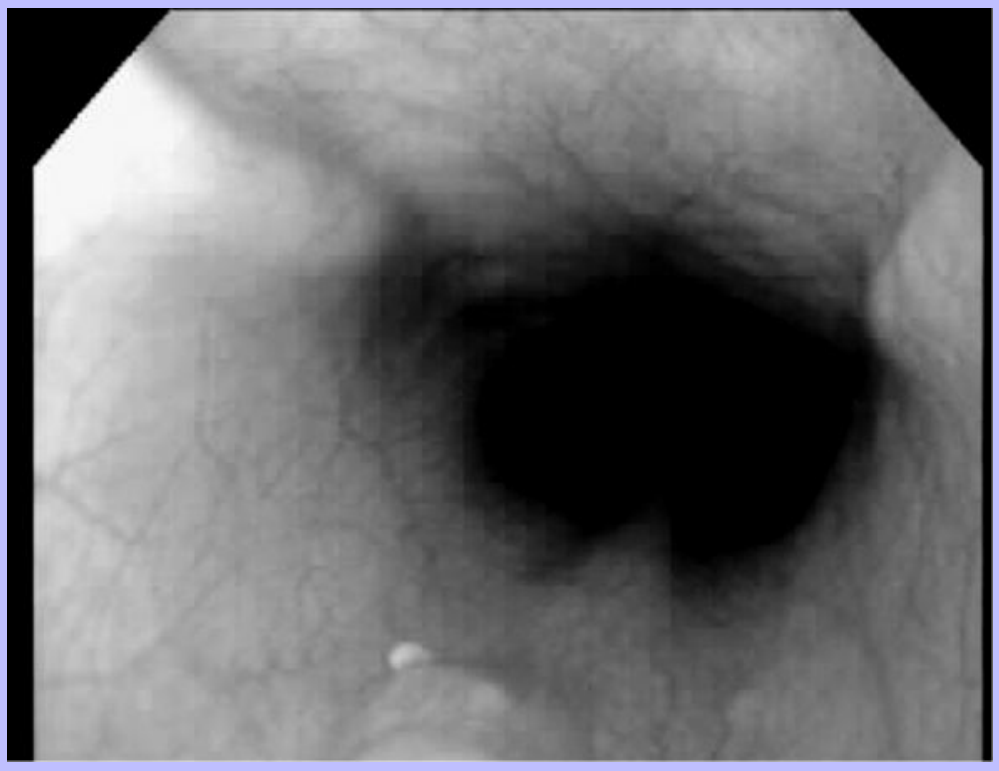

Figure 211-2 Nasopharyngeal stenosis in a young cat with a history of progressive stertor and open-mouth breathing.

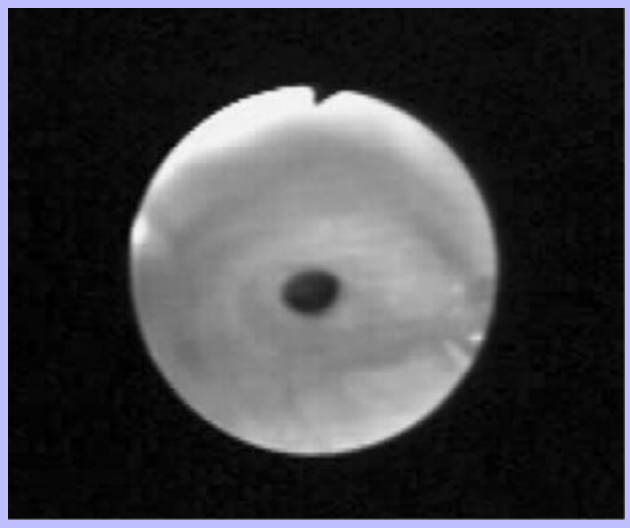

211.5 SOFT PALATE ABNORMALITIES

The palate is an important anatomic structure because it divides the oral and nasal cavities. Abnormalities of the palate result from incomplete closure of the primary or secondary palate (or both) during fetal development. The primary palate develops into the lip and incisive bone.[33] The secondary palate becomes the hard and soft palate. Cleft palate and soft palate hypoplasia are two of many palatine defects that have been described. Brachycephalic breeds have a higher incidence of cleft palate. Many factors have been implicated in these abnormalities, but inherited traits seem to be found in Shih Tzus, bulldogs, pointers, Swiss sheepdogs, and Brittany spaniels.[1,34] Teratogens (e.g., vitamin A, griseofulvin) have also been shown to cause palate abnormalities.[35,36] Midline soft palate defects are most common with unilateral or bilateral defects occurring less frequently. Neonates with a cleft palate usually fail to thrive because the defect makes nursing difficult, allows milk to enter the nasal passages, or milk is aspirated into the lower airways. If the neonate is able to survive, chronic rhinitis is the most common clinical sign. Diagnosis is based on oral examination of the soft palate. A cleft palate will have a midline defect usually involving both the hard and soft palate. Soft palate hypoplasia reveals a severely shortened length, with a midline remnant of muscular tissue covered by mucosa (Figure 211-3). Animals with soft palate defects should also be evaluated for middle ear disease because concurrent middle ear disease has been identified as a potential complication.[37] Treatment of both types of soft palate defects involves surgical correction. A variety of techniques have been described to correct midline defects, with good results.[38,39] Correction of soft palate hypoplasia has a poor prognosis due to the absence of adequate tissue for repair. In animals with this problem, it is hoped that addressing the way intake of food and water occurs (i.e., elevation) will decrease the severity of reflux into the nasal cavity.

Figure 211-3 Soft palate hypoplasia in a young adult dog with a history of chronic nasal discharge.

In contrast, brachycephalic breeds can suffer from soft palate excess. Stenotic nares and everted laryngeal saccules are the other components of the upper airway obstructive syndrome known as the brachycephalic syndrome. English bulldogs, pugs, Shih Tzus, Lhasa apsos, and Himalayan cats are all breeds that suffer from brachycephalic syndrome.[40] Hypoplasia of the trachea, especially in the English bulldog, may also be present.[41] Normally the caudal edge of the soft palate should just touch the tip of the epiglottis. Because maxillae are shortened in brachycephalic breeds, the caudal edge extends beyond the tip of the epiglottis. During exercise the soft palate will be sucked into the glottis, reducing the diameter of the airway. Over time this will cause trauma and tissue edema that will further hinder airflow. Clinical signs associated with an obstructing elongated soft palate include stertorous breathing, gagging, coughing, and exercise intolerance or collapse. Diagnosis is based on oral examination and direct visualization of a soft palate that extends beyond the tip of the epiglottis. Treatment involves shortening the length of the soft palate, either with conventional techniques or carbon dioxide laser.[42–44]

211.5.1 Neoplasia

Oral tumors (which include pharyngeal neoplasia) are the fourth most common neoplasia in dogs. Oral neoplasms occur 2.6 times more frequently in dogs than in cats, and males are more likely to develop oropharyngeal neoplasia than females.[45] The three most common oral tumors in the dog are malignant melanoma, squamous cell carcinoma, and fibrosarcoma.[46] Squamous cell carcinoma and fibrosarcoma are the two most common oral tumors in the cat. If the feline nasopharynx is specifically evaluated for neoplasia, lymphosarcoma is the most common tumor diagnosed.[14] Most tumors of the oral cavity are malignant, highly locally invasive, and have a variable degree of metastasis.[45,46] Clinical signs include inappetence or anorexia due to pain, dysphagia, halitosis, ptyalism, and facial deformity (swelling, exophthalmos, or bony thickening). Cats with nasopharyngeal lymphosarcoma will have nasal discharge, sneezing, stertor, or phonation changes. Diagnosis of an oropharyngeal tumor includes a histologic diagnosis and tumor staging. Direct visualization during an oral examination (and endoscopy for nasopharyngeal tumors) is performed prior to obtaining a tissue sample for cytology and histopathology. Thoracic radiographs are part of the staging, as is either skull radiographs or CT. Regional lymph nodes should be aspirated to determine metastasis. Treatment options include surgery, radiation therapy, hyperthermia, chemotherapy, and photodynamic therapy. Treatment protocol depends on tumor type and location, but local control is most effective with surgery and radiation therapy.[47] Prognosis is variable, based on a number of factors.

211.5.2 Tonsillitis and Pharyngitis

When discussing tonsillitis, one is referring to the palatine tonsil. The palatine tonsil is found within the palatine fossa in the lateral wall of the oropharynx. It is rare for either tonsillitis or pharyngitis to occur as a primary disease. It is much more common for the tonsils and the pharynx to be inflamed secondary to other diseases. Clinical signs are not specific for either the tonsils or pharynx but will support oropharyngeal disease. Inappetence or anorexia, ptyalism, and oral pain are all common clinical findings. Diagnosis is based on history and physical examination findings. Fever is common when infectious agents are involved. Acute tonsillitis will reveal bright-red, friable tonsils on oral examination. It is not unusual for tonsils at this stage to be enlarged and protruding from the palatine fossa. Occasionally the tonsils will have petechiae or small abscesses. The pharynx of acute pharyngitis will be visibly inflamed and can have ulcerations, petechiae, or small abscesses. Bacterial or viral isolation is usually not indicated unless clinical signs are chronic or relapsing. The most common causes of tonsillitis and pharyngitis is upper respiratory infection. FHV-1 and

FCV are the two most common feline viral pathogens. FCV is more likely to cause ulcerations than FHV-1.[48,49] Canine infectious tracheobronchitis (ITB) will occasionally cause problems, although it is more likely to cause laryngitis. *Bordetella bronchiseptica* has caused URT disease in cats as well.[50] Other possibilities include chronic vomiting or regurgitation, periodontitis, and ingestion of caustic or toxic substances (e.g., cleaning detergents, liquid potpourri).[51] Rarely, bacterial infection will be incriminated as the cause. Cats can also develop a progressive, nonspecific inflammatory condition termed gingivitis-stomatitis-pharyngitis complex. Young purebred cats are predisposed to the disease, and the most severely affected cats develop ulceroproliferative lesions in the caudal oropharynx.[52] Treatment of pharyngitis or tonsillitis is directed toward eliminating the underlying cause, if possible, as well as supportive care and antibiotics, if indicated.

211.5.3 Oropharyngeal Dysphagia

Dysphagia refers to abnormal or difficulty swallowing. Oropharyngeal dysphagia indicates an inability to move a bolus from the oral cavity into the proximal esophagus. This symptom can be either secondary to an isolated lesion or manifestation of systemic disease. Clinical signs are variable, depending on severity and location of the problem. Signs include difficulty with prehension, dropping food from mouth, exaggerated head movements during eating, regurgitation with no correlation in time of eating, and repeated attempts to swallow food. Occasionally, respiratory signs such as nasal discharge, coughing, and aspiration pneumonia will occur secondary to nasopharyngeal or laryngotracheal aspiration. Diagnosis of oropharyngeal dysphagia requires multiple areas to be evaluated. Accurate historical information is imperative to differentiate regurgitation from vomiting. It is rare that an owner will recognize the difference until the history and examination occurs. A standardized questionnaire has been evaluated as a sensitive tool to detect oropharyngeal dysphagia.[53] Observing the animal eating and drinking is also extremely helpful. The physical examination should include a thorough oral examination to evaluate for structural abnormalities and foreign bodies. A complete neurologic examination is also critical during the evaluation of oropharyngeal dysphagia. Radiographs of the area can identify radiopaque foreign bodies or masses. Thoracic radiographs can determine if the animal has aspiration pneumonia secondary to the dysphagia. Videofluoroscopy is an excellent diagnostic tool to localize the dysphagia.[54] Other possible diagnostics could include ANA test, evaluation for acetylcholine receptor antibodies, endocrine screening, electromyography, or biopsy for histopathology.

Causes of dysphagia include anatomic abnormalities, neoplasia, foreign bodies, or neuromuscular disorders. Brain stem tumors can also cause dysphagia, but it is usually not the only clinical or physical examination finding. The most common neuromuscular disorder is myasthenia gravis, a disease of altered neuromuscular transmission secondary to autoantibodies against acetylcholine receptors. Akitas, Scottish terriers, German shorthaired pointers, Chihuahuas, and Abyssinians are all breeds identified at increased risk for acquired myasthenia gravis.[55,56] Manifestations of myasthenia gravis may either be focal (pharyngeal or esophageal) or generalized (generalized muscular weakness or collapse). Oropharyngeal dysphagia can be one clinical sign of many that is associated with myopathies. Bouvier des Flanders have been identified with a muscular dystrophy in which oropharyngeal dysphagia is the primary clinical sign.[57] Cricopharyngeal achalasia can be acquired as a polymyopathy, or it can be congenital. Cricopharyngeal achalasia is the failure of the upper esophageal sphincter to relax and allow a food bolus into the proximal esophagus. Cocker spaniels are at increased risk for congenital cricopharyngeal achalasia, but any breed can be affected.[58] It is important to differentiate between congenital and acquired disease, because cricopharyngeal myotomy is indicated in congenital disease but should be avoided with acquired disease. Treatment of oropharyngeal dysphagia should be based on the

underlying disease process. If possible, the underlying cause should be removed; if that is not possible, providing a means of adequate nutrition should be pursued.

211.6 DISEASES OF THE LARYNX

211.6.1 Laryngeal Paralysis

Laryngeal paralysis is a common cause of upper airway obstruction in dogs. Cats can be diagnosed as well, but it is not a common cause of upper airway obstruction for the species.[59] Laryngeal paralysis results when the arytenoid cartilage fails to abduct during inspiration, leading to narrowing of the glottic lumen. Several causes of laryngeal paralysis have been identified, but it is most often idiopathic. Most acquired idiopathic cases are older, large breed dogs. Damage to the recurrent laryngeal nerve from trauma, infiltrative disease, masses, or surgical manipulation (e.g., feline thyroidectomy) can lead to laryngeal paralysis.[59] Polyneuropathies secondary to immune-mediated disease, hypothyroidism, or other systemic disorders can be observed primarily as laryngeal paralysis.[60] Congenital laryngeal paralysis does occur but is uncommon. A hereditary form has been described in Bouvier des Flanders and is presumed in Siberian huskies and husky crossbreeds.[61,62] In Bouvier des Flanders an autosomal-dominant trait causing a loss of motor neurons in the nucleus ambiguus has been identified.[63] A laryngeal paralysis-polyneuropathy complex has been described in young dalmatians and rottweilers.[64,65]

1201 1202

Clinical signs are usually progressive because the ability of the arytenoid cartilage to abduct fails. Clinical signs of laryngeal paralysis include stridor, exercise intolerance, coughing, gagging, and voice change. Animals with laryngeal paralysis can present in respiratory distress, especially after an episode of excitement, exercising, and when environmental temperatures are elevated. Moderate airway obstruction is worsened by laryngeal edema and inflammation secondary to turbulent airflow in the larynx. Although ultrasound has been described as a diagnostic tool for laryngeal paralysis, most clinicians will use laryngoscopy to definitively diagnose laryngeal paralysis.[9] Laryngeal function is assessed when the animal is under a light plane of anesthesia. Paralysis may be unilateral or bilateral, although most animals with moderate to severe clinical signs have bilateral dysfunction of the arytenoid cartilages. It is important not to be fooled by paradoxic movement of the arytenoid cartilages. Paradoxic movement indicates opposite movement (i.e., medially) by the arytenoid cartilages when negative pressure occurs during inspiration. A thorough oral examination should be performed during the same anesthetic episode to identify any underlying causes. Once laryngeal paralysis has been diagnosed a complete neurologic examination that includes pharyngeal and esophageal function should occur to evaluate for concurrent or underlying problems. Thoracic radiographs are indicated to identify aspiration pneumonia or metastatic disease. When the animal presents in respiratory crisis, stabilization includes sedation and establishing an airway. This is accomplished by either tracheal intubation or tracheotomy. Short-acting corticosteroids are helpful if significant laryngeal edema exists. Once stabilized, surgery is indicated to alleviate the upper airway obstruction caused by laryngeal paralysis. Multiple surgical techniques have been described to palliate the clinical signs associated with laryngeal paralysis. The current surgical technique of choice is unilateral arytenoid lateralization, a technique that attempts to increase the area of the rima glottidis.[66] This procedure has been shown to have the most favorable outcome compared with other possible surgical techniques such as bilateral arytenoid lateralization and partial laryngectomy.[67] Postoperative complications include aspiration pneumonia, laryngeal webbing, surgical failure, and respiratory distress. Postoperative complications are common, and death can occur. In one retrospective study, 34.3% of dogs had postoperative complications and the mortality rate was 19.3%.[67] In the same study, prognosis was

poor if the dog had concurrent neurologic disease. Limited information exists regarding surgical outcome in cats. The surgical technique used was unilateral arytenoid lateralization. Postoperative complications included laryngeal edema that necessitated a temporary tracheotomy tube and an altered ability to vocalize. All cats survived.[68]

211.6.2 Laryngeal Neoplasia

Primary neoplasms of the canine and feline larynx occur uncommonly. The most common canine laryngeal tumors reported are malignant epithelial tumors and rhabdomyoma. The most common laryngeal tumor in the cat is lymphosarcoma, with squamous cell carcinoma the second most common.[10,69,70] Most patients with laryngeal tumors are older, with 8 years as the median age.[69] Other report tumor types are adenocarcinoma, rhabdomyosarcoma, osteosarcoma, chondrosarcoma, mast cell tumor, and melanoma.[10,69–71] Clinical signs are similar regardless of tumor type and include dysphonia, coughing, gagging or choking, and respiratory distress. Occasionally an abnormal larynx can be palpated, but most laryngeal tumors are identified by laryngoscopy (Figure 211-4). Radiographs, CTs, and ultrasound all have diagnostic value in determination of extent of disease and potential metastasis.[10] Definitive diagnosis should be made by histopathology; caution should be used when diagnosis is based on gross appearance alone. This is especially true with feline tumors because granulomatous disease has been reported. Therapy is based on tumor type but, in general, surgical resection and creating an unobstructed airway are goals. Complete laryngectomy and permanent tracheostomy are options with variable success.[72,73] Cats with severe respiratory compromise secondary to laryngeal lymphosarcoma will respond well to radiation therapy. The prognosis of benign tumors is good if complete resection is successful; malignant laryngeal neoplasms have a poor prognosis.

Figure 211-4 Laryngeal neoplasia in a geriatric dog, causing complete obstruction of glottis.

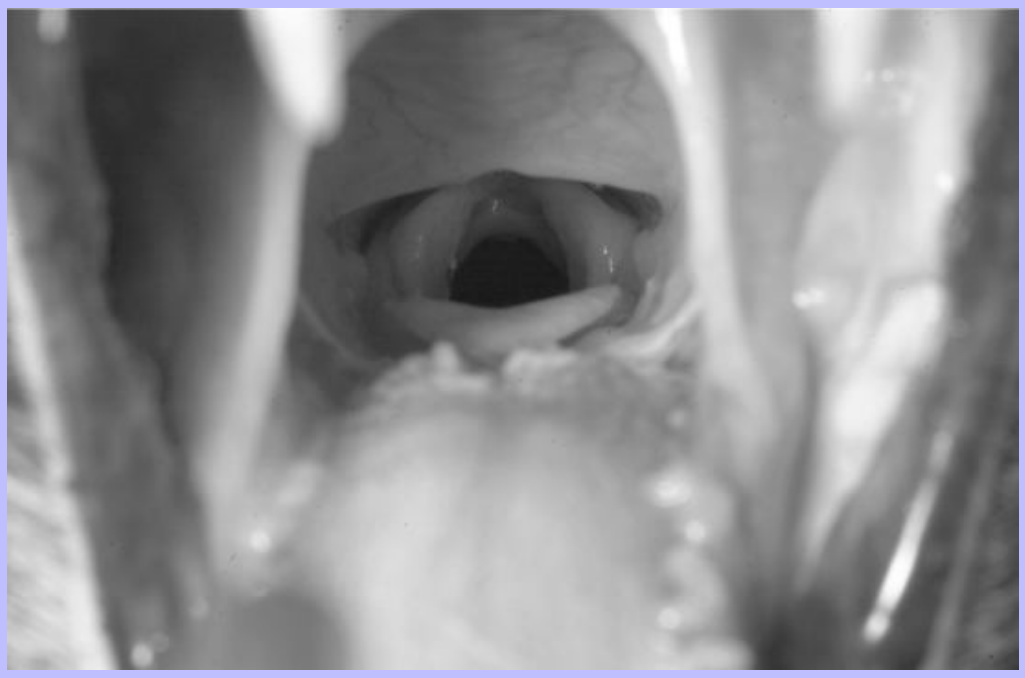
211.6.3 Laryngeal Collapse

Brachycephalic dogs are at increased risk to develop laryngeal collapse secondary to their congenital airway malformations. Stenotic nares, elongated soft palate, and if present, a hypoplastic trachea, create an increased negative pressure during inspiration to move air through the narrowed air passages. It is believed that laryngeal cartilages become deformed from this chronic increased negative pressure and will finally weaken and collapse. Finding that older brachycephalic dogs will often have laryngeal collapse when presenting for upper airway disease support this theory. However young brachycephalic dogs are also diagnosed with laryngeal collapse, which may indicate a defect in cartilage structure.[74] Dogs with laryngeal collapse will experience stridor, episodes of respiratory distress, and a respiratory crisis due to upper airway obstruction. 1202
Determination of laryngeal collapse is possible with laryngoscopy. The corniculate and cuneiform processes 1203
of the arytenoid cartilage will be medially displaced and occasionally will touch. In severe cases these processes will overlap, and the epiglottis will appear to be rolled up or flattened.[74] No specific treatment has been effective for laryngeal collapse. Surgical treatment should be directed toward altering the underlying congenital abnormality (i.e., stenotic nares correction, soft palate resection, everted laryngeal saccule excision) to improve airflow. In cases of severe laryngeal collapse, a permanent tracheostomy is recommended.[44,75] Dogs with severe laryngeal collapse have a poor prognosis.[75]

211.7 LARYNGITIS

Inflammatory laryngeal disease is common in both the dog and the cat. The most common cause of acute inflammation of the larynx is infectious agents such as canine infectious tracheobronchitis (ITB), commonly called kennel cough, or the feline upper respiratory agents (i.e., FHV-1, FCV). ITB is a result of coinfection of *Bordetella bronchiseptica* with either canine parainfluenza virus or canine adenovirus-2 (CAV-2).[76] With most cases of ITB, the only clinical sign is paroxysmal coughing in an otherwise healthy dog. Due to inflammation of the larynx the cough is a loud, high-pitched, “goose honk” cough. Occasionally a dog may be febrile, lethargic, and inappetent. ITB is usually self-limiting, but the severity of the cough, combined with the possibility of pneumonia complicating the disease, warrants treatment. Doxycycline at 5 to 10 mg/kg orally once daily is the antimicrobial of choice for *B. bronchiseptica*. Short-term administration of an anti-inflammatory dose of glucocorticoids can be effective in decreasing laryngeal edema. Antitussives, such as butorphanol tartrate or hydrocodone bitartrate, are effective in minimizing the severity of the cough but should not be used if pneumonia is suspected. Other causes of inflammatory laryngeal disease include endotracheal intubation, insect bites, foreign body penetration, or trauma from bite wounds, leash and choke chain injuries, or being hit by cars. Frequently no cause for acute laryngeal inflammation is found. Acute inflammatory laryngeal disease is usually self-limiting, and no specific treatment is indicated if the animal has only mild signs. However, if moderate to severe signs exist, a short course with an anti-inflammatory dose of glucocorticosteroids can be initiated to decrease laryngeal edema. Respiratory obstruction secondary to laryngeal inflammation is an uncommon clinical presentation but can occur in severe instances such as in laryngeal trauma. A tracheostomy is indicated if the patient is dyspneic, cyanotic, or extremely anxious due to laryngeal inflammation.[7]

Figure 211-5 Normal feline larynx during inspiration.



211.8 OBSTRUCTIVE INFLAMMATORY DISEASE

An obstructive inflammatory laryngeal disease has been described in cats and dogs.[70,77–79,80] Although rare, it is a disease worth noting because the gross appearance can mimic laryngeal neoplasia. The underlying cause of inflammation is unknown. Feline immunodeficiency virus (FIV) and feline leukemia virus (FeLV) have not been found to be associated with this disease. In the feline reports, dyspnea secondary to upper airway obstruction was reported in all cats; retching, coughing, and dysphonia were also common. Stridor and dysphonia was reported in dogs. Direct visualization of the larynx reveals a laryngeal mass that cannot be distinguished from neoplasia or severe swelling and edema (Figures 211-5 and 211-6). Histopathology is imperative to distinguish between neoplasia and obstructive inflammatory disease. Histopathology reveals either granulomatous or nongranulomatous laryngitis (neutrophilic and lymphoplasmacytic). Most patients with obstructive inflammatory laryngeal disease need to be stabilized. This is accomplished by establishing an airway through tracheostomy tube placement. Treatment with corticosteroids (dexamethasone, prednisone, or prednisolone) has variable success, and occasionally surgical resection of the proliferative tissue is indicated. The prognosis is guarded, with a high mortality rate during the initial diagnostic and treatment period.

Figure 211-6 Middle-aged cat presented in respiratory distress. Laryngeal examination revealed bilateral arytenoid masses. Biopsy revealed pyogranulomatous inflammation.

Respiratory diseases can be extremely challenging to manage and diagnose. The respiratory system is one of the four major body systems that require evaluation and treatment on an emergency basis. Respiratory dysfunction can result in severe physiologic compromise and imminent death if not dealt with appropriately. The respiratory workup is often dictated by the patient's condition, rather than the convenience of the clinician and the client. In patients with severe respiratory compromise, a tentative diagnosis and preliminary therapeutic plan must be guided by signalment, history, physical examination findings, and response to therapy pending stabilization for more definitive diagnostics (see Pulmonary Emergencies in Critical Care chapter). It is rare that a definitive diagnosis for the underlying cause of the respiratory problem is found using the signalment, history, physical examination, and response to therapy alone. Ancillary diagnostics are almost always required.

212.1 SIGNALMENT

The animal's signalment can provide direction for the diagnostic workup of the respiratory patient. For example, pediatric or juvenile patients are more likely to contract infectious conditions. Animals with inherited pulmonary disorders tend to manifest signs at an early age and certain breeds are predisposed to specific respiratory abnormalities. Feline asthma is noted more frequently in Siamese cats compared with other breeds. Brachycephalic breeds, particularly bulldogs, may have hypoplastic tracheas and upper airway conditions that result in respiratory difficulties. Respiratory distress due to heart failure is noted more frequently in male than female cats. Signalment provides clues to the underlying disorder but never provides a definitive diagnosis.

212.2 GENERAL MEDICAL HISTORY

A thorough history can provide important clues to the underlying respiratory problem. Questions regarding how long the owners have had the pet are important. For example, have they had the pet since it was a puppy or kitten, or did they obtain the animal when it was an adult? Obviously, owners that obtained their pet as a puppy or kitten will have a more comprehensive life history compared with owners that obtained a pet at a more advanced age. What is the travel history of the pet? This may assist in determining clinical suspicion for infectious or parasitic respiratory disease.

Establishing a clear picture of the pet's environment gives the veterinarian a sense of potential exposure to toxins or infectious diseases that might cause pulmonary problems. Animals that are allowed to run free or are unobserved can potentially be exposed to anything, such as anticoagulant rodenticide, forest fire, or house fire smoke. Was there a recent change in a living environment that is coincident with the development of the respiratory signs? Cats may develop airway hypersensitivity reactions to antigens in a new environment.

It is also important to determine the vaccination status of the animal. Similarly, is the pet in a heartworm endemic area and, if so, is the animal on an appropriate heartworm preventative plan? Are there other pets in the environment that this animal has been exposed to? Multiple animals with similar clinical signs points toward an environmental cause such as an infectious disease or a toxin. Similarly, is the owner or anyone in the family having medical problems that might suggest a zoonotic disease (e.g., trichosporonosis, rickettsial or fungal diseases, leishmania)?

Does the patient have any known hypersensitivities to dietary allergens or medications? Both are diagnostically and therapeutic important. What is the previous medical history of the patient? Has the animal had previous respiratory problems? If so, did the clinical signs improve? Has there ever been a history of trauma suggesting diaphragmatic hernia or pneumothorax?

212.3 PHYSICAL EXAMINATION

A complete physical examination is essential (see Chapter 1). In animals with severe respiratory compromise, the physical examination may point towards a tentative diagnosis from which empirical therapy can be chosen to stabilize the patient (see Approach to Respiratory Distress). Clinical signs combined with physical examination findings provide the initial steps in guiding the diagnostic workup.

Animals with nasal disorders commonly have clinical signs such as sneezing, nasal discharge, loud nasal respiratory sounds and, rarely, open mouth breathing secondary to occlusion of the nasal passages. Pure nasal disorders rarely cause severe respiratory distress, although some cats are reluctant to breathe through the mouth to relieve the obstruction. Palpation over the nasal cavities may reveal pain, asymmetry, or distortion of the nasal cavity due to destructive or proliferative diseases. Examination of the oral cavity may reveal bony abnormalities, severe dental disease, or abnormalities of the hard and soft palate that contribute to, or cause, the nasal disorder. Purulent nasal discharge may be due to primary or, more often, secondary bacterial infections. Unilateral discharge suggests tooth root abscess, cyst or hematoma, oronasal fistula, foreign body, or neoplasia. Bilateral discharge occurs secondarily to neoplasia, infectious agents, or any disease process that is caudal to the nasal septum. Epistaxis is due to any of the aforementioned causes of purulent nasal discharge, although severe bleeding is relatively rare with these conditions. Causes of epistaxis that are not due to primary respiratory abnormalities include thrombocytopenia, thrombocytopathia, coagulopathy, erosive immune-mediated diseases, or, rarely, hypertension. Definitive diagnosis of the underlying nasal disease is rarely derived from clinical signs and physical examination findings alone. Further diagnostics are typically required.

Upper and large airway disease (pharynx, larynx, and trachea) typically manifest as stridor and stertor that is audible without the stethoscope. Localization of the respiratory disease to the upper or large airways does not preclude disease in other parts of the respiratory systems but does warrant specific evaluation of the upper airways and trachea. Extrathoracic dynamic airway disease typically has louder sounds during inspiration, whereas intrathoracic dynamic lesions tend to be louder during exhalation. However, distinguishing the diseased anatomic location in the clinical patient with respiratory distress is often challenging. Auscultation over the specific location of the lesion reveals the most dramatic of sounds. Pharyngeal diseases include abscess, cyst or hematoma, cellulitis, neoplasia, foreign body, nasopharyngeal polyp, and enlarged lymph nodes. Direct visualization during physical examination or under general anesthesia usually localizes the problem. Palpation of the pharyngeal area may reveal swelling, pain, or asymmetry, indicating that the pharyngeal region is at least part of the disease process.

1206
1207

Laryngeal disease typically manifests as inspiratory stridor, voice change, coughing while drinking water, exercise intolerance, and an exacerbation of the clinical signs during exercise or periods of high environmental temperature. The most common laryngeal diseases include laryngeal paralysis, neoplasia, edema, and inflammation.

Tracheal disease is typically manifested as stridor and coughing, especially with exercise or excitement. A cough is easily elicited upon tracheal palpation when the trachea is inflamed. Respiratory compromise may vary from mild to severe. Distress may be more severe during inspiration, expiration, or both, depending upon whether the

lesion is extrathoracic, intrathoracic, or both, respectively. The most common tracheal abnormalities include infectious tracheobronchitis (kennel cough), tracheal collapse, neoplasia, foreign body, trauma, and parasites.

Small airway and alveolar disease can be particularly challenging to diagnose. Physical manifestations of diseases in this portion of the respiratory tract include varying degrees of respiratory distress, coughing, and increased breath or adventitial sounds such as crackles or wheezes upon auscultation. Location of the increased breath or adventitial sounds may help in identifying the underlying disease process. Adventitial sounds heard loudest over the cranioventral or right middle lung lobe regions are suggestive of aspiration pneumonia. An increase in breath or adventitial sounds over the thorax in dogs with auscultable heart abnormalities is supportive of cardiogenic pulmonary edema. Auscultation abnormalities heard loudest over the caudodorsal regions of the lungs in animals with head trauma, electrocution, seizures, or upper airway obstruction may indicate neurogenic pulmonary edema. Diffuse, fine crackles throughout the thorax in a dog without significant signs of respiratory distress suggests chronic or slow onset of pulmonary parenchymal disease such as pulmonary fibrosis or metastatic neoplasia. Other lower airway and pulmonary parenchymal diseases include pulmonary thromboembolism, pulmonary contusions, pulmonary hemorrhage, acute respiratory distress syndrome (ARDS), heartworm disease, pulmonary infiltrates with eosinophilia, allergic bronchitis, feline bronchial disease, near drowning, smoke inhalation, re-expansion pulmonary edema, and inhalation of toxins.

Pleural space disease is caused by fluid, air, soft tissue, or abdominal organs in the pleural space. Patients with pleural space disorders commonly exhibit a short, shallow breathing pattern, tachypnea, and intermittent attempts at a deep respiration (especially in cats with pleural effusion). Decreased breath sounds of the thorax are ausculted. Diminished breath sounds in the ventral regions of the thorax are suggestive of fluid, whereas a dorsal distribution suggests air accumulation. Most pleural effusions and pneumothoraces are bilateral in dogs and cats, although unilateral fluid or air accumulation may occur. Diaphragmatic rupture often results in an asymmetry of auscultation findings. Diminished breath sounds are typically noted on the side where the abdominal contents are located, and loud heart and lung sounds are commonly heard on the opposite side. Rarely, a diaphragmatic hernia may result in substantial fluid accumulation on both sides of the chest, especially when the liver is present in the pleural space.

A complete, thorough physical examination should be performed even though the primary clinical signs are associated with the respiratory tract. It is rare that primary respiratory problems result in problems elsewhere in the body, but the reverse is not uncommon. Findings in other areas may provide clues as to the underlying cause of the respiratory disease or at least guide the diagnostic evaluation. Weight loss or cachexia suggests more chronic systemic disease, such as neoplasia that has metastasized to the lungs and resulted in respiratory difficulty. Additionally, the presence of masses elsewhere in the body might indicate a primary neoplastic process. Diseases that cause an acute abdomen commonly result in secondary respiratory diseases such as aspiration pneumonia or an acute respiratory distress (ARDS)-like condition subsequent to a severe inflammatory disease process. Petechiation or evidence of an abnormality of hemostasis elsewhere in the body might suggest pulmonary parenchymal hemorrhage or hemorrhagic pleural effusion as the cause of the respiratory distress.

In summary, signalment, previous medical history, clinical signs, and physical examination findings provide a solid foundation to further develop a diagnostic plan. There are numerous diagnostic modalities available to further evaluate respiratory function and identify specific disease processes in order to accurately and most effectively treat these patients.

212.4 DIAGNOSTIC TECHNIQUES

The diagnostic approach to the animal with respiratory disease largely depends on the patient's history, signalment, physical examination findings, cardiopulmonary stability, and the expected diagnostic yield versus

risk of a given diagnostic test. It remains important to take into account the sensitivity and specificity of any test performed when interpreting the results. A general algorithm is displayed in Figure 212-1.

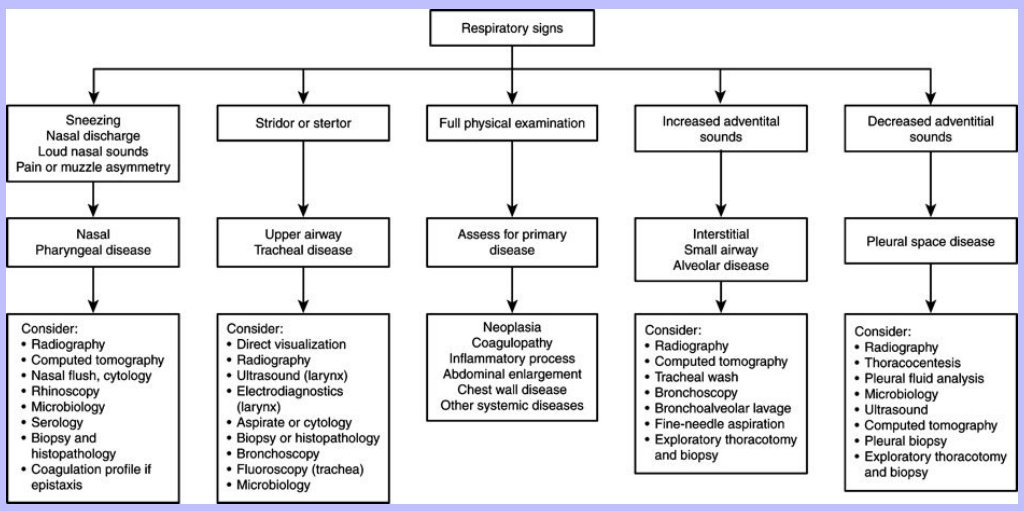
212.5 LABORATORY DIAGNOSTICS

Hematologic and biochemical profiles are important in the assessment of an animal's health status and evaluation of nonrespiratory diseases that may have a substantial effect on the respiratory system, such as acidemia, anemia, or endocrinopathies. Chronic hypoxia stimulates the release of erythropoietin from the kidneys, which results in an increased red blood cell turnover and subsequent polycythemia. Anemia leads to a decrease in total oxygen content, which increases respiratory effort and rate. Leukocytosis with a left shift with moderate to severe airway inflammation, infection, or neoplasia, and leukopenia occurs with acute bacterial bronchopneumonia or sepsis. Parasitic airway disease, asthma, bronchitis, or pulmonary infiltration with eosinophilia (PIE) commonly cause an elevated peripheral eosinophil count, and a basophilia is frequently seen in animals with Dirofilaria immitus or PIE. Hypercalcemia may be associated with a neoplastic or fungal disease process. Hypoalbuminemia may be seen in animals with pleural effusion (cause or effect), and systemic illness or multiple-organ dysfunction can lead to ARDS. Hemorrhagic infiltrates or effusions may occur secondary to severe thrombocytopenia, thrombocytopathia, or coagulopathies.

Animals with no obvious cause of respiratory distress should be examined for other systemic diseases that may predispose to pulmonary thromboembolism (PTE). Underlying diseases might include hyperadrenocorticism, diabetes mellitus, immune-mediated anemia or thrombocytopenia, protein losing nephropathy or enteropathy, or pancreatitis. Coagulation profiles, platelet counts, blood smear analysis, fibrin and fibrinogen degradation products, D-dimer assays, antithrombin III measurements, and/or thromboelastography (TEG) may be useful in the diagnosis of disseminated intravascular coagulation that might lead to PTE or pulmonary hemorrhage.

1207
1209

Figure 212-1 General diagnostic algorithm for evaluation of the respiratory tract. As with any algorithm, this provides only guidelines. Numerous exceptions to this algorithmic approach exist.



There are many serologic tests available for the identification of viral diseases, mycoses, and allergens. Specific infectious disease testing will depend on the animal's environment, travel history, and lifestyle. Feline leukemia virus and feline immunodeficiency virus infection commonly leads to secondary opportunistic infections. Additional infectious causes of respiratory disease in the dog or cat that may require further diagnostics include viral diseases (canine distemper, canine parainfluenza, canine adenovirus-2, herpevirus, feline rhinotracheitis, feline calicivirus), bacterial diseases (e.g., *Bordetella bronchiseptica*, streptococci, *Escherichia coli*, *Klebsiella*, *Pasteurella*, eugoic fermenter-4, mycobacteria, *Yersinia* spp., *Pseudomonas mallei*, *Mycoplasma* spp., *Bacteroides* spp., *Clostridium perfringens*, fusobacteria, *Peptostreptococcus* spp.), parasitic or protozoal diseases (e.g., *Dirofilria immitus*, *Paragonimus kellicotti*, *Capillaria aerophila*, *Aelurostrongylus abstrusus*, *Toxoplasma* spp., *Acanthamoeba* spp.), fungal infections (e.g., *Blastomyces*, *Histoplasma*, *Cryptococcus*, *Coccidiodes*, *Aspergillus*, and *Penicillium* spp.), or rickettsial diseases (e.g., *Rickettsia rickettsii*, *Ehrlichia canis*). Bacterial and fungal cultures, serologic testing, cytologic examination, electron microscopy, immunocytology and immunohistochemistry, immunoblotting, and/or polymerase-chain reaction amplification may be required for a definitive diagnosis of infectious diseases.[1] Heartworm disease in the cat may require echocardiography in addition to antibody and antigen testing.[2] Fecal studies should be performed in animals with suspected parasitic pneumonia. A zinc sulfate fecal flotation, including several drops of sediment, is indicated to identify *Paragonimus kellicotti* or *Capillaria aerophila* ova, and a Baermann technique should be used to identify *Aelurostrongylus abstrusus* larvae.

212.6 DIAGNOSTIC IMAGING

212.6.1 Radiography

Radiography remains an essential tool in the diagnostic approach to respiratory tract disease. Serial radiographic studies serve as an important method of monitoring a patient's respiratory disease and response to therapy. Proper radiographic technique is critical when viewing the nasal cavity or chest cavity owing to the nature of the fine nasal turbinates and air-tissue interface in the lungs, respectively.

Nasal radiography is typically used to evaluate animals with clinical signs of sneezing, nasal discharge, or upper airway obstruction. Morphologic changes in the air passages, turbinates, and frontal sinuses may be confirmed and the extent of the lesions defined. Nasal radiography does require anesthesia in order to obtain proper positioning and avoid motion artifact. Three views should be taken to assess the nasal cavity and frontal sinuses: a lateral, frontal, and open-mouth ventrodorsal, or intraoral dorsoventral view. It is important to look for symmetry, obliteration of air spaces between the nasal turbinates or frontal sinuses suggestive of fluid or swelling, destruction of nasal turbinates indicating a neoplastic or severe, chronic inflammatory process, or destruction/deformation of proximal facial structures which is commonly due to neoplasia or *Cryptococcus* spp.[3,4]

Radiography of the neck and extrathoracic airway is indicated in dogs or cats with inspiratory stridor or stertor, gagging, coughing, and/or recent voice change. Lateral radiographs are most useful in assessing these structures; however, tracheal displacement may be more visible on a ventrodorsal view. Both inspiratory and expiratory views are helpful in assessment of dynamic changes in airway diameter. Radiographs may assist in the identification of pharyngeal, laryngeal, or tracheal disease due to radiopaque foreign bodies or soft tissue masses (abscesses, polyps, neoplasms, granulation tissue), anatomic displacement due to mass lesions, tracheal narrowing or hypoplasia, or tracheal collapse.[5] Tracheal displacement secondary to mass lesions, soft tissue masses, hypoplasia, and invagination of the dorsal tracheal membrane are commonly seen in older

symptomatic or asymptomatic dogs with chronic coughing, but rarely in cats. Cervical emphysema or pneumomediastinum following endotracheal intubation or trauma in cats is readily diagnosed with cervical radiography.[4]

Survey thoracic radiographs are commonly used in the diagnostic evaluation of dogs and cats with respiratory disease.[6] There are fewer breed-related and age-related changes seen in the feline thorax compared with the canine thorax.[4,6] A technique chart should be made to avoid over-or under-diagnosis of pulmonary disease when thoracic radiographs are viewed. In addition, a lateral and dorsoventral or ventrodorsal radiograph should comprise the minimum thoracic study. Three views (including both laterals) are commonly taken when looking for metastatic pulmonary disease or unilateral disease, although this practice has been questioned.[7] In cats, the use of high-detail x-ray intensifying screens may help in the identification of small airway disease.

The chest wall, diaphragm, pleural space, mediastinum, airways, and pulmonary parenchyma should be assessed. The thoracic wall should be evaluated for evidence of trauma (rib or sternal fractures), soft tissue masses, lytic, and/or sclerotic processes.[8]

Diaphragmatic abnormalities such as loss of the diaphragmatic silhouette or changes in the shape and position of the diaphragm are assessed in evaluation of thoracic radiographs. The diaphragmatic position and shape varies with the respiratory cycle, species and breed, conformation, coexisting diseases, and body fat content. Changes in the shape of the diaphragm are due to thoracic masses or lung disease adjacent to the diaphragm, diaphragmatic hernias, gastroesophageal intussusception, diaphragmatic masses, and chronic pleural inflammatory conditions. Cranial displacement of the diaphragm occurs secondary to abdominal disease, generalized diaphragmatic paralysis, or muscular dystrophy and caudal displacement occurs secondary to severe respiratory disease or pleural space disease. Decreased visualization of the diaphragmatic line, the presence of abdominal viscera within the thorax, displacement of abdominal or thoracic structures, pleural fluid, and divergence of the diaphragmatic crura or cranial angulation of the diaphragm might indicate a diaphragmatic hernia or diaphragmatic defect. Additional diagnostics that might be performed to confirm a diaphragmatic hernia include an upper gastrointestinal barium contrast study, horizontal beam radiographs, ultrasonography, positive contrast celiography, portography, cholecystography, angiocardiography, angiography, and non-selective cardiography, computed tomography, or magnetic resonance imaging.[9,10] Radiographs of animals with a peritoneopericardial diaphragmatic hernias also display an enlarged, round cardiac silhouette, abdominal organs within the pericardial sac, confluent silhouette between the diaphragm and heart, and an indistinguishable border of the ventral thoracic diaphragmatic surface and the caudal ventral cardiac silhouette. A dorsal mesothelial remnant between the heart and the diaphragm on the lateral view in normal cats is commonly seen.[10]

The presence of fluid, air, or soft tissue within the pleural space should be identified with thoracic radiography. As little as 100 mL of pleural fluid is detectable in a medium-sized dog using standard thoracic radiographic views. A lateral and erect ventrodorsal view enables the detection of as little as 50 mL of fluid in a 15-kg animal.[11] Removal of fluid or air prior to taking radiographs will help stabilize the animal and will improve the radiographic visualization of the lung fields, heart, and mediastinum. Radiographic changes associated with pleural effusion include blurring of the cardiac silhouette, interlobar fissure lines, rounding of the lung margins at the costophrenic angles, widening of the mediastinum, separation of the lung borders from the thoracic wall, and scalloping of the lung margins at the sternal border.[12] Hemothorax, pyothorax, chylothorax, or transudative effusions may be present. Cytology, cultures, and fluid analysis are necessary to classify the effusion (see Pleural and Extrapleural Diseases).

Radiographic changes associated with pneumothorax include dorsal displacement of the heart on the lateral view, retraction of the lung from the chest wall, and an increased density of the collapsed lung lobes. Potential causes might include chest wall trauma, an esophageal perforation leading to severe pneumomediastinum, or rupture of the trachea or lung (commonly secondary to infection, bulla, neoplasia, or positive pressure ventilation).[12]

The mediastinum should be evaluated radiographically for evidence of a mediastinal shift, masses, lymphadenopathy, fluid, or pneumomediastinum. Mediastinal shifts and mediastinal masses are most readily seen on ventrodorsal or dorsoventral radiographs. If mediastinal fluid is suspected, horizontal beam radiographs and ultrasonography may yield further diagnostic information. Pneumomediastinum is best appreciated on lateral films of the chest, and pneumomediastinum may lead to subcutaneous emphysema, pneumoretroperitoneum, and/or pneumothorax in severe cases. Potential causes of pneumomediastinum include alveolar rupture, perforation of the trachea or esophagus, extension of gas in the neck or retroperitoneal space, or a gas-producing organism within the mediastinum.[13] The cardiac silhouette and pulmonary vasculature should also be assessed since left atrial enlargement leading to compression of the left mainstem bronchus, pleural effusion, and/or pulmonary edema commonly leads to respiratory impairment. The pulmonary artery may be prominent in animals with PTE, pulmonary hypertension, or heartworm disease.[14]

Evaluation of the lungs in animals with respiratory disease may reveal an increase in opacity, hyperlucency, and/or pulmonary mass lesions. It is important to assess the distribution of pulmonary abnormalities in conjunction with clinical signs. An increase in opacity of the lung is further separated into three categories of radiographic patterns: bronchiolar, interstitial, and alveolar. Differential diagnoses for the various lung patterns can be found in Box 212-1. Cats may prove more challenging to diagnose since the pattern and distribution of lung abnormalities are often not as reliable as with dogs. For example, the distribution of pulmonary infiltrates in cats with cardiogenic pulmonary edema is often patchy and asymmetric, rather than perihilar, and cats with pneumonia often do not have cranioventral distribution and alveolar patterns, as seen in dogs (Figure 212-2).[4] Pulmonary hyperlucency might be seen secondary to overexposure, hypovolemia, hyperinflation, PTE, cavitary masses, bronchiectasis, or areas of pulmonary parenchymal dissolution (emphysema, pneumatocoele, bulla). Neoplasia is the most common cause of solitary or multifocal mass lesions in the lungs, although abscess, granuloma, or fluid-filled structures cannot be ruled out.[15]

Fluoroscopy allows for real-time imaging of the thoracic structures. The motion studies obtained are often helpful in evaluation of the animal with tracheal collapse. The animal is placed in lateral recumbency and the trachea and bronchi are examined during both quiet respiration and induced coughing. Coughing is induced by gentle digital palpation of the trachea near the thoracic inlet. A videotape of the fluoroscopic study is useful for reviewing the airway changes in slow motion and diagnosing subtle dynamic airway disease.

212.6.1.1 **Box • 212-1 Differential Diagnoses for the Various Lung Patterns Seen on Thoracic Radiographs**

212.6.1.1.1 **Bronchial Pattern**

Chronic bronchitis (irritant, allergic, parasitic)

Calcification

Peribronchial cuffing (edema, bronchopneumonia, pulmonary infiltrates with eosinophilia)

212.6.1.1.2 Interstitial Pattern

Nodular

- Neoplasia
- Granuloma (eosinophilic, fungal, parasitic or heartworm-associated, foreign body)
- Bulla with fluid
- Hematoma, abscess, cyst
- Mucus-filled bronchus
- Bronchiectasis

Hazy and unstructured

- Diffuse
  - Artifact (underexposure, obesity, end-expiratory film)
  - Degenerative changes (“old dog lung”)
  - Neoplasia (lymphosarcoma, metastasis)
  - Pneumonitis (toxic, inhalant, metabolic, viral, parasitic)
  - Acute respiratory distress syndrome
  - Transitional stages of diseases such as edema, hemorrhage, bronchopneumonia
- Localized
  - Hemorrhage

PTE

Foreign body

Partial atelectasis

Transitional stages of disease such as edema, bronchopneumonia, hemorrhage, or parasites

212.6.1.1.3 Alveolar Pattern

Diffuse

Edema (cardiogenic or non-cardiogenic)

Bronchopneumonia

Hemorrhage

Smoke inhalation

Near-drowning

Acute respiratory distress syndrome

Localized

Edema

Bronchopneumonia

Hemorrhage

Primary lung tumor or metastasis

Lobar collapse or atelectasis

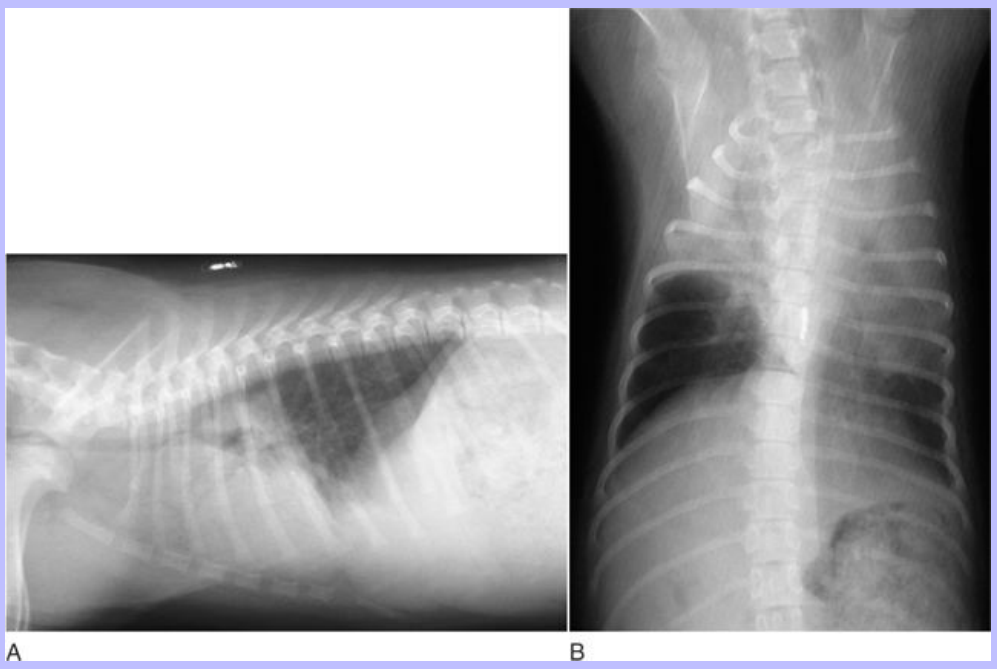
Heartworm disease

Infarct

Bronchography creates an outline of the mucosal surfaces of the trachea and bronchi using radiopaque contrast material.[16,17] Since bronchoscopy is now widely available, this diagnostic test is rarely used. The current use of bronchography may be limited to the evaluation of the severity and distribution of severe bronchiectasis prior to considering a lobectomy or pulmonectomy. Bronchography is typically performed under heavy sedation or anesthesia using fluoroscopic guidance to place a catheter through the endotracheal tube and into the pulmonary areas of interest. Contrast material such as Dionosil or sterile barium sulfate is injected and allowed to distribute during patient respiration. Fluoroscopic imaging and/or thoracic radiographs are then obtained. Potential complications (rare) include allergic reactions to the contrast, bronchospasm, retention of contrast in the small airways, or chemical pneumonitis.

1210
1211

Figure 212-2 A lateral **(A)** and ventrodorsal **(B)** chest radiograph in a puppy with aspiration pneumonia. Cranioventral air bronchograms are evident.



Pulmonary angiography is useful for the detection of vascular anomalies (congenital or acquired) and pulmonary thromboembolism. Pulmonary angiography is performed by injecting iodinated contrast intravascularly in order to opacify the pulmonary arteries and veins. Selective pulmonary angiography is superior to nonselective angiography but does require injection of a medium-density, nonionic contrast material into a catheter in the pulmonary artery or a branch thereof. With nonselective angiography, the

contrast material is injected into the jugular or cephalic vein and films are taken at a speed of 1 to 2 per second or a fluoroscopic recording is made for both procedures (up to 5 to 30 seconds with severe vascular obstruction or cardiac dysfunction).[18] Potential complications include vascular injury, thrombosis secondary to injury, embolization of air, blood clots, or catheter material, infections associated with unsterile techniques, cardiac arrythmias due to endocardial stimulation from the catheter, or immune reactions to the contrast agent (including asystole and death).[19]

212.6.2 Ultrasonography

Ultrasonography can be useful in animals with nasopharyngeal soft tissue or fluid-filled masses.[20] Ultrasound has also been used to assist in the diagnosis of tracheal collapse and laryngeal paralysis in dogs.[21,22] Identification of pulmonary consolidation, masses, atelectasis, or torsion, as well as pleural or mediastinal abnormalities, may be detected using ultrasound. Ultrasound guided aspirates or biopsies are readily obtained using real-time visualization of the needle entering the tissue or fluid lesion.[23–25] Potential risks include bleeding, iatrogenic pneumothorax, or the introduction of infectious agents during the procedure. Using ultrasound, it may be easier to distinguish pleural or pulmonary opacities seen on radiographs or better visualize peripheral, pulmonary lesions that may be obscured by pleural effusion. In dyspneic patients, ultrasound is easily performed with the animal in sternal recumbency and may be better tolerated than radiographs. However, ultrasound is unable to allow visualization of lesions within an aerated lung since air impedes the transmission of sound. Ultrasound is operator-dependant and requires an experienced user for good results.

212.6.3 Nuclear Imaging

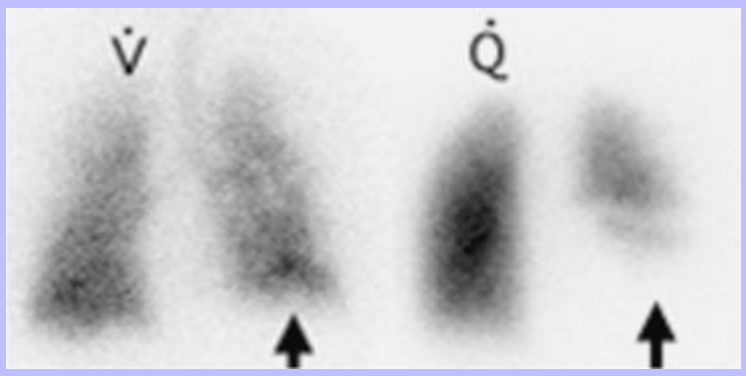
Nuclear scintigraphy is performed by the administration of a radioactive nuclide to the patient and detection of the energy from the radionuclides as they decay, with use of a camera that records the results to a computer monitor or photographic film.[26,27] Technetium 99m (^{99m}Tc) is the most common nuclide utilized. If pulmonary mineralization is suspected, bone-seeking radiopharmaceuticals can also be used.[28] (see Chapter 100).

Nuclear scintigraphy is most commonly utilized with lung disease in small animals to evaluate pulmonary perfusion in animals with suspected pulmonary thromboemboli or vascular anomalies.[27,29–31] It is relatively specific and sensitive for this purpose in dogs.[32] The radioactive particles are given intravenously and go through the pulmonary arteries, where they are trapped in the capillary bed. A normal animal shows uniform radioactivity throughout the lung fields. Vascular occlusion secondary to pulmonary emboli appears as deficient radioactive areas or photopenic defects on the perfusion scan. The specificity of diagnosing ventilation/perfusion inequalities is increased if the nuclear scan is combined with a ventilation scan.[33]

1211

1212

Figure 212-3 A ventilation-perfusion scan in a dog with a pulmonary thromboembolism. Normal ventilation is seen on the left (*V, arrow*), and a perfusion deficit is present on the right (*Q, arrow*).



The ventilation scan is performed using ^{99m}Tc-labeled diethylenetriamine pentaacetic acid, which is delivered via a nebulizer to the patient.[27,33] The radioactive aerosol is distributed in the air spaces, and areas of deficient radioactivity indicate poorly ventilated locations. A simultaneous ventilation and perfusion scan (Figure 212-3) enables the calculation of the ventilation: perfusion ratio (normal is 1:1). However, results are dependent on blood flow and ventilation differences in various parts of the lung and are difficult to interpret in the face of pulmonary interstitial lung disease.

Positron emission tomography (PET) is another noninvasive nuclear imaging technique that uses radioactive positrons to assess the chemical and physiological changes related to metabolism in a specific organ.[34] PET has been used in human medicine to diagnose and stage lung masses, monitor the size and activity of cancerous lesions, diagnose pulmonary thromboembolism, and assess changes in vascular permeability.[35,36] This technology is not often available for use in veterinary medicine but has been used experimentally in dogs to measure lung water, pulmonary vascular permeability, regional pulmonary blood flow, degree of lung injury, and regional pulmonary function.[37–45]

212.6.4 Alternative Imaging

Computed tomography (CT) and magnetic resonance imaging (MRI) are useful to detect or monitor nasopharyngeal, tracheal, or thoracic cavity lesions, assess the involvement of surrounding structures, and determine anatomic relationships. This imaging modality requires general anesthesia but may provide more valuable information regarding the pathogenesis, extent, and changes of many disease states.[46–55]

Computed tomography (CT) utilizes a 360-degree x-ray beam to create a three-dimensional, computer-processed cross-sectional image of body tissues or organs. The CT scanner acquires images incrementally, at a rate that varies with the type of machine and settings. The speed of the image acquisition is especially important when viewing the lung, since respiratory and cardiac motion will interfere with image quality. Most conventional CT machines have dynamic modes that acquire 8 to 12 scans per minute, although this rate is still incapable of obtaining suspended respiratory images. CT scans produce images with superior

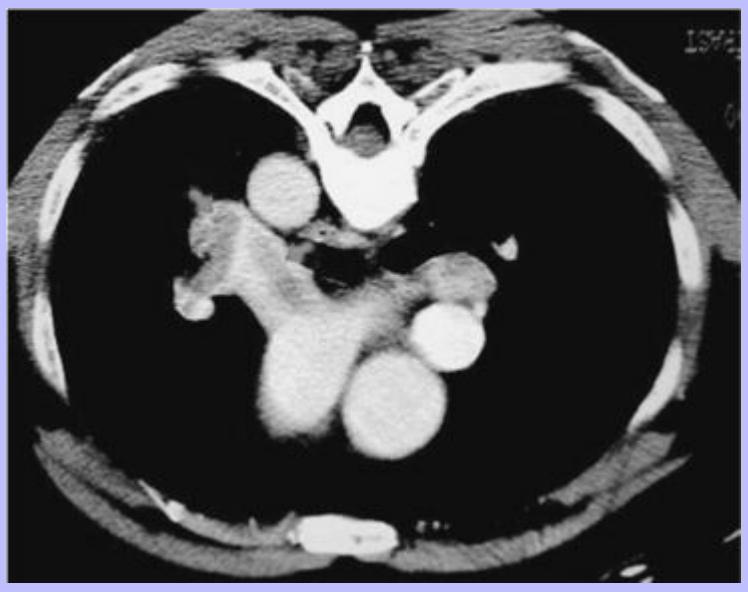
density discrimination that are free of superimposition from overlapping thoracic structures when compared with radiographs.[56] CT scanning is therefore the preferred tool for pulmonary imaging in people and is often used to differentiate pleural, extrapleural, or mediastinal tissues, or to better visualize the lungs when pleural effusion makes radiographic evaluation of the lungs difficult. A CT scan may be indicated to evaluate the lungs when thoracic radiographs are normal, but there is clinical suspicion of pulmonary disease, in animals that have abnormalities present on radiographs that require further clarification (i.e., prior to surgical intervention), or to assist in cancer staging and monitoring changes. Metastatic nodules are more easily detected using CT than radiography, and newer technologies such as spiral CT and high-resolution CT have made CT imaging faster and more diagnostically useful.[47,50,57–60]

High-resolution CT has excellent spatial resolution and is able to demonstrate pulmonary structures that are only 300 μ, as well as monitor changes in airway and vascular diameter in vivo following various stimuli, revealing differences that may not be detectable with spirometry. It has been used in dogs to measure changes in airway diameter and assess the function of pulmonary vessels and airways.[61–63]

Helical or spiral CT utilizes a “slip-ring” technique and high-energy x-ray tubes that allow the tube and detector to continuously circle the patient, taking pictures as the patient is transported through the scanner. It takes approximately 1 second for the scanner to complete a single rotation so that 20-to 30-cm organs can be scanned in under 30 seconds, much more quickly than conventional CT methods.[64] This eliminates the motion and artifacts secondary to inconsistent lung inflation from one slice to the next, a current problem with conventional CT scanners.[65]

Spiral CT angiography enables scanning to occur simultaneously with maximum contrast medium opacification, which obviates the need for selective catheterization. This is especially beneficial in animals since catheterization requires general anesthesia, a potentially risky procedures in dyspneic animals with suspected PTE. Spiral CT angiography has been studied in humans to discover filling defects within the pulmonary arteries secondary to emboli, even in the face of underlying pulmonary disease (Figure 212-4).[66–70] Acute and chronic emboli may be differentiated by their appearance.[71] The clinical usefulness of CT angiography in small animals remains to be determined but may be preferable to nuclear scintigraphy due to its superior diagnostic accuracy and speed.[67,68] The procedure has been used experimentally to effectively diagnose pulmonary thromboembolism in dogs and clinically in dogs with metastatic pulmonary lesions.[72,73] The detection of pulmonary metastases has shown limited success.[73]

Figure 212-4 Spiral CT angiography in a dog with pulmonary thromboemboli. The arrows point to the filling defects within the pulmonary artery. (Courtesy Tobias Schwarz and Steve Cole.)



MRI is based on the principles of nuclear magnetic resonance, a spectroscopic technique that reveals chemical and physical characteristics of the examined tissues using the absorption and emission of energy in the radio frequency range of the electromagnetic spectrum. Conventional MRI is based on the spin magnetism of the hydrogen nucleus and the fact that water is abundant in biologic tissue. However, the air spaces in the lungs are challenging to image since they are porous, which causes large internal magnetic field gradients, and contain primarily air rather than water (which contains the hydrogen proton). The use of hyperpolarized (HP) noble gas (specifically ^{3}He and ^{129}Xe) has emerged over the past decade to circumvent this problem. The polarized or inert gas is inhaled by the patient and subsequently detected with the use of MRI in the airways of the lungs and dissolved in the proximal blood.[74,75] In addition, the use of novel paramagnetic aerosol ventilation and perfusion MRI imaging using gadolinium diethylenetriamine pentaacetic acid (Gd-DTPA) has been used experimentally to diagnose airway obstruction and PTE in dogs.[76] More recently, noncontrast, electrocardiography (ECG)-gated fast-spin-echo (FSE) MRI has shown promise experimentally as a means of rapidly assessing dynamically altered regional lung perfusion or airway obstruction in dogs.[77] The MRI technique has also expanded to include three-dimensional reconstruction abilities, so the user can view surface details and internal structures and dissect each layer of tissue in a mock, on-screen approach.
Two-dimensional and three-dimensional techniques have been developed to perform angiographic studies without the need for contrast agents, based on the knowledge that the image intensity of flowing blood is proportional to the velocity of the flow. Although the use HP MRI, vascular MRI (VMRI) or MR angiography (MRA) is limited in veterinary medicine, future studies may prove worthwhile.

212.7 SCOPING PROCEDURES

Laryngoscopy allows visualization of the short cartilaginous lumen between the lower portion of the pharynx and the trachea. It is indicated in patients with suspected upper airway obstruction, palpable or radiographically visible mass lesions in the area of the larynx, or unexplained changes in vocalization. Clinical signs that are commonly related to laryngeal disease include coughing, choking while eating, cyanosis or syncope with exertion, inspiratory dyspnea with stertor or stridor, and changes in vocalization or sound production (meow, purr, or bark). Laryngoscopy is useful in the diagnosis of an elongated soft palate, laryngeal paralysis, laryngeal edema, acute laryngitis, laryngeal collapse, chronic granulomatous or proliferative laryngitis, traumatic lesions, everted laryngeal saccules, laryngeal or pharyngeal foreign bodies, polyps or neoplasms of the larynx, and glosso-epiglottic mucosal displacement.[78,79] In animals with severe clinical signs, stabilization with a tracheostomy or other bypassing maneuver might be necessary prior to examination.[80] The procedure can be performed with use of a standard intubating laryngoscope and mouth speculum to hold the mouth open, although a rigid or flexible bronchoscope may be required if areas distal to the vocal folds or infraglottic region require examination. The tongue is depressed to allow adequate examination of the pharynx, soft palate, lingual and glottal surfaces of the epiglottis, arytenoid cartilages, aryepiglottic folds, and vocal folds. Abnormal shape, color, and/or motility should be noted. The soft palate should be examined and palpated and the nasopharynx is examined by retracting the soft palate rostrally with a spay hook and visualizing the area with a heated dental mirror. Laryngoscopy should be performed with neuroleptanalgesia, if possible, rather than general anesthesia to prevent relaxation of the laryngeal muscles and distortion of the larynx. Propofol or thiobarbiturates are often recommended for examination of laryngeal function. The routine administration of doxapram prior to evaluation has been studied and recommended to increase intrinsic laryngeal function and aid in the diagnosis of laryngeal disease in dogs.[81] The arytenoid cartilage and vocal folds should abduct symmetrically during inspiration and relax during exhalation. The correlation of movement of these structures during the respiratory cycle should be examined.[78]

The pharynx is the crossroads of the respiratory and digestive tracts and consists of the nasopharynx, oropharynx, and laryngopharynx. If a flexible endoscope is used, retroflex nasopharyngoscopy will enable superior visualization, with or without biopsy sampling of the nasopharynx. Respiratory signs that might warrant pharyngoscopy include dyspnea, coughing after swallowing, oronasal reflux of liquid or food, open-mouth breathing, or stertorous breathing. Dysphagia, retching, gagging, and inappetance may also be present in animals with pharyngeal disorders. A standard intubating laryngoscope allows adequate visualization of the pharynx, although an endoscope may be used if further scoping is to follow. Prior to anesthesia in animals with the above clinical signs, cervical and thoracic radiographs, a thorough neurologic examination, and/or a esophagram with fluoroscopy may be indicated. Propofol or thiobarbiturates should be used and examination of the pharynx is performed prior to intubation. The soft palate, tonsils and tonsillar crypts, palatopharyngeal arches, and lateral pharyngeal wall should be carefully examined.[78]

Rhinoscopy is most commonly used in animals with chronic nasal disease, although more emergent cases may benefit as well (nasal foreign body retrieval, nasal parasite detection, and evaluation of epistaxis in animals with normal coagulation parameters).[78] Rhinoscopy has proven to be a useful tool in the animal with nasal disease, having a diagnostic success rate of 83% when performed by an experienced endoscopist and used in conjunction with rhinoscopy-assisted biopsy.[82] Rhinoscopy greatly decreases the morbidity and mortality associated with surgical rhinotomy when used to visualize the nasal passages and obtain biopsy samples. A surgical plane of anesthesia is required for rhinoscopy since the nasal mucosa is extremely sensitive (prior administration of topical anesthetic may be beneficial as well). An otoscopic speculum may be used to visualize the proximal 2 cm

of the nasal passages in most animals. Since a majority of neoplastic and mycotic diseases are in the caudal half of the nasal cavity, this method has limited diagnostic usefulness. In order to perform rhinoscopy, a rigid arthroscope, flexible or rigid cystourethroscope, or flexible pediatric bronchoscope is used. Width, length, and flushing/biopsy port availability makes the various scopes more or less desirable for specific situations.

Bronchoscopy may be useful in animals with suspected lower airway disease. Clinical signs that may indicate the need for a bronchoscopic examination include chronic coughing, hemoptysis, unexplained pulmonary infiltrates on thoracic radiographs, and the suspicion of an airway mass or foreign body. Bronchoscopy allows visual inspection of the airways and the collection of samples from the respiratory tract. Bronchoscopy may be used therapeutically for the removal of foreign bodies, resolution of mucus plugs, and removal of copious secretions or blood.[83,84] Diagnostically, bronchoscopy allows the clinician to visualize, lavage, brush, and/or biopsy the airways. In animals with intraluminal tracheal tumors, bronchoscopically guided biopsies may be obtained.[85] Bronchoscopy is valuable in the diagnosis and staging of tracheal collapse in dogs (Figure 212-5).[86,87] Bronchoscopy must be performed under general anesthesia to prevent coughing and laryngospasm. Intubation may not be possible if the endotracheal tube size is equal to that of the bronchoscope. If the animal must be extubated for a bronchoscopic examination, oxygen should be supplied via a catheter placed in the trachea beside the bronchoscope, through the biopsy channel of the bronchoscope, or by jet ventilation through a catheter. A T-shaped adaptor can be used in larger animals so the scope can be passed through the endotracheal tube while administering inhalant anesthesia.[83,84]

212.8 RESPIRATORY SAMPLING TECHNIQUES

It is often necessary to obtain fluid, cells, and/or tissue from the respiratory tract for analysis. There are a variety of techniques that will be discussed in order to obtain specimens from the upper and lower respiratory tract.

Cytologic sampling of the upper respiratory tract can be challenging. Since there is a wide range of normal bacteria in the nasal cavity in small animals,[88] bacterial cultures of nasal swabs are not routinely performed. If a significant nonresponsive bacterial infection is suspected, a surgically obtained sample from the caudal nasal cavity may prove most useful for culture and sensitivity analysis, since cultures from this area are sterile approximately 50% of the time in dogs.[89] Most nasal disease results in inflammation of the mucosal epithelium and secondary bacterial infections, which tends to obscure the underlying disease. In addition, the disease process may be focal or multifocal, rather than diffuse. Nonsurgical techniques for the collection of diagnostic nasal samples include superficial and deep nasal swabs, nasal flushing, traumatic nasal flushing, pinch biopsy, and core biopsy. *Cryptococcus* and *Aspergillus* spp. infection can be diagnosed on examination of a superficial nasal swab; however, these agents may be encountered occasionally as normal flora or colonizers of abnormal sites. Confirmation of the disease typically requires further testing. Serologic testing, tissue biopsy, or fungal isolation should be considered in cats with a chronic nasal discharge.[90,91] Neutrophils commonly predominate in diseases such as trauma, neoplasia, infection, and foreign bodies,[92] whereas eosinophils may predominate in allergic or parasitic diseases.[93]

Biopsy collection techniques should be performed under general anesthesia. The patient should be intubated with a cuffed endotracheal tube and the caudal pharynx packed with gauze to prevent aspiration of blood or discharge. Potential complications include hemorrhage and inadvertent puncture of the cribiform plate.

Transtracheal aspiration may be indicated in dogs with clinical or radiographic evidence of airway disease. It is contraindicated in animals with severe dyspnea or coagulopathies. The procedure is often performed on awake or lightly sedated animals in sternal recumbency or a sitting position with the neck extended. The area over the cricothyroid membrane is clipped and sterilely prepared. A local anesthetic is administered subcutaneously and a relief incision is made in the skin over the cricothyroid membrane. A shielded catheter-through-a-needle or catheter-through-a-catheter (18-to 20-gauge, 8-to 12-inch Intracath with wire stylet jugular catheter by Becton Dickinson, Sandy, UT, works well) system is used to puncture the cricothyroid membrane and the catheter is advanced into the distal trachea.[94] The needle is removed from the airway and covered. A syringe containing 1 to 10 mL of preservative-free 0.9% saline is attached to the end of the catheter. The saline is injected into the trachea and negative pressure is applied to the plunger of the syringe as the animal is gently coupaged. If possible, the catheter is moved up and down the trachea during the syringe aspiration. Fluid injection and aspiration may need to be repeated two to three times. Fluid retrieved is saved for cytologic analysis and microbiologic testing. Potential complications include catheter related trauma to the lower airways, which results in hemoptysis, coughing, and respiratory impairment or needle-related trauma to the laryngeal region that might cause bleeding, subcutaneous emphysema, pneumomediastinum, pneumothorax, or pneumopharynx and airway obstruction.[94] Airway samples from cats or very small dogs should be collected via an endotracheal tube using a long catheter inserted through the tube to infuse and aspirate fluid.[95]

Bronchoalveolar lavage (BAL) may be performed with or without bronchoscopic guidance. BAL cytology has been described in normal cats and dogs.[94,96–101] It is indicated in dogs and cats with alveolar or interstitial lung disease to help identify neoplastic, infectious, or inflammatory diseases.[102] Microbiologic, biochemical, and

immunologic testing of the lavage fluid may be performed. Potential side effects are primarily related to general anesthesia, although transient hypoxemia or exacerbation of respiratory insufficiency may develop during the BAL. In order to obtain a diagnostic sample, the bronchoscope is cleaned and the biopsy port flushed with sterile saline before advancing it into the diseased airway. The scope is wedged into the smallest bronchus possible and 10 to 25 mL of warmed (37° C) nonbacteriostatic saline is instilled (alternatively, polyethylene tubing can be passed through the biopsy channel and wedged into a smaller airway). The fluid is removed by suction into a mucous suction trap or by hand using a 35 mL syringe. Between 40% and 60% of the fluid instilled is typically retrieved, depending on the wedging of the bronchoscope and patency of the airway.

At least two distant segments should be lavaged to increase the likelihood of disease identification.[102] A modified stomach technique has also been described for BAL in dogs.[103] Analysis should include a differential cell count on a cytocentrifuged sample and a culture and sensitivity if indicated. Normal cell counts in the dog and cat are approximately 200 to 400 cells per milliliter, with 65% macrophages in the cat and 83% macrophages in the dog. Neutrophils typically make up 5% of the cells in dogs and cats, lymphocytes 4% to 6%, mast cells 1% to 2%, and eosinophils up to 25% in the cat and 4% in the dog.

Bronchial brushing may be performed through the bronchoscope to obtain samples of focal lesions within the airway. This procedure should be performed after the BAL to prevent blood contamination. A sterile cytology brush with a protective polyethylene tubing is inserted through the instrument channel, placed against the bronchial wall, advanced out of the sheath, and rotated along the lesion site. A smear is made onto a glass slide or the brush is placed in sterile saline solution and swirled to release cells for cytologic analysis and culture/sensitivity testing.[104] Mild bleeding at the site is the most common complication.

1214 1215

Healthy dogs and cats have a certain percentage of bacteria (*Pasteurella* spp., *Mycoplasma* spp., *Streptococcus* spp., *Staphylococcus* spp., *Acinetobacter* spp., Moraxella spp., *Enterobacter* spp., *Pseudomonas* spp., *Escherichia* coli, *Klebsiella* spp., and *Bordetella bronchiseptica*) isolated from samples taken with a sterile culture swab at the level of the lower trachea or carina.[98,105,106] Therefore the culture results must be interpreted in conjunction with cytologic findings. Intracellular bacteria and suppurative inflammation are supportive of a true bacterial infection.

Biopsies may be obtained using bronchoscopic guidance for histopathologic evaluation of focal abnormalities or for electron microscopic (EM) evaluation in animals with suspected ciliary dyskinesia. Biopsy samples are acquired using the biopsy port of the bronchoscope and samples should be fixed in formalin for histopathology or glutaraldehyde for EM. The animal should be monitored for hemoptysis from biopsy-site hemorrhage following the procedure.[94,107]

Transthoracic fine-needle aspiration (FNA) or biopsy might be indicated in patients with a single or multifocal pulmonary mass lesion greater than 1 cm and easily accessible or animals with diffuse air space or interstitial disease.[108,109] Fluoroscopic or ultrasonographic guidance is useful.[110,111] Contraindications include pulmonary cysts or bullae, unco-operative patients, refractory coagulopathies, or pulmonary hypertension. Animals with respiratory distress, preexisting pneumothorax, or behavior problems are not good candidates. Animals with clinical evidence of an infectious process such as a fever, inflammatory leukogram, and lethargy may be better candidates for endotracheal, transtracheal, or bronchoalveolar lavage.

Potential complications include pneumothorax, empyema, bleeding, implantation of neoplastic cells along the needle or biopsy tract, or death. One study revealed a 12% death rate and 5% incidence of pneumothorax following transthoracic FNA procedures.[112]

212.9 THORACOTOMY AND BIOPSY

An open-chest lung biopsy may be necessary in some cases where other less invasive techniques are nondiagnostic or histopathology is required to confirm a diagnosis. Contraindications include coagulopathy or an unacceptable anesthetic candidate. It requires greater expense, invasiveness, and risk, however it does allow the opportunity to visualize the lung and obtain an adequate sample size for a diagnosis. A standard thoracotomy is typically performed, although a “keyhole” technique is often effective for obtaining a histologic diagnosis of interstitial lung disease in dogs and cats.[113] The tissue sample is cultured, an impression smear analyzed, and the remainder placed in formalin for histopathologic evaluation. Potential complications include hemorrhage, pneumothorax, or secondary infections.

212.10 PULSE OXIMETRY AND ARTERIAL BLOOD GAS ANALYSIS

Pulse oximeters are commonly used to continuously and noninvasively measure the oxygen saturation of hemoglobin. Pulse oximetry measurements can be used to determine the need for oxygen administration and to monitor patients that are receiving oxygen supplementation. A hemoglobin saturation of 95% to 100% is normal in dogs and cats. There are, however, many limitations, especially in critically ill animals, which makes this technology less reliable than direct arterial blood gas analysis.

Arterial blood gases (ABGs) are extremely useful in the assessment of an animal's oxygenation, ventilation, and acid-base balance. ABGs are commonly used to quantitate the severity of respiratory impairment and monitor response to therapy. With the advent of fairly inexpensive, handheld blood gas analyzers, ABGs are routinely used in many private practices. Normal arterial blood gases in the dog and cat are pH=7.36–7.44, PaO_2=90–100 mmHg, $PaCO_2$=36–40 mmHg, HCO_3=20–24 mEq/L, and BE +/– 4 mEq/L.[114]

Arterial blood gas sampling is the most accurate method of evaluating the partial pressure of oxygen in the arterial blood. In dogs, arterial puncture is commonly performed using the dorsal metatarsal or femoral arteries, although the radial artery or digital palmar arteries may also be used. In cats, the femoral artery is typically the only easily accessible artery that is large enough to readily obtain an adequate sample. Preheparinized syringes will help prevent the sample from clotting prior to analysis, and the sample should be capped with material that is not permeable to gas to prevent air contamination and equilibration. Following arterial puncture, direct pressure should be applied to the site for 3 to 5 minutes to prevent bleeding. Hypoxemia is defined as a PaO_2 less than 80 mm Hg and possible causes include a right-to-left shunt (patent ductus arteriosus, ventricular septal defects, intrapulmonary shunts due to atelectasis or consolidation), ventilation perfusion mismatch (due to various types of pulmonary disease), diffusion impairment (relatively uncommon), hypoventilation (secondary to anesthesia, neuromuscular disease, pleural space or chest wall abnormalities), or a decrease in the fraction of inspired oxygen (oxygen tank empty and hooked up to patient, high elevations).[115] The animal's ability to oxygenate is assessed by examining the PaO_2 and determining the difference between the partial pressure of oxygen in the alveolar and the arterial blood, often referred to as the “A-a gradient.” This equation is based on the knowledge that there is almost complete equilibration of gases between the alveolar gas and the pulmonary capillary when alveolar ventilation and pulmonary perfusion (V/Q) are matched. The partial pressure of oxygen in the alveolus (PaO_2) is calculated as follows:

$$PaO_2 = [(PB - PH_2O)FiO_2] - PaCO_2/RQ)$$

where PB = barometric pressure in mm Hg, PH_2O = water vapor pressure in mm Hg, FiO_2 = fraction of inspired oxygen, RQ = respiratory quotient (normally 0.8), and $PaCO_2$ = partial pressure of carbon dioxide in the alveolus in mm Hg.

The normal alveolar to arterial difference is less than 15 mm Hg when the patient is breathing room air. The A-a gradient is increased in animals with a right-to-left shunt, low mixed venous oxygen saturation, ventilation/perfusion mismatching, and diffusion impairment. Another method of assessing the severity of oxygenation impairment is to calculate the PaO_2: FiO_2 ratio. Healthy people and animals have a ratio of 400 to 500, but a value less than 300 is suggestive of acute lung injury and less than 200 indicates acute respiratory distress syndrome in people.[114–116]

Ventilation refers to the movement of gas into and of the alveolus and is measured by the animal's ability to maintain normal arterial CO_2 levels. The carbon dioxide tension in arterial blood represents the balance between the production of CO_2 in the tissues and CO_2 excretion in the alveolus. Carbon dioxide excretion is dependent upon the amount of CO_2 delivered to the alveolus, alveolar ventilation, and the amount of deadspace ventilation that does not contribute to gas exchange. If there is inadequate elimination of CO_2 in the lungs or excessive CO_2 production in body tissues (less common), carbonic acid and hydrogen ions accumulate, resulting in a respiratory acidosis. Potential causes of inadequate ventilation include diseases of the central respiratory center, airways, pulmonary parenchyma, pleural space, pulmonary vasculature, or chest wall. Respiratory fatigue, a primary metabolic alkalosis, or anesthetic drugs may also lead to hypoventilation. If the problem is maintained for 24 to 48 hours, the kidneys respond over hours to days by increasing the excretion of hydrogen ions and retaining bicarbonate.[114–116]

1215 1216

If alveolar ventilation is increased, a respiratory alkalosis will develop. Potential causes include hypoxemia, primary metabolic acidosis, and central nervous system disease. Anxiety, pain, fear, and excitement may also lead to hyperventilation. If the problem is maintained, the kidneys will again compensate slowly by retaining hydrogen ions and excreting bicarbonate.[114–116]

In order to interpret a blood gas measurement, the pH should first be assessed. Determine whether the pH is normal or if there is a primary respiratory or metabolic cause for the disorder, if there is compensation for the primary disorder, or if there are two primary abnormalities present.

212.11 PULMONARY FUNCTION TESTING

Pulmonary function testing (PFT) is used to objectively assess functional respiratory deficits. It often serves as a valuable tool to provide information regarding the severity of pulmonary dysfunction as well as response to therapy. The information acquired quantifies the degree of dysfunction and is able to localize the site of respiratory dysfunction. There are, however, a few limitations to the use of pulmonary function testing in small animal medicine. Many animals require anesthesia in order to perform the testing, the equipment utilized is expensive and requires operational expertise, and there is a large amount of individual variation that makes isolated measurements in time less valuable in an individual animal.[117]

Since veterinary patients are not able to understand instructions to perform a maximal forced exhalation, it is not possible to perform the noninvasive, rapid spirometric tests that are commonly used in human medicine. Alternatively, the tidal breathing flow-volume loop (TBFVL), which was originally developed for human infants,

can be used in the unanesthetized and untrained veterinary patient to assess and quantify airflow, volume, or respiratory cycle changes.[118]

To measure TBFVL, a pneumotachograph and a differential pressure transducer are used in accordance with the size of the patient.[118–121] The Fleisch pneumotachograph is commonly used in small animals. This device measures the pressure gradient as air follows across a resistance device. The rate of airflow is proportional to the drop in pressure inside the instrument, and is plotted on the x-axis. An electronic integration of the instantaneous flow rate is used to determine flow, which is plotted on the Y-axis, generating a "flow-volume" or "F-V loop."[120] Cats or dogs are allowed to sit or stand during the testing procedure. A tight-fitting mask is placed over the muzzle, including the commisure of the lips. A 1-to 3-minute recording of the TBFVL waveforms is obtained once the animal is calm and free of extraneous movements. Computerized pulmonary mechanics analyzer systems are now available to create the F-V loops (Respiratory Loop Analysis Software, BUXCO Electronics, Sharon, CT) and provide fast, accurate data analysis.[118,122] Information acquired from the flow, volume, and time analysis may be combined to determine time ratios, inspiratory to expiratory flow ratios at indicated lung volumes, flow ratios at different lung volumes, or changes in volume during a selected period of time.[118,121] In order to improve the diagnostic sensitivity and reproducibility of the TBFVL test, application of positive pressure to the external chest wall, negative pressure to the airway, increased concentrations of the inspired CO_2 or doxapram hydrochloride have been used.[123–126] When CO_2 is used adjunctively, an increase in the inspired oxygen concentration may be helpful to prevent hypoxic pulmonary or vascular changes.

TBFVL from normal healthy cats and dogs with differing nasal anatomy have been described.[118,121,127] TBFVL have been used clinically in veterinary medicine to diagnose and/or evaluate treatment modalities in dogs with chronic obstructive lung disease, laryngeal paralysis, tracheal collapse, brachycephalic syndrome, and cats with chronic lower airway disease.[118,121,127–134] Loops are easily obtained in most non-sedated, naïve dogs and cats. It is contraindicated in animals with severe dyspnea since placement of the mask may exacerbate the animal's condition.

The measurement of upper airway pressures can be obtained with use of a transcutaneously placed catheter into the trachea, using the same technique as described for transtracheal aspiration above. Using a pressure transducer, the pressure changes in the upper airways are readily measured. A face mask technique can be used, as described for TBFVL measurements, to obtain the flow and volume measurements and the pressure transducers matched to a defined frequency.[135] The change in pressure is divided by the change in flow to calculate resistance in the upper airway, and this is easily performed using a mechanics analyzer and designated software analysis program. Normal values for upper airway resistance have been established in dolichocephalic and mesaticephalic dogs.[136] Measurements of upper airway resistance might be beneficial in diagnosing and quantifying airway obstruction and changes in response to therapy.

Pulmonary mechanics measurements typically require general anesthesia in small animals in order to pass an esophageal balloon for the measurement of transpulmonary pressure,[137] whereas flow and volume measurements are made via an endotracheal tube. Measurements have therefore been used primarily in the research setting and it is important to recognize the potential effects of the endotracheal tube and anesthetic agents used on measurements obtained.[138–146] Clinical evaluation may be performed using a nasoesophageal canula and a tight-fitting face mask.[147–150] Dynamic pulmonary compliance is calculated as the change in lung volume divided by the change in transpulmonary pressure from the beginning to the end of inspiration. Static compliance

is similarly calculated by measuring changes in volume and pressure during an incremental inflation and deflation of the lungs.

Normal values for dynamic compliance (Cdyn) and pulmonary resistance (RL) have been measured in cats and dogs.[151–154] Due to differences in body conformation, weight, age, and sex, measurements in dogs have considerable variation between studies. In medium-sized dogs, Cdyn may correlate most accurately with trunk length rather than body weight or chest circumference.[154] Measurement of pulmonary mechanics such as tidal volumes, minute ventilation, peak inspiratory pressure, resistance, and compliance may be helpful in the mechanically ventilated patient to assist in identifying pulmonary parenchymal, pleural space or chest wall disorders, deciding when to wean the patient, monitoring changes over time and in response to therapy, identifying, and detecting bronchospasm or mucous plugs during ventilation.[155–159] Clinically, the CO_2SMO (Novametrix Medical Systems Inc., Wallingford, CT) is an extremely useful pulmonary function monitoring device for the ventilated patient. However, positive pressure ventilation may interfere with esophageal pressure measurements.[160] Additional techniques that might be used to assess pulmonary function in dogs or cats include a forced oscillation measurement, forced deflation techniques, whole body plethysmography or dual-chamber plethysmography, and static thoracic compliance using a pediatric spirometer and a water manometer.[157,161–164]

1216

1217

212.12 ADDITIONAL DIAGNOSTICS

Nitric oxide (NO) has been shown to play a key role in the modulation of airway relaxation and responsiveness in cats.[165–168] Exhaled nitric oxide (ENO) levels might be a noninvasive means of detecting airway inflammation and its response to therapy. Preliminary data have shown that cats with a clinical diagnosis of asthma have increased ENO levels compared with control populations. (Matt Mellema, DVM, Harvard University, unpublished observations, personal communication.)

213 CHAPTER • 213 Diseases of the Trachea

Stephen J. Ettinger

Brett Kantrowitz

213.1 ANATOMY AND PATHOPHYSIOLOGY

The normal trachea is a semi-rigid, flexible tubular passageway connecting the larynx to the bronchi. It is made up of 35 to 45 C-shaped cartilages, each alternating with an elastic annular ligament. The cartilage-free, dorsal portion of the trachea is composed of mucosa, connective tissue, and tracheal muscle (the dorsal tracheal membrane). The trachea bifurcates into the mainstem bronchi at the level of the fourth or fifth thoracic vertebrae.

The cranial and caudal thyroid arteries are the major blood supply to most of the trachea. The recurrent laryngeal and vagus nerves supply parasympathetic innervation to the tracheal mucosa and its smooth muscle, which stimulates muscular contraction and glandular secretion. The inhibitory sympathetic fibers arise from the middle cervical ganglion and sympathetic trunk.

The tracheal mucosal layer is composed of a pseudo-stratified, ciliated columnar epithelium with goblet cells; mucus-secreting tubular glands are found in the submucosa. The ciliated cells of the epithelium act as part of the mucociliary transport system to propel mucous and inspired debris toward the pharynx.

The trachea has a limited number of ways to respond to an insult. Changes seen during examination of the trachea are usually not pathognomonic for a given disease state. The immediate response of the tracheal mucosa to irritation of any cause is increased mucus secretion. With continued insult, epithelial cells desquamate and goblet cell hyperplasia occurs. Squamous metaplasia occurs with continued insults if there is insufficient time for healing between episodes. Superficial defects in the tracheal mucosa begin to heal as early as 2 hours after cessation of an injury. Large areas of damaged epithelium devoid of functional cilia can impair the mucociliary transport system and predispose to infection and delayed healing.

The primary pathophysiologic response to stenotic disease is increased airway resistance that cannot be overcome through mouth breathing and decreased pulmonary compliance. With impaired air flow, hypoventilation and respiratory acidosis occur. Chronic obstruction can result in secondary pulmonary hypertension and right heart failure (cor pulmonale).

213.2 HISTORY AND PHYSICAL EXAMINATION

The most commonly recognized clinical signs of tracheal disease are coughing, stertorous noisy inspiratory sounds, stridulous or wheezing expiratory sounds, pulmonary edema, and occasionally cyanosis. See Chapter 53 for the clinical differentiation of coughing and its most commonly encountered causes and Chapter 54 for dyspnea and tachypnea. A thorough physical examination should follow a record of the history in evaluating patients with suspected tracheal disease. The physical examination should cover all aspects of the animal with particular attention to the entire upper and lower respiratory tracts as well as the cardiovascular system.

The neck should be palpated for evidence of surrounding disease such as subcutaneous emphysema, lymphadenopathies, abscess, cyst, neoplasia, thyroid gland enlargement, or any other mass that may involve the trachea. In most animals, except for the heavy or obese, the trachea can be palpated from the larynx to the thoracic inlet. The trachea is relatively noncollapsible, and obvious borders or angles usually cannot be felt.

Often a cough can be elicited with light tracheal palpation at the thoracic inlet when laryngeal or tracheal irritation or inflammation is present.

Auscultation of the lung sounds as well as respiratory sounds directly over the trachea, larynx, and nose should be compared to help localize the site of the lesion. Sounds are usually most intense near their site of origin. Examination of the oral and pharyngeal cavities is best done with the aid of anesthesia (e.g., Propofol, Thiopental) or light sedation.

213.3 DIAGNOSTIC TESTS

213.3.1 Radiography

Two views of the trachea should be obtained for routine radiographic examination—lateral and ventrodorsal or dorsoventral. Radiographs to evaluate the cervical trachea should be obtained separately from those of the thoracic trachea. The lateral radiographic examination must be performed with careful positioning of the patient to avoid artifactual deviations of the trachea, especially in the caudal cervical and cranial mediastinal regions. Excessive flexion of the occipitoatlantal articulation may cause deviations of the trachea, which may artifactually suggest extra tracheal masses (Figure 213-1). Dorsal deviation of the intra-thoracic trachea can be due to ventroflexion of the neck. Other causes include cardiac enlargement, pleural effusions, and cranial mediastinal masses. Ventral deviation of the thoracic trachea can be seen with a dilated esophagus or with diseases of the dorsal cranial mediastinum. Ventrodorsal (VD) or dorsoventral (DV) views are used to evaluate the course of the trachea. VD oblique views are occasionally needed when the thoracic tracheal lumen is superimposed over the vertebral column and sternum to prevent sufficient radiographic detail. These views are usually not necessary since the intrathoracic trachea normally courses to the right of the vertebral column and reaches the midline only at the tracheal bifurcation (carina).

Figure 213-1 Kinking of the trachea may occur with excessive flexion of the neck in small animals and in those with tracheal malacia. These undesirable causes of narrowing of the trachea must be avoided while the dog is radiographed and, more importantly, while the dog recovers from an anesthetic.

Tracheal radiographs should be surveyed for luminal filling defects, continuity of the mucosal lining, diameter, and placement within the cervical and thoracic regions. Normal aging may result in dystrophic mineralization of tracheal rings. This is not pathologic. The normal tracheal diameter generally decreases slightly from larynx to thoracic inlet but then increases.[9] The normal diameter of the trachea at the third rib should be approximately three times the width of the third rib at the level of the trachea.[1] Another method of determining tracheal diameter uses the ratio of the inner diameter of the trachea at the thoracic inlet to the distance between the ventral edge of the first thoracic vertebra and dorsal edge of the manubrium. The normal ratio is 0.16 or greater.[1] The tracheal lumen is similar to the caudal laryngeal lumen. Measurement of the degree of tracheal luminal stenosis using radiography or tracheoscopy did not correlate with necropsy measurements in one study.[2] Computed tomographic studies in 18 breed dogs determined the correlation coefficient between inner diameters the cross-sectional lumen areas and body weight and found a high correlation between the inner transverse and vertical diameters and the cross-sectional area of the lumen except at the level of the intrathoracic trachea.[48]

Motion studies (fluoroscopy) of the diseased trachea are highly desirable for evaluation of pathodynamics. Image intensification equipment is necessary to safely obtain adequate radiographic detail. These studies are extremely valuable for the evaluation of the collapsed trachea and other coughing syndromes. Patients should be placed in lateral recumbency and the entire trachea visualized. A cough usually can be induced by digital pressure applied at the thoracic inlet. Videotape recordings add to the usefulness of dynamic studies. Playback observations in slow motion can result in the detection of functional features missed during the initial examination.

Fluoroscopic equipment may not be available to the general practitioner. Motion dynamics of the trachea can often be inferred from static images obtained at different phases of respiration. Lateral inspiratory and expiratory projections are used to evaluate changes in the tracheal lumen. A forced expiration can be obtained by inducing a cough with tracheal palpation. Mild physiologic changes in tracheal diameter during respiration are normal. The cervical trachea may narrow slightly with inspiration while the intrathoracic trachea and carina narrow slightly during expiration.

Contrast studies of the trachea and bronchi (bronchography) have been advocated in the past for further evaluation of the trachea and airways. This procedure has generally been eclipsed by bronchoscopy, a more effective and safer technique for evaluation of the lumen and lining of the major airways. Ultrasound examination of the trachea may demonstrate an alteration in the shape of the lumen on ventrodorsal projection.[49]

213.3.2 Tracheoscopy and Bronchoscopy

Endoscopic examination is a useful tool for evaluation of pathologic states of the trachea. It may be performed with a rigid or flexible scope to help localize the site and extent of a lesion. Endoscopy directly visualizes the tracheal mucosa and identifies inflammation, ulceration, and edema. It is used to visualize and to obtain biopsy specimens of tumors and masses; for brush cytology, fluid aspiration, and cultures; for removal of foreign bodies; for demonstration of collapsed, hypoplastic, stenotic, disrupted, or compressed areas; and for evaluation of disease progression or response to therapy.

Small animal respiratory endoscopy requires general anesthesia. The use of atropine sulfate generally is not recommended because of its detrimental effects of thickening and decreasing respiratory epithelial secretions.

There are several options for sedation for tracheoscopy. Short-acting barbiturates (Propofol) permit the rapid and gentle sedation of an animal for intubation and can be given on a continuous basis if the procedure is to be relatively short. Maintenance for a longer period of time is best handled using isoflurane gaseous anesthesia since the animal may quickly awaken after the procedure with few side effects and short duration of the sedation. On occasion, ketamine-diazepam–type sedation proves useful for longer procedures, but the problems associated with waking up are enhanced, especially in difficult-to-manage pets such as those with severe lung disease, obese animals, and brachycephalic breeds. Another option is Numorphan, although its respiratory depressive effects may necessitate manual (bagged) breathing for the patient (see Chapter 104).

213.3.3 Tracheobronchial Culture and Cytology

Examining cytologic specimens can often be an efficient and practical means of helping to support a diagnosis while others are eliminated. There are multiple ways to obtain diagnostically significant samples from the trachea for culture and cytology. In all cases, culture specimens should be obtained before cytology specimens. If tracheal endoscopy is being performed and the equipment has a biopsy port, specimens may be obtained through this instrument with sterile endoscopic brushes. A protected sterile culture swab or cytology brush can also be introduced directly through the mouth and larynx and into the trachea for specimen retrieval.

Bronchoalveolar lavage (BAL) is the preferred method of obtaining cytologic and culture samples from the lower respiratory tract and occasionally from the upper portions of the tract. The endoscope is cleaned externally and the channels flushed with sterile saline. It is then repositioned at the sampling site and gently wedged into position. Multiple aliquots of sterile saline are passed through the channel and immediately suctioned back into the syringe. Multiple samples may be obtained in this manner from one or more positions using BAL.

Another method[1] that works well in smaller animals is to place a sterile endotracheal tube, flush a small amount of sterile saline through the tube and into the trachea, hold the animal upside down, and collect draining fluid in a sterile vial as it runs out of the endotracheal tube. Although this method is not as precise as other methods, it is practical and easy to perform with equipment found in most small animal hospital settings. 1218 1219

An alternative technique that does not usually require general anesthesia is transtracheal aspiration. This usually requires either local anesthesia or mild sedation while a long sterile needle is used to puncture the mid-cervical trachea or cricothyroid membrane. A catheter designed to pass through the needle is threaded into the tracheal lumen and is used for aspiration.

Numerous bacterial culture studies have been made from transtracheal and bronchoscopic aspirations. These samples have principally but not exclusively been taken from the lower tracheal and respiratory tract. In a study evaluating 264 cases of lower respiratory tract specimens, 203 bacterial species were isolated in 116 of 264 dogs. Most (57%) contained a single species of bacteria. Those cultured most commonly were *E. coli* (45.7%), *Pasteurella* spp. (22.4%), obligate anaerobes (21.6%), beta-hemolytic streptococci (12.1%), *Bordetella bronchiseptica* (12.1%), non-hemolytic *Streptococcus* and *Enterococcus* sp. (12.1%), coagulase-positive *Staphylococcus* spp. (9.5%) and *Pseudomonas* spp. (7.8%).

Of these cultures, the most active antimicrobial agents for aerobic micro-organisms, which inhibit more than 90% of the isolates were amikacin, ceftizoxime sodium, enrofloxacin, and gentamicin sulfate.[3] In an earlier study, *Mycoplasma* spp. recovery in normal dogs and those with pulmonary disease was about 25%. Only young dogs under 1 year of age and those with *Bordetella* spp. or streptococci isolations had a significant association between their disease and *Mycoplasma* spp. recovery during tracheobronchial lavage.[4] Following this study, the role of *Mycoplasma* spp. in lower (trachea and lung) respiratory tract disease has been further

elucidated. Half of 224 samples obtained from dogs and cats with lower airway disease were negative for *Mycoplasma* spp. but 49.5% were positive, either alone (15%) or in combination (85%) with aerobic bacteria. *Mycoplasma* spp. are present frequently in patients with lower respiratory tract disease. It remains to be determined whether *Mycoplasma* spp. play a primary or secondary role.[50] *Bordetella bronchiseptica* infection was reported in a series of cats mostly under 8 weeks old with dry nonproductive coughing. Transtracheal washings were positively cultured for *B. bronchiseptica*.[5]

Bronchoalveolar lavage cytology from 33 normal dogs identified alveolar macrophages (79.4%), lymphocytes (13.5%), eosinophils (3.6%), mast cells (2.1%), epithelial cells (0.8%), and neutrophils (0.6%).[6] These numbers vary from earlier reports of limited numbers of macrophages and lymphocytes.[7] Deviations from these numbers, although not usually diagnostic, provide valuable information on the type of response and the type of disease process present. Neutrophilic inflammation most often results from bacterial infection, which can be secondary to a number of other problems including, but not limited to, collapsed trachea, chronic bronchitis, neoplasia, allergic disease, and viral, mycotic, or parasitic infections. Such cytologic findings could include an increased number of neutrophils, degenerative changes within the neutrophils, and phagocytized bacteria.[8]

Eosinophilic inflammation is usually considered significant although it has been noted in clinically normal dogs and cats.[8,9] Eosinophils and mast cells imply an allergic or parasitic tracheobronchitis.[10] A concurrent, nonseptic neutrophilic or chronic inflammatory response is frequently present. Major differential diagnoses include allergic bronchitis, pulmonary parasites, heartworm disease, and hypersensitivity responses secondary to bacterial, protozoal, fungal, or neoplastic diseases. Chronic inflammation is indicated by a mixed inflammatory cell population with a predominant number of activated macrophages.[8] This type of response is nonspecific and has a long list of differentials.

All slides should be carefully examined for organisms or atypical cells. Tight coils of inspissated mucous can be washed out in association with small airway disease.[10] Hemorrhagic inflammation consists of chronic or chronic-active inflammatory cells with erythrophagocytosis and increased numbers of red blood cells.[8] Many diseases of the respiratory tract can cause hemorrhage including systemic clotting disorders. Large numbers of reactive lymphocytes and plasma cells are nonspecific indicators of immune stimulation.[8] Primary ciliary dyskinesis may be suggested when associated with chronic bronchopneumonia, ultrastructural abnormalities, and a lack of sperm motility on testicular aspiration.[11] Neoplastic cells may be identified. Differentiation of criteria of malignancy in epithelial cells is often difficult, especially when accompanied by marked inflammation. Histologic examination may be necessary. Organisms may be found on cytology to make a definitive diagnosis but their absence does not eliminate infectious disease.

213.3.4 Clinicopathologic Studies

Tracheal diseases only rarely have definitive, demonstrable clinicopathologic findings. Hematologic and biochemical analysis of the blood, serology, and a urinalysis should be used as a reflection of the patient's overall health and an indication of systemic or allergic disease. Blood gas analysis is helpful to demonstrate severity of the disease and acid-base status.

213.4 SPECIFIC TRACHEAL DISEASES

213.4.1 Noninfectious Tracheitis

213.4.1.1 Etiology

Tracheitis refers to an inflammation of the epithelial lining of the trachea. This inflammatory response may be infectious or noninfectious; primary or secondary. The noninfectious causes of chronic tracheitis are probably more common and will be discussed as a group. Noninfectious tracheitis is usually a secondary problem to prolonged barking, collapsing trachea, chronic cardiac disease, and disease of the oropharynx. Tracheitis is unusual in cats and when it does occur in the cat it is associated with infectious feline respiratory disease. Allergic lower airway disease may also promote a secondary tracheitis.

213.4.1.2 Clinical Signs and Diagnosis

Since tracheitis may be primary (inhalation of smoke or other noxious gases) or secondary, the history varies with the etiology. Most patients with tracheitis are asymptomatic except for a cough, which is characterized as resonant, harsh, paroxysmal, and often terminated by nonproductive or slightly productive gagging. The physical examination is often normal, and no fever is present. Firm palpation of the trachea near the thoracic inlet elicits the typical tracheal cough. Examination of the oral cavity and oropharynx is unlikely to reveal abnormalities unless the tracheitis is secondary to an oropharyngeal disease process. The tonsils may be enlarged and extend further out of the crypts than normal. Auscultation of the heart is usually normal. If a cardiac murmur or arrhythmia exists, cardiac disease must be eliminated as the primary cause for the coughing (see Chapter 53) or as the cause of chronic tracheitis. A prominent snapping of the second heart sound may be present over the pulmonic valve region. Findings on auscultation of the lungs are normal unless tracheitis is secondary to pulmonary disease (see Chapters 212 and 215), in which case coarse bronchial lung sounds are expected.

Tracheitis as a primary disease often has no specific radiographic features. In acute tracheitis edema of the mucosal lining may result in a reduction of the lumen diameter. Care must be taken not to confuse this for a fixed, hypoplastic trachea. The radiographic features that occur when tracheitis is secondary to other diseases are included in the discussions of those conditions. Hematology and blood chemistries are usually within reference ranges unless a systemic disease state concurrently exists.

Table • 213-1 Drugs Used for Tracheal Diseases

GENERIC NAME (TRADE)	MECHANISM OF ACTION	DOSAGE
Theophylline/aminophylline (IV)	Bronchodilator; specific mechanism unknown	5 mg/lb q6-12h PO/IV
Terbutaline (Brethine, Bricanyl)	Beta-2 adrenergic receptor	0.625–1.25 mg BID PO-Sml 1.25–2.5 mg BID PO-Med 2.5–5.0 mg BID PO-Lg 0.01 mg/kg IV, IM, SQ
Prednisone and trimprazine (Temaril-P)	Antihistamine/cortisone combination	1 tab/20 lb q12h PO
Dextromethorphan (Delsym, Silphen DM)	Antitussive-expectorant	0.5–1 mg/lb q8-12h PO
Dextromethorphan/guaifenesin (Robitussin DM)	Antitussive-expectorant	Dosage similar to dextromethorphan PO
Codeine	Narcotic antitussive	0.5–1 mg/lb q6-12h PO
Hydrocodone with homatropine (Hycodan, Tussigon)	Narcotic like antitussive	1/4-1 tab (or tsp) q6-24h PO Approx 2 mg/kg
Tussionex syrup	Antitussive narcotic syrup-longer acting	Same dosage as hydrocodone
Butorphanol (Torbutrol)	Opioid agonist/antagonist	0.25 mg/lb q6-12h PO

213.4.1.3 Therapy

Therapy should be directed at the primary underlying disease process, and these treatments are discussed in their appropriate sections. The cough associated with secondary tracheitis may act as a continued source of irritation, which perpetuates the tracheitis, and a vicious cycle ensues. Treatment of the underlying disease process may not always be adequate to relieve the cough because of this cycle of "cough-induced tracheitis," which perpetuates the cough as well as the tracheitis. Therefore treatment aimed specifically at the tracheitis is often beneficial, if not mandatory.

Tracheal coughing is often treated with antitussive and bronchodilating preparations (Table 213-1). Many of these preparations also contain expectorants. Occasionally, short-term therapy with corticosteroids is warranted. It is important to emphasize that this provides symptomatic relief only and it could exacerbate the primary condition. With chronic coughing, nebulization four to six times daily may help to soften mucoid material collecting in the trachea. When nebulization is not possible, the dog or cat can be placed in a bathroom filled with steam from a hot shower. This should last 15 to 20 minutes, three times daily. Following either method, gentle couppage of the chest wall helps to loosen secretions and stimulate expectoration.

213.4.2 Infectious Tracheobronchitis

213.4.2.1 Etiology

Infectious canine tracheobronchitis, also known as *canine respiratory disease complex* and *kennel cough*, is not a single disease, but rather a clinical disease syndrome. Involved in this multi-etiology syndrome include infectious agents such as viruses, bacteria, mycoplasma, fungi, and parasites. A combination of *Bordetella bronchiseptica* with canine parainfluenza or canine adenovirus (CAV; CAD-2) is the most frequently encountered cause. Other incriminated agents are, canine herpes virus (CHV), reovirus, *Mycoplasma* spp.,[50] and occasionally canine distemper virus.[12] Most cases of infectious canine

tracheobronchitis involve a primary viral infection. *B. bronchiseptica* infection in cats is unusual but has been described.[5,13] The role of *B. bronchiseptica* has recently been reviewed.[47]

213.4.2.2 Clinical Signs and Diagnosis

Infectious canine tracheobronchitis is highly contagious and most commonly occurs where groups of dogs of different ages and susceptibility are congregated. There is almost always a history of exposure to other animals, as in a kennel, hospital, or dog show. Aerosol or direct contact is considered the main source of exposure. Clinical signs usually develop 3 to 5 days after initial exposure. The clinical signs are generally mild and self-limiting. A dry, hacking, paroxysmal cough is the most consistent sign. A purulent nasal discharge may be noted. Generally, the animal is healthy in other respects.

Diagnosis is made most often on the basis of circumstantial evidence. History of exposure with a dry hacking cough is usually sufficient. Thoracic auscultation, thoracic radiographs, and hemograms are usually unremarkable. Tracheal cytology may reveal increased numbers of neutrophils and bacteria. Bacterial or *Mycoplasma* spp. isolation, as well as virus isolation and serologic evaluation, can be performed but are usually unnecessary. *B. bronchiseptica* commonly associated with this condition may require 3 months for full clearance to occur.

213.4.2.3 Therapy

Uncomplicated cases of tracheobronchitis probably do not require antimicrobials. Even though antibiotics have not been shown to reach significant concentrations in tracheobronchial secretions or to shorten the course of infection, prophylactic therapy has been recommended by some.[14] Antibiotic treatment is indicated if there is deeper respiratory involvement or if the animal is showing signs of systemic illness. Drugs chosen should be based on results of bacterial culture and sensitivity testing. In the absence of culture results, choices of oral antibiotics include chloramphenicol, fluoroquinolones, or cephalosporins. More potent injectable agents such as amikacin, gentamicin, and ceftizoxime should be chosen only after culture results indicate their effectiveness. Doxycycline (5 to 10 mg/kg once daily) is appropriate if mycoplasma are suspected.

Glucocorticoids, administered at anti-inflammatory doses can be effective in suppressing the cough of uncomplicated infectious tracheobronchitis. However, glucocorticoids do not appear to shorten the clinical course of the disease.[14] They may worsen the illness in immunocompromised individuals. If glucocorticoids are used, a bactericidal antibiotic should be chosen over a bacteriostatic one for concurrent use.

Antitussives, either alone or in combination with bronchodilators are recommended. Narcotic cough suppressants seem to be the most effective. These agents can compromise ventilation and should not be used in the presence of concurrent bacterial pneumonia. Methylxanthine bronchodilators may also be of benefit in suppressing the cough through their ability to prevent bronchospasm. Patients with tracheobronchial disease also benefit from nebulization, which can help to loosen excessive accumulations of bronchial and tracheal secretions. Nebulization with sterile saline is as acceptable as mucolytic agents.

213.5 TRACHEAL PARASITES

213.5.1 Lungworm (Oslerus osleri; Filaroides osleri)

213.5.1.1 Etiology

Filaroides osleri renamed *Oslerus osleri* (*O. osleri*) is a worldwide parasitic disease in dogs under 2 years of age. It can be seen in individual situations but is more often a kennel-related problem (especially in greyhounds).[1] Although most often described in young dogs, it does persist in older animals, often without significant pathophysiologic effects.

Although described as a lungworm, this parasite most commonly affects the region proximal to the tracheal carina. It may affect the lumen and lining of the larger bronchi, but only rarely does it extend deeper into the pulmonary system.

Reports of direct transmission through larvae in the stool and saliva suggest that this metastrongyle may not require an intermediate host to complete its life cycle. First-stage larvae are directly transmitted through salivary and airway secretions. These molt in the small bowel followed by migration of the larvae to the lungs and bronchi. Experimental and natural direct transmission have been demonstrated.[1] Transmission to pups has also been reported to occur through parental food regurgitation and licking and cleaning of pups by a nursing bitch.[15]

213.5.1.2 Clinical Signs and Diagnosis

Dogs usually present with chronic, mild to severe inspiratory wheezing sounds, dyspnea, coughing, and/or debilitation. Panting usually is not prominent except in advanced cases. The severity of the clinical signs may be overplayed in the literature. Most dogs experience definite but mild, often nonprogressive respiratory signs. Exercise intolerance does occasionally occur and coughing is typically characterized as a harsh tracheobronchial sound associated with attempts at terminal retching. A small amount of white to blood-tinged mucus is common, but at times larger amounts of exudate are brought up.

Figure 213-2 Lateral thoracic radiograph of an immature male terrier showing multiple nodules in the lumen of the caudal trachea due to *Filaroides osleri*. Note the hyperexpansion of the thoracic cavity, which is probably due to increased resistance within the trachea during expiration.

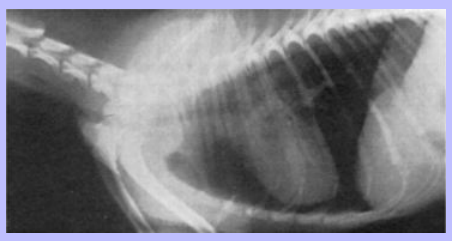

Figure 213-3 **A,** Photomicrograph of a biopsy taken from the trachea just proximal to the carina of the animal in Figure 213-2. The tracheal lining is surrounded by a larval representative of *O. osleri*. Note the kinked tail characteristic of this worm larva. **B,** Parasitic tracheitis that exhibits prominent infestation by adult filarial worms. The worms contain microfilaria (*mf*), which are within the cuticle (*cu*) and are surrounded by mucosal tissue (*ms*) from the host's pulmonary system.

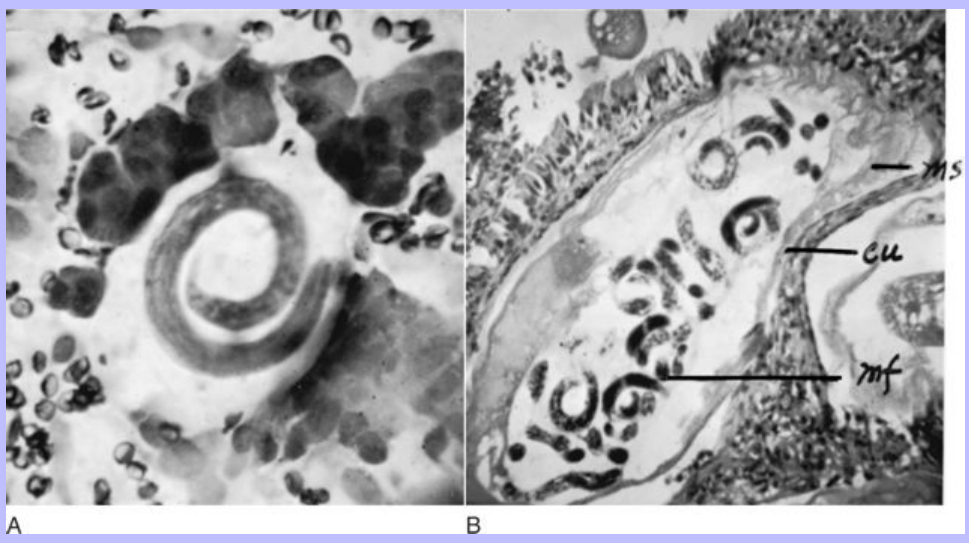


Tracheal sensitivity occurs but physical palpation is normal. Heart sounds are normal. When obvious respiratory embarrassment occurs wheezing, ronchi, or pulmonary edema may be present.

The radiographic examination is helpful if the disease process is extensive and the nodules are large. The tracheal lining may be diffusely thickened, interrupted with indistinct solid masses, or show ill-defined, 2-to 10-mm semicircular lesions protruding into the lumen (Figure 213-2). Endoscopically, cream-colored nodules, 1 to 5 mm high and wide are usually diagnostic. The larvae are often seen peeking into the luminal edge of the growth. Brushings and biopsies of the nodules provide a definitive diagnosis (Figure 213-3).

Larvae are occasionally detected in the feces. Although some flotation methods dehydrate the larvae, zinc sulfate flotation techniques are as diagnostic as is the Baermann technique. Eggs, when seen, are 50 × 80 µm, thin shelled, colorless, and larvated. The larvae are 230 µm long with a distinct kinked tail. Both larvae and eggs may be visualized in the sputum and in washings from the trachea of an affected dog. 1221 1222

213.5.1.3 Therapy

Many drugs have been reported to be effective in treating lungworms, such as thiacetarsamide sodium, diethylcarbamazine, levamisole, fenbendazole, and albendazole.[1] We have treated several dogs with oral

ivermectin at 1000 µg/lb once weekly for 2 months. The nodules were reduced in size but did not resolve entirely. All of these dogs became asymptomatic and continued to thrive. Thiabendazole was administered at 35 mg/kg twice daily for five days and then at 70 mg/kg twice daily for 21 days. Along with thiabendazole, prednisone at 0.5 mg/kg was given twice daily every other day.[16]

Surgical removal is not recommended owing to the large number of nodules. Removal of a large obstructing nodule may potentially be therapeutic in rare situations.

213.5.2 Cuterebrosis

Cuterebra spp. larvae are expected in rabbits and rodents. Several cats have been described with inspiratory dyspnea. Upon tracheoscopy, *Cuterebra* larvae were observed in the trachea, at or just cranial to its bifurcation. Successful treatment consisted of removal of the larva during tracheoscopy in one cat and by thoracotomy and removal through a tracheal incision. The cases were described by the authors as third-stage instar of the *Cuterebra* spp.[51] A fatal case of second stage instar has been reported in another cat.[37]

213.5.3 Tracheal Hypoplasia

213.5.3.1 Etiology

First described in 1972, the hypoplastic tracheal syndrome is a congenital defect resulting from inadequate growth of the tracheal rings.[1] The condition varies from mild to severe. This disease is recognized primarily in young, brachycephalic animals. The first complete report involved a series of dogs, most of which were English bulldogs.[1] In another report, the highest incidence was in English bulldogs (55%), with Boston terriers also being commonly affected (15% of their cases).[17] Other congenital abnormalities, including elongated soft palate, stenotic nares, cardiac defects, and megaesophagus may be associated.

213.5.3.2 Clinical Signs and Diagnosis

Since tracheal hypoplasia is a congenital disease, it can be diagnosed early in life. In one study, the median age at diagnosis was 5 months (range: 2 days to 12 years).[17] Common clinical signs include dyspnea, stridor, and coughing. Occasionally, dogs present with a moist, productive cough, moist rales on auscultation, and a fever associated with bronchopneumonia.

Physical examination may be normal (except for a palpably small trachea) or may reveal a sensitive trachea that, when palpated, evokes coughing. Excitement is likely to exacerbate the coughing episode, which is usually more severe and serious during daytime hours. Heart sounds are normal unless an associated congenital cardiac malformation is present. Clinical pathology reveals a leukocytosis with a left shift if there is a concurrent bronchopneumonia. The radiographic features are most important and usually provide a definitive diagnosis (Figure 213-4). Dorsoventral and lateral radiographs of the thorax and lateral views of the cervical region should be obtained to assess the tracheal diameter and the presence or absence of pulmonary changes. Methods for measurement and determination of normal trachea diameter have been reviewed earlier in the chapter.

The diagnosis of hypoplastic trachea is generally made when the lumen diameter is less than two times the width of the third rib where they cross. The tracheal lumen will also appear smaller than the caudal

laryngeal lumen in these patients. Care must be taken in the young patient, in which the adult proportions of the tracheal lumen may not yet be obtained. *Tracheal edema associated with tracheitis may mimic a hypoplastic trachea on the radiograph*. For this reason it is best to take radiographs when the patient is asymptomatic.

213.5.3.3 Prognosis and Therapy

The prognosis for dogs with a hypoplastic trachea depends on the degree of hypoplasia as well as the presence or absence of concurrent congenital defects. Many patients with slight to moderate hypoplastic tracheas can live normal, satisfactory lives with only an occasional need for bronchodilator therapy and antibiotics. Young dogs with this diagnosis often outgrow the condition. One report suggests that tracheal hypoplasia may be clinically insignificant in the absence of concurrent cardiac or other obstructive upper respiratory disease. Further it supports the idea that the degree of hypoplasia does not correlate with the presence or absence of clinical signs.[17]

Clinical experience has shown that many dogs present with this condition in various states of severity as puppies and young dogs. With effective empirical therapy a significant number of these dogs develop and grow into healthy mature dogs. Because the initial impression is one of a very advanced condition, the veterinarian may wish to advise the client on the potential for the dog to overcome this problem. This is particularly true if there are no associated congenital defects present. Owners who are experienced with these breeds are familiar with the problem and are often quite capable of dealing with the extensive nursing care required. One should be firm on recommending therapy for these patients. Many who have suggested euthanasia have come to regret their haste after seeing some of these dogs as mature adults. The prognosis remains guarded and it is prudent to identify the possibilities to the new pet owner who presents a pet with this condition. Similarly, the veterinarian must carefully evaluate the pet for associated congenital defects (cardiac or other upper airway).

It is important to prevent bronchopneumonia from developing by keeping the affected animal in a draft-free environment and preventing excessive exposure to moisture and cold. Prevention of excessive weight gain also helps the animal by limiting the strain placed on the respiratory system by obesity. When recurrent upper respiratory tract infections do occur, the use of antibiotics is in order, preferably as determined by culture and sensitivity testing.

It is advisable to discourage the breeding of animals affected with this congenital defect, even though at this time there is no absolute evidence indicating a hereditary basis. There are no known surgical corrective procedures.

213.5.4 Segmental Tracheal Stenosis

213.5.4.1 Etiology

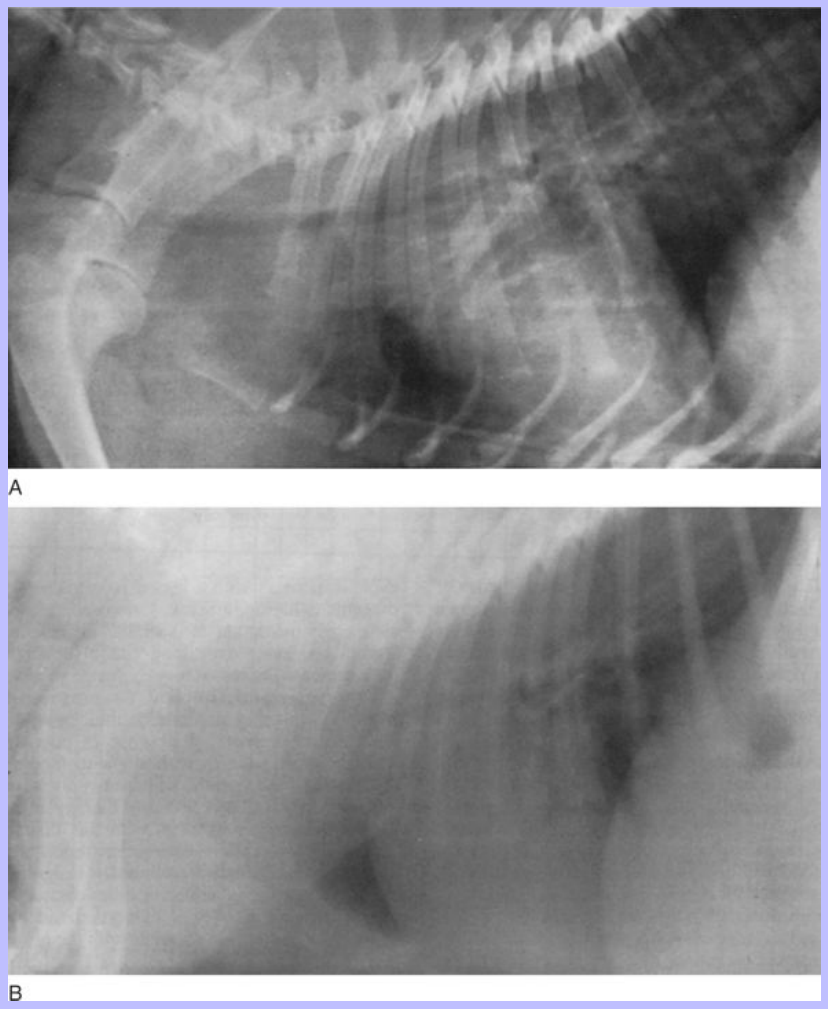
Segmental tracheal stenosis is an unusual condition that affects small animals. It may occur as a congenital lesion or it may result from trauma to the trachea. The congenital absence of tracheal rings that causes a focal stenotic area has been described.[18] Many examples of young cats and dogs with segmental tracheal strictures of unknown cause have been recorded.[1]

Segmental tracheal stenosis can also occur secondary to a tracheotomy procedure, with necrosis and thickening of the tracheal wall from excessive endotracheal cuff pressures, as a complication of thoracic surgery, result of bite wounds to the cervical area, foreign bodies lodged in the trachea and result of massive chest trauma.

213.5.4.2 Clinical Signs and Diagnosis

This syndrome produces stridulous respiratory distress and subsequent cyanosis. Secondary upper airway tract infections may result and develop into overwhelming pulmonary disease.

Figure 213-4 **A,** Lateral cervical and thoracic radiographs of a 1-year-old female bulldog. The radiograph of the thorax clearly demonstrates a markedly hypoplastic trachea in addition to pulmonary changes suggesting bronchitis. The ratio of the tracheal diameter to the height of the thoracic inlet was 0.07. The normal ratio is 0.16 or greater. The indistinct outline of the trachea is due to the accumulation of large amounts of mucous in the trachea. **B,** Hypoplasia of the trachea in a 4-month-old female boxer presented with a productive gagging cough and moderate respiratory distress. Lateral thoracic radiographs show a severely hypoplastic trachea. The ratio of the tracheal diameter to the height of the thoracic inlet was 0.05.



Radiographic studies usually establish the diagnosis. Survey tracheal radiographs often show the stenotic region as an abrupt, segmental reduction in lumen diameter. Inspiratory/expiratory projections or fluoroscopic examination demonstrate little dynamic change in the stenosis during the respiratory cycle. Bronchoscopy identifies the stenotic lesion and its severity and anatomic extent. It is possible that accurate measurement of the degree of tracheal stenosis cannot be made. Percentage of tracheal luminal stenosis as determined by antemortem methods in 15 normal dogs that underwent tracheostomy procedures were determined by radiography, tracheoscopy, and necropsy. The antemortem methods did not correlate well with control planimetric methods.[52]

213.5.4.3 Therapy

The management of segmental tracheal stenosis is similar regardless of cause. The mainstay of treatment is surgical resection of the stenotic region. Several types of procedures have been used and they are well reviewed.[1,18,19] Tracheal resection and anastamosis without excessive tension,[18,19] balloon dilatation[20], placement of polypropylene total ring prostheses applied to the external surface of the trachea and tracheal wall stent placement internally have all been used successfully.[53] The reader is referred to an appropriate surgical textbook for additional information.

1223 1224

213.5.5 Collapsing Trachea

There are two types of collapsing trachea, the dorsoventral and lateral forms. The lateral form is very unusual. It has been reported without obvious cause but it also has developed after central chondrotomy was performed to treat the dorsoventral form of tracheal collapse. Lateral collapse rarely occurs spontaneously.[21] Dorsoventral flattening (narrowing of the trachea) is a very commonly described lesion that is often associated with a pendulous, redundant dorsal tracheal membrane that prolapses into the tracheal lumen.

The collapsing trachea usually involves the cervical region, but often both the cervical and thoracic areas of the trachea are involved and the collapse may extend into the bronchi. Extension of the tracheal collapse to the bronchi is also described as collapsing of the trachea at the carina. Extension into the cartilage of the lower airways is referred to as bronchomalacia. Regardless of the focal or diffuse nature of the problem, increasing respiratory work leads to dynamic collapse of the dorsal tracheal membrane into the tracheal lumen. This further irritates and inflames the mucous membranes, disrupts the mucociliary apparatus, and increases the risk for associated small airway problems.[22] This condition has been described in cats in association with an intraluminal obstructing lesion[22] and by others but unusually.[23]

213.5.5.1 Etiology

The etiology of the collapsing trachea is unknown. The condition is an acquired disease that usually occurs in middle-aged to aged dogs, although it has been described in young dogs as a congenital lesion.[1] The clinical syndrome and findings in congenital cases are essentially similar to those described in acquired disease. In dogs with an acquired collapsing trachea, there is no loss of potential tracheal ring size, but the rings lose their ability to remain firm and thus subsequently collapse. They become hypocellular and the matrix varies from normal. Glycoprotein and glycosaminoglycan are deficient or totally lacking in dogs with collapsing tracheas.[1] The essential lesion is a deficiency in the organic matrix of the tracheal cartilage. This has led some to associate the condition with tracheal and bronchomalacia. There may be a failure of

chondrogenesis or simple degeneration of hyaline cartilage, decreasing its turgidity. This in time leads to stretching of the dorsal membrane and finally collapsing of the trachea.

Biomechanical and biochemical parameters were similar when comparing cervical to thoracic tracheal rings of young and middle-aged healthy dogs.[24] Tracheal cartilages of normal adult dogs did have significantly higher proteoglycan content and lower water content than an immature group of dogs.

Chronic coughing caused by long-term airway and/or pulmonary parenchymal disease, chronic cardiac disease with tracheal and bronchial compression, tracheal trauma, denervation of the dorsal tracheal membrane, congenital defects, obesity, increased mediastinal fat, and thoracic and extrathoracic masses are likely associated problems rather than primary inciting causes of this anatomical condition. Laryngeal dysfunction and bronchial collapse significantly alter the prognosis negatively.[54]

213.5.5.2 Clinical Signs and Diagnosis

Tracheal collapse produces a “respiratory distress syndrome.” The disease is usually paroxysmal in nature, often with a long history of chronic coughing. The cough may be described as chronic, harsh, or dry. If the owner is asked specifically, the cough often is described as a “goose honk” sound that occurs initially during the day and occasionally into the evening hours. With rare exception, the disease is recognized in toy and miniature breeds, most often Chihuahuas, Pomeranians, toy poodles, Shih Tzus, Lhasa apsos, and Yorkshire terriers. It may occur concurrently with chronic mitral valvular heart disease and must be differentiated from heart failure due to this condition. A slow heart rate helps to distinguish heart failure from primary collapsing trachea. Patients in a compensated cardiac state are presented with a cough due to a collapsed trachea. The pressure of the enlarged left atrium on the left mainstem bronchus may aggravate or precipitate the tracheal cough, even in the absence of heart failure. The characteristic cough is elicited by excitement, tracheal pressure (such as that caused by pulling on a leash), and drinking water or eating food. Often, the owner indicates that the dog begins to cough when it is picked up under the chest or held when excessive pressure is placed on the thoracic inlet.

Physical examination usually reveals a normal dog, which may be obese or thin. Depending on the state of anxiety and the respiratory distress of the moment, the patient's color varies form normal to cyanotic. Most dogs are afebrile but an elevated temperature develops with extreme respiratory distress and agitation. Hyperthermia may result if the distress is not relieved. Perhaps the most significant finding during the physical examination is the elicitation of a “goose honk” cough when the trachea is pressed in the region of the thoracic inlet. In thin patients, dorsoventral compression of the trachea and an angle at the lateral edges of the trachea can be palpated. This is not observed in obese dogs. The cardiac sounds vary from normal to that associated with simultaneous mitral valvular insufficiency. In the normal dog, the second heart sound is less pronounced than the snapping second heart that is often auscultated in dogs with collapsing trachea. The lung sounds vary from normal vesicular sounds to rattling, stridulous sounds associated with sibilant rales and wheezing. Stridor implies inspiratory sounds associated with upper airway obstruction, including laryngeal paresis/paralysis, everted laryngeal saccules, and cervical tracheal collapse. Varying degrees of inspiratory or expiratory dyspnea (respiratory distress), inspiratory noises, and an expiratory grunt (abdominal press) with an abdominal effort are recognized in all cases.

A significant feature of the physical examination is the frequent association of hepatomegaly. Hepatomegaly occurs in a large percentage of patients with this syndrome. It may be associated with fat deposition in the liver (see other rule outs for hepatomegaly, Chapter 225). The relationship of hepatomegaly to the clinical syndrome is unclear.

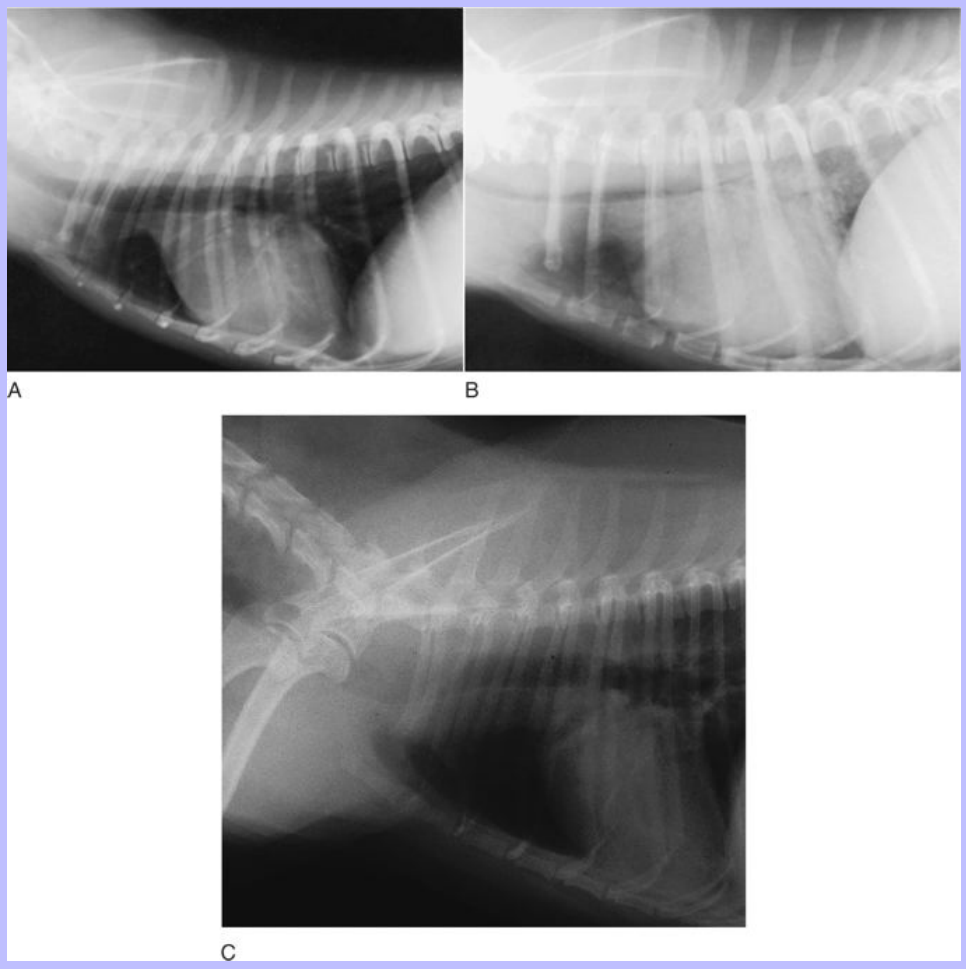
In most uncomplicated cases, there are usually no electrocardiographic abnormalities other than P-pulmonale resulting from right-sided heart strain. Examination of the oral cavity is usually normal (dental excluded). Culture of the tracheal lining using a protected brush identified aerobic growth in 24 of 29 dogs. Cytologic confirmation of inflammation or infection was not consistent.[55] *Mycoplasma* spp. were identified in patients cultured with lower airway disease. Some of these animals had tracheal diseases[50] and may culture commonly identified bacteria but most have no growth. Tracheoscopy reveals a decreased dorsoventral diameter of the trachea with a pendulous dorsal tracheal membrane. Dynamic changes such as intrathoracic collapse are noted as are other structural abnormalities, such as specific single or multiple flattening or collapse of tracheal rings. In most cases, the tracheal mucous membranes are hyperemic but usually show no exudate. On occasion, a copious, frothy catarrhal exudate may be present.

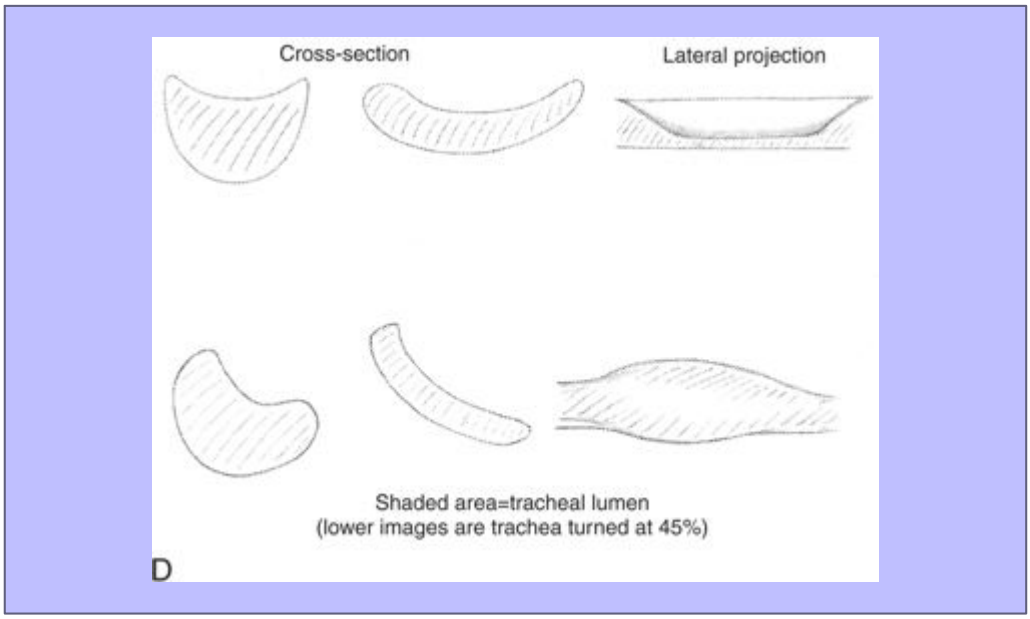
1224

In a study of 20 surgically managed cases, 30% of the dogs were observed to have concurrent laryngeal paresis or paralysis.[1] The high figure does not correlate with the authors' experience with large numbers of dogs that cough intermittently with this disease for many years. It may represent an important specific subset of patients, however, and should be looked for when a diagnosis of tracheal collapse is made. Further, laryngeal paresis results in a classic stridulous inspiratory effort in marked contrast to this expiratory wheeze, cough, and grunting syndrome. Upon completion of the visual examination, bronchoalveolar lavage, brush cytology, and/or biopsy samples are taken. The risks of bronchoscopy/tracheoscopy are relevant. Extreme caution is required. Brachycephalic dogs with diminished laryngeal motility or everted saccules are additionally at risk as may be obese patients and those with severe tracheobronchial malacia, concurrent pulmonary disease, small airway collapse, accumulated bronchial secretions, and hypoventilation. Post bronchoscopy recovery requires careful patient attention, minimized stress, occasionally long-term intubation, and on occasion intratracheal administration of 1% lidocaine spray.[25]

1225

Figure 213-5 Lateral thoracic radiographs of an 8-year-old Yorkshire terrier during **(A)** peak inspiration and **(B)** peak expiration. Note the dramatic change in tracheal diameter that can occur during the respiratory cycle in animals with collapsing trachea and how important it is to obtain inspiratory as well as expiratory views. In severe cases such as this, the expiratory collapse is not limited to the thoracic segment of the trachea but extends into the cervical region as well. **C,** Collapsing trachea observed at the thoracic inlet in a dog with moderate rotation of the trachea. As a result of the rotation, the trachea appears wide rather than collapsed in the lateral view.**D,** Drawing of the actual tracheal position and the line of the x-ray beam explains the appearance of the trachea on the lateral view.





1225

1226

Radiographic examination of patients with collapsing trachea uses both still and motion studies. The trachea should be examined on dorsoventral and lateral radiographs. Separate lateral radiographs of the cervical and cranial thoracic regions should be obtained to assess the contour of the entire trachea. Lateral radiographs made during both the maximum inspiratory phase and expiratory phase of the respiratory cycle are needed to demonstrate a dynamic collapsing trachea (Figure 213-5). Collapse of the cervical tracheal segment is usually best demonstrated during the inspiratory phase.

Conversely, the study made on expiration usually shows a collapse of the thoracic segment (and occasionally mainstem bronchi) and an unchanged or slightly dilated cervical segment. Care should be taken not to overflex or overextend the occipitoatlantal articulation when obtaining the lateral views, since this may produce pressure on the trachea that can artifactually induce narrowing of the lumen (Figure 213-6) or cause an abnormal tracheal course in the caudal cervical or thoracic region. There can be a subtle loss of radiographic detail at the dorsal luminal margin, which is produced by inversion of the dorsal tracheal membrane. The ventral margin of the tracheal lumen remains well demarcated and is unaffected by the collapsing process. The collapsed region usually involves approximately one third of the tracheal length, and the extremities of the collapse blend into normal lumen size over a distance of 2 to 3 cm. The course of the trachea is usually normal in uncomplicated cases. A redundant dorsal tracheal membrane which invaginates into the tracheal lumen can be seen as soft tissue opacity along the dorsal aspect of the caudal cervical tracheal lumen (Figure 213-5, *E*). This condition is seen in both small and large breed dogs, and can be distinguished from a superimposed esophagus or other structure by the sharp soft tissue-gas interface along the ventral margin. DV or VD views of the thorax do not usually demonstrate changes in the trachea. Concomitant lung disease may be seen.

Ultrasound examination of the trachea may demonstrate an alteration in the shape of the lumen on ventrodorsal projection.[49] Motion studies of normal respiratory function and cough, using fluoroscopy, can be made in order to assess the severity of the lesion. Some cases may show collapse only during the forced expiration of coughing. Slow-motion studies of videotape recordings are often helpful in delineation of the magnitude of the collapse, especially when produced by coughing.

The differential diagnosis of collapsed trachea requires consideration of such common conditions as tonsillitis, laryngeal paralysis or collapse, stenosis of the nares or trachea, eversion of the lateral saccules, elongation of the soft palate, bronchitis or primary tracheitis, foreign body tracheitis, and decompensated chronic mitral valvular disease. The list of causes of coughing that could be confused with collapsed trachea is extensive (see Chapter 53).

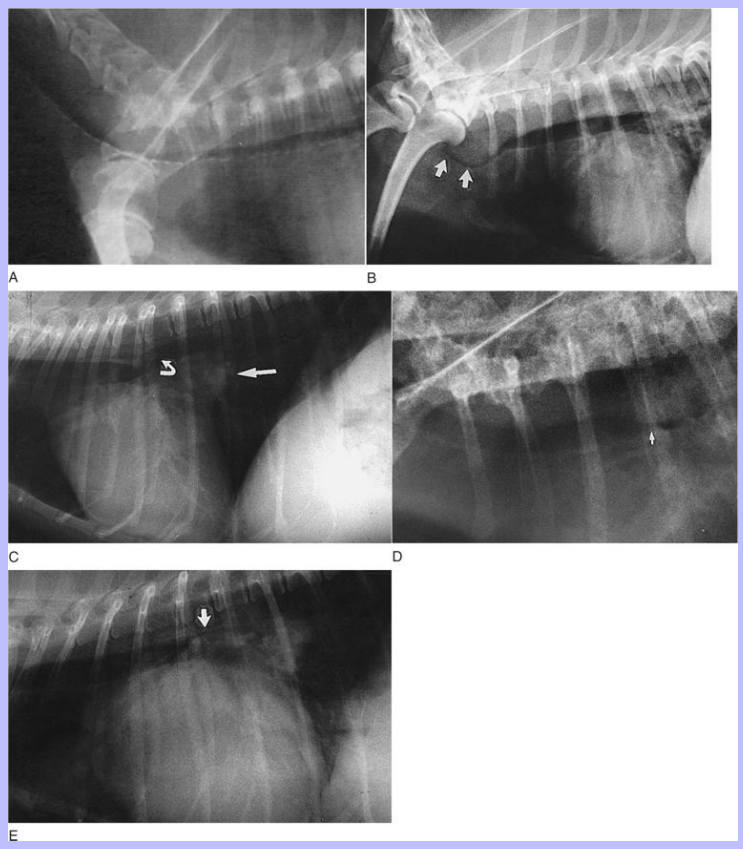
213.5.5.3 Therapy

The therapeutic approach to the collapsing trachea patient covers both the acute and chronic state. Although both conditions use the same common drugs, the need to deal quickly and aggressively with the acute state differs conceptually. Clients are often very anxious and the pet may be equally so, which demands immediate attention and reassurance for the owner.

In the acute state the clinician is concerned with calming the patient as quickly as possible. This may require the use of oral antitussive agents such as butorphanol or dihydrocodeinone. In the event that these products are not rapid or potent enough, injectable butorphanol may be considered. Other agents that are effective in more advanced conditions include dilute acetylpromazine, diazepam intravenously, or morphine by injection. Separating the extremely anxious pet from the client (this can often be very difficult to do) may be very useful and allows the clinician to appropriately sedate the dog and reduce the external stimuli that are continuing to occur. Not infrequently, simply removing the pet from view of the owner acts to calm the dog. In the event of cyanosis, oxygen in a humidified environment such as an oxygen-enriched cage or by nasal catheterization is suggested. The latter is made more difficult by the extreme anxiety of the patient. In such situations any physical manipulation or stress may aggravate the problem and make the cure worse than the disease. The use of short-term corticosteroids has a place in such situations since there likely is tracheal edema present. Injectable steroids initially, followed by oral dosages, tapered slowly is quite helpful during acute treatment. In some cases, pets are sent home with the owner after instructing on the administration of dilute acetylpromazine in the event of an acute exacerbation of the problem.

Throughout treatment, bronchodilators remain effective in treating this condition. The theoretical benefits accrue to reduction in spasm of the smaller airways, which reduces intrathoracic pressures and thus decreases the tendency of the larger airways to collapse. Additionally there is improved mucociliary clearance and reduced diaphragmatic fatigue. In some cases the authors even believe that the alcoholic content of an elixir compound seems to benefit the patient as much as the actual medication. Caution is required concerning the side effects of methyl xanthine drugs, which include vomiting and excitability. Similar results may be obtained by having the owner place a small dab of an alcoholic liquid in the buccal region during acute episodes of coughing at night when at home.

Figure 213-6 **A,** Lateral radiograph of a 13-year-old Chihuahua with a pliable, collapsible trachea showing caudal cervical tracheal collapse due to overextension of the neck. **B,** Lateral thoracic radiograph from a 14-year-old male castrate Pomeranian. Notice the reduced size of the cervical trachea as compared with the thoracic trachea on inspiration *(arrows)*. **C** and **D,** 11-year-old Poodle, female spay, with severe chronic coughing. There is marked left atrial enlargement with bronchial dilatation on inspiration and on expiration there is narrowing and reduction in size of the two mainstem bronchi. Such pathology usually precludes surgical correction of the disease. **E,** Lateral radiograph from a 7-year-old Pomeranian, female spay, with severe coughing. Note the normal tracheal size until the carina at which point the mainstem bronchi shows compression and constriction *(arrow)*. This patient required long-term aggressive medical therapy.



Treating the patient long term on an outpatient basis utilizes the same principles as set above except on a more relaxed level. Usually, medications can be administered on an as required basis and often may not be required throughout every day. The backbone of such therapy remains the bronchodilator agents (usually the methylxanthine derivatives such as aminophylline, theophylline elixir, or another bronchodilator, see Table 213-1). Beta-agonists (terbutaline and albuterol) are reported to be effectively used by some in place of the methylxanthine agents. No clinical studies demonstrating any proof of benefit are available. Antitussive agents butorphanol or dihydrocodeinone (hydrocodone) are quite effective in controlling symptoms. Side effects include oversedation, anorexia, and constipation. Occasionally longer use of low-dose steroids are given, often in combination with a sedative-antihistamine. Some combination products work well here (also see Table 213-1) but many have been removed from the market. Often the clinician will need to change therapies from time to time to find a newer effective agent. The neuroendocrine effect of digitalis may play a role in the effectiveness of this product, although the treatment of the cor pulmonale is considered to be another possible role.

Weight reduction in the obese patient is essential. This is accomplished principally with high-fiber, low-fat diets since exercise modification is unlikely. Weight loss alone can be curative in terms of dealing with the symptoms of this disease. Likewise removal of neck collars and utilizing only a harness when the dog is taken outside can be most effective in reducing clinical signs.

The majority of cases can be successfully treated symptomatically. Bronchodilator preparations containing expectorants and sedatives usually suffice to control this disease (see Table 213-1). Nebulization or vaporization may provide additional relief. Hospitalization with sedation for a period of several days, associated with corticosteroid therapy and nebulization, helps to reduce the degree of associated tracheitis. It is important to recognize that other disease states, specifically chronic lung disease, hepatomegaly, or chronic mitral valvular fibrosis, may be present. Antibiotics are not indicated in treating this disease unless there is concomitant bacterial infection. Removing the dog from respiratory irritants such as noxious gases, smoke, and dust is good common sense.

Several authors have reported on the surgical correction of this condition.[1,25–27] There are no evidence-based studies to link central chondrotomy with effective control of this disease. In one survey evaluating 100 dogs with tracheal collapse, 71% had long-term resolution of clinical signs with conservative care.[29] Of these 100 dogs, 4% required upper airway surgery and 11% were sent for tracheal reconstruction when no other medical conditions were recognized. Only half of this latter group had an asymptomatic recovery. These authors of this study and of this chapter suggest that surgery should be reserved only for younger dogs and those that fail to respond to aggressive medical care.[29]

Surgical methods that have been described include plication of the dorsal tracheal membrane, external tracheal ring prostheses, and intraluminal stent devices. These surgical efforts do not resolve the co-existing problem of mainstem and distal bronchial collapse and may not effectively resolve isolated thoracic inlet disease. Polypropylene C-shaped stent placement has been described with good results.[27,28,30] These authors suggest that surgery involving the thoracic portion of the trachea has been unrewarding because of high morbidity and that dogs with mainstem bronchial collapse are not good surgical candidates. In a group of dogs that did have surgery, 17 of the 90 (19%) required a follow-up tracheostomy and a high percentage of these developed complications due to occlusion with mucous or skin folds. Yet, extraluminal placement of polypropylene C-shaped stents was an effective method of controlling the clinical signs of collapsing trachea in some dogs.

Weight, severity of tracheal collapse, duration of the clinical signs, and the need for a tracheostomy did not affect the long-term outcome. Dogs over 6 years of age had more postoperative complications and a poorer long-term outcome than did dogs under 6.

Twenty-five dogs were treated surgically for tracheal collapse with use of extraluminal polypropylene ring prostheses plus a left arytenoids lateralization.[31] The authors reported a lower complication rate of 4% and a 75% success rate. They felt that this was due to reduced complications as a result of the tie back procedure.[31]

Various intraluminal stenting techniques have been considered and utilized. Varying results have been recorded using Palmaz[56] (negative), Nitinol[57] (no conclusions), Ultraflex, and Smart Stents (manufactured by Boston Scientific) with no strong positive literature to date to support unqualified recommendations. Failure to function well and migration following stent placement are problems that have been identified.

Surgical correction of a 4-year-old Poodle with a lateral collapsing trachea using ring prosthesis provided definitive relief of the symptoms. The authors evaluated the dog postoperatively and found little change anatomically. Since there was so much improvement the authors attributed the improvement to increased airway rigidity, which alleviated the effects of dynamic collapse resulting in improvement of the air flow.[21] Surgical management utilizing polypropylene spiral ring prostheses was identified in two large breed dogs with extra thoracic tracheal collapse.[32]

213.5.6 Obstructive Tracheal Masses

213.5.6.1 Etiology

Obstructive tracheal masses have varied etiologies. Lesions may be intraluminal, as in the case of primary tracheal neoplasia or extraluminally compressive. Tracheal tumors in dogs and cats include squamous cell carcinoma, histiocytic lymphosarcoma, lymphoblastic lymphosarcoma, osteosarcoma, adenocarcinoma, osteoma, chondroma, osteochondroma, chondrosarcoma, and leiomyoma.[1,33,34,58] Also, plasmacytoma, mast cell tumors, seromucinous carcinoma and rhabdomyosarcoma.[59] In dogs and cats, primary tumors of the trachea are uncommon. Other intraluminal masses include tracheal parasites, nodular amyloidosis, eosinophilic granulomas, abscesses, chronic granulomas,[1,35] and inflammatory polyps.[33] A single second-stage instar larval stage of *Cuterebra* spp. was identified in a 7-year-old cat's trachea.[37]

Tracheal foreign bodies can also cause an intraluminal obstruction.[1,38,39] Foreign bodies are not common, but when they do occur, they are usually small enough to pass beyond the tracheal bifurcation, causing subsequent development of inhalation pneumonia. When foreign bodies are relatively large, they are likely to come to rest at the carina.

Tracheal obstruction by external compression has been associated with thyroid and parathyroid tumors; enlargement of the mandibular, retropharyngeal, or prescapular lymph nodes due to infection, mediastinal hemorrhage and abscesses,[60,61] neoplasia, mycotic granuloma; peritracheal abscesses and cysts; extramedulary tracheal masses,[62] cranial mediastinal masses such as thymomas; esophageal tumors; and esophageal granulomas secondary to *Spirocerca lupi*.[1,40,41]

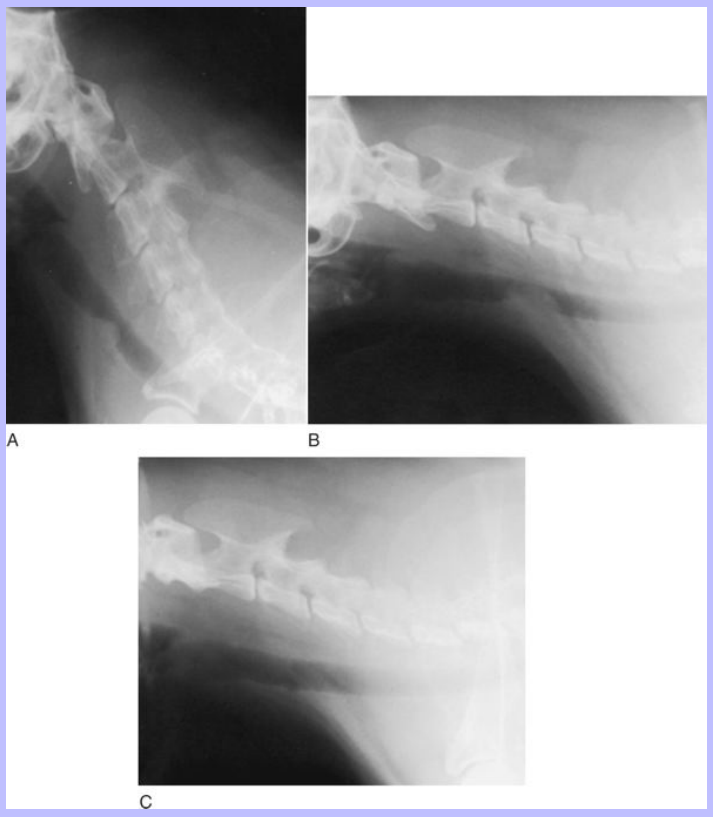
213.5.6.2 Clinical Signs and Diagnosis

Obstructive diseases are associated with a dramatic increase in airway resistance at the point of obstruction, impeding air flow, which causes hypoventilation and respiratory acidosis.[42] Clinical signs depend on the degree of obstruction. Up to one half of the airway diameter may be compromised without obvious clinical signs.[43] Even in these cases, however, close inspection of the patient will reveal an obstructive breathing pattern, which consist of a slow inspiratory phase followed by a more rapid expiratory phase.[43] Most animals present with stridor, loud ronchi (rattling in the throat), and often chronic coughing. Respiratory distress and dyspnea are usually obvious.

1228

1229

Figure 213-7 **A** and **B,** Lateral cervical radiograph of an 8-year-old cat with inspiratory dyspnea and open-mouth breathing. A tracheal mass can be seen arising from the ventral tracheal wall and growing into the lumen at the level of C4-C5. The air in the trachea provides a natural negative contrast agent. **C,** Cervical radiographs 3 months after surgical resection of the mass. The mass is no longer seen. Histopathologic diagnosis was tracheal adenocarcinoma.

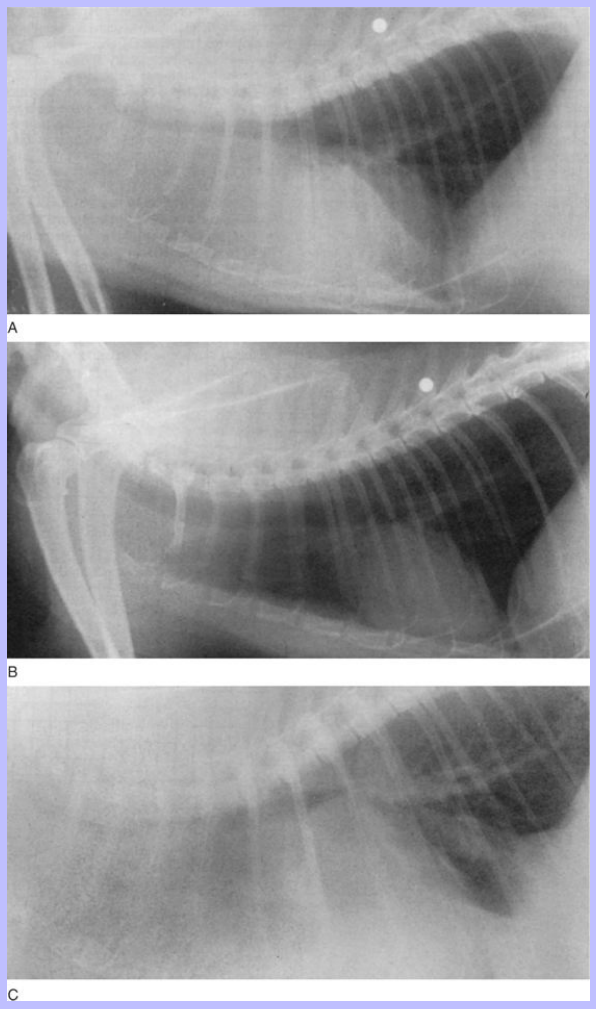


Overzealous examination and performance of laboratory studies may disturb the patient, thereby worsening the condition. Every effort should be made to keep the animal calm, and initial diagnostic tests should be done with as little stress as possible.

The work-up for the patient with suspected tracheal obstructive disease usually begins with radiography. Lateral views should be obtained if the patient can tolerate recumbency without struggling. Ventrodorsal radiographs often put the patient in a stressful position; instead dorsoventral views should be obtained. Tracheal masses may decrease luminal size in a nonlinear manner, resulting in a mass protruding into the lumen. These masses are outlined by tracheal air, which provides a good natural negative contrast medium (Figure 213-7).

Disruption of the mucosal continuity is seen at the base of the mass. This is in contradistinction to the silhouette produced by masses that are extraluminal, in which the line produced by the luminal air-mucosa interface is seen to pass uninterrupted through the mass. Non-radiopaque foreign bodies can be rendered invisible to radiographic examination if they travel distal enough in the bronchi, which results in atelectasis of the obstructed lobe with transudation of serous fluid distal to and around the foreign body. Extraluminal masses that cause tracheal obstruction are generally recognized radiographically as linear decreases in the lumen diameter over a length determined by the size of the mass (Figure 213-8).

Figure 213-8 **A,** Lateral thoracic radiograph of a 5-year-old domestic short-hair cat, presented for dyspnea and emesis, shows elevation and compression of the trachea at the thoracic inlet along with pleural fluid. The cranial lung lobes are displaced caudally. These signs were secondary to lymphosarcoma of the cranial mediastinum. **B,** Same cat as in **A**, 5 weeks after chemotherapy. Notice the re-expansion of the previously compressed trachea. **C,** Lateral thoracic radiograph of an 8-year-old female Burmese cat with pleural fluid secondary to cardiomyopathy. Note that the tracheal elevation is not accompanied by tracheal compression as in the previous case of a mediastinal mass.



In the mediastinal region a mass must be quite large to result in tracheal compression. The trachea is easier to displace then to compress in this location. High-level airway obstruction is most likely to be associated with hypoinflated, small lung fields. Intrathoracic tracheal obstruction may present as a hyperinflated lung due to air trapping as a result of narrowing of the airway during expiration. This creates a ball valve effect and traps air distal to the obstructing lesion. In a cat with an inflammatory polyp partially obstructing the trachea, thoracic radiography suggested increased airway resistance during expiration (hyperinflated lungs and a caudally displaced flattened diaphragm).[36] Contrast esophageal studies are sometimes needed to differentiate the etiology of the tracheal narrowing or displacement in the cranial mediastinal region, particularly in brachycephalic breeds in which cranial mediastinal masses are often difficult to delineate. Concomitant narrowing of the trachea and esophagus in the cranial mediastinum is highly suggestive of an extraluminal mass.

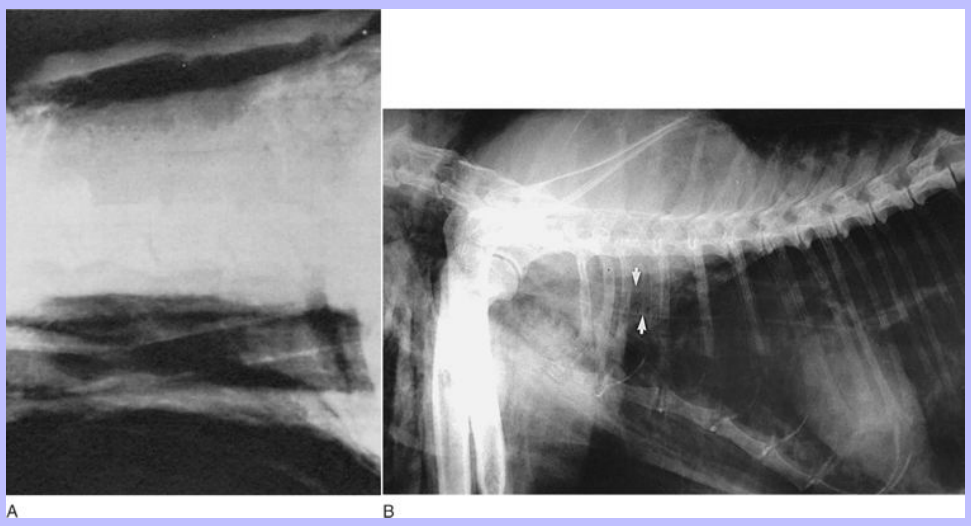
Bronchoscopy allows visualizing tracheal masses and foreign bodies (especially radiolucent foreign bodies), retrieving cytologic specimens of masses, or obtaining biopsies.

213.5.6.3 Therapy

In addition to its diagnostic value, bronchoscopy can be used as part of the treatment. Some foreign bodies can be removed endoscopically, and some tracheal masses may be removed by means of a suction biopsy device attached to the bronchoscope.[34]

For foreign bodies that cannot be retrieved through the bronchoscope and for large or firm tracheal masses, the mainstay of therapy is surgical removal or resection. Surgical procedures of the trachea have been well described. Some foreign bodies may be removed in smaller patients by holding the pet upside down (head down) while under general anesthesia and gently but firmly tapping the thorax. Occasionally the foreign body is actually coughed out and other times it is moved into a more proximal position for easier bronchoscopic retrieval.

Figure 213-9 **A,** Lateral cervical radiograph of a 10-year-old male cocker spaniel with tracheal narrowing and rupture at the level of C3 resulting from a dog fight. There is extensive cervical and subcutaneous emphysema. Not that the outer tracheal wall is visible throughout its length because of the free extraluminal air that provides contrast. **B,** Pneumomediastinum in a cat associated with subcutaneous air collection. Note the prominent tracheal stripes both dorsally and ventrally as a result of the trachea being outlined by air both inside and outside of the trachea lumen.



The prognosis for patients with tracheal obstruction depends on the specific primary disease as well as the present degree of respiratory embarrassment. Stressful diagnostic measures may push the patient into a state of decompensation. With tracheal tumors, the prognosis varies with the amount of trachea involved and with the specific biologic behavior of the tumor type present.

213.5.7 Tracheal Trauma

213.5.7.1 Etiology

Laceration of the tracheal wall causes subcutaneous and mediastinal emphysema. Traumatic injury to the trachea is unusual in small animals. Bite wounds to the neck incurred during a dog or cat fight, transtracheal wash procedure, and inadvertent laceration of the trachea during jugular venous puncture are causes. However, overinflation of endotracheal cuffs, often during dentistry in cats, is another important etiology.[63–65] An uncommon sequela to trauma is a tracheoesophageal fistula.

213.5.7.2 Clinical Signs and Diagnosis

A ventrolateral tear of the annular ligament may produce secondary subcutaneous emphysema over the entire body.[44] This latter condition develops frequently in dogs or cats involved in fights during which a tooth punctures or lacerates the tracheal wall. Air escapes from the tracheal opening and enters the subcutaneous tissue of the neck (Figure 213-9). The subcutaneous emphysema may involve only the peritracheal region or be more extensive and involve the entire subcutaneous area of the body. Such tears may also be responsible for the development of pneumomediastinum in both the dog and the cat (Figure 213-10). Subcutaneous emphysema is recognized by the crackling sensation of the animal's skin. The tissue beneath the skin appears swollen. The presence of such a lesion should immediately indicate the possibility of a tracheal tear.

1231
1232

Figure 213-10 Lateral thoracic radiograph of a 10-year-old Great Dane with pneumomediastinum. Note how the free air in the mediastinum provides a negative contrast and allows detection of the dorsal tracheal wall *(arrow)*.

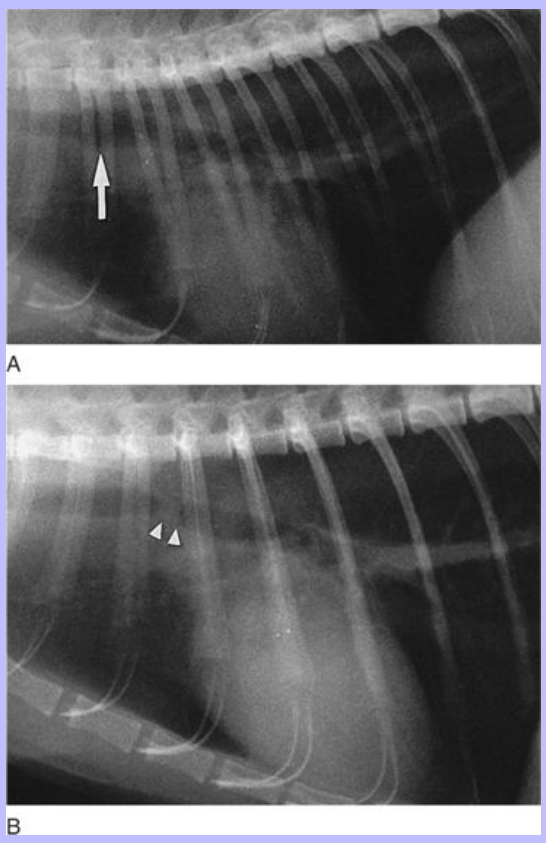
Fractures of the trachea produce radiographic signs of peritracheal, intermuscular, and subcutaneous emphysema. Pneumomediastinum may also be present with a cervical or intrathoracic lesion. Fractures or lacerations of the trachea or tracheobronchial tree should always be considered in cases of persistent, increasing subcutaneous emphysema even when no cutaneous lacerations can be located. Bronchoscopy visualizes the point and extent of tracheal mucosal interruption. Occasionally traumatic injury of the intrathoracic trachea results in a circumferential rupture (*avulsion*), leaving the mucosal or serosal lining intact. This prevents air from dissecting into the mediastinum. Clinical signs develop one to twenty eight days post trauma. Radiographs will reveal the separation of the tracheal rings (Figure 213-11) referred to as

a “pseudo-tracheal” sign.[66–68] A focal widening of the tracheal lumen at the separation during inspiration and narrowing during expiration is often identified.

213.5.7.3 Therapy

If the subcutaneous air collection is regressing and there are no signs of pulmonary distress, it is usually recommended that the patient be cage rested, which allows the emphysema to regress by slow absorption, mild sedation, and occasionally by aspiration through a large-bore needle and wrapping the body with elastic bandages, being careful not to mechanically restrict respiration. Medical treatment alone was effective in 15 of 20 such cases and a sixteenth case died before surgery was attempted.[63] Perhaps of greater importance is the effort to detect other pathologic conditions such as pneumothorax or hemothorax. If another such condition is present, the clinician should consider thoracocentesis.

Figure 213-11 Lateral thoracic radiographs of a cat following thoracic trauma. **A,** Note the focal increased size of the trachea at the level of the fourth rib, which suggests trauma to the tracheal wall. In the lateral view **(B)** taken 1 week later, there is marked diminution in the size of the trachea at the fourth intercostal space due to tracheal stenosis.



Surgical repair of a torn tracheal ligament may be required. Most tears have been found dorsolaterally on the trachea at or near the thoracic inlet.[63] Surgical repair with good results are reported in cats with intrathoracic tracheal avulsion associated with dyspnea, exercise intolerance, and exertional cyanosis.[45]

214 CHAPTER • 214 Diseases of the Small Airways

Lynelle R. Johnson

The primary role of the small airways is conduction of gases to and from the gas exchange region of the lung at the least energy cost to the animal. Cartilaginous support in large airways and smooth muscle tone in small airways keep airways open to facilitate gas flow. A ciliated, cuboidal epithelial layer that contains mucus-producing goblet cells and submucosal mucus glands lines smaller airways. Production of excessive airway mucus in response to inflammation or infection reduces luminal diameter, increases resistance to airflow, and augments the work of breathing. Activation of the inflammatory cascade and production of inflammatory mediators can cause bronchoconstriction in cats, which further reduces airflow.

214.1 CANINE CHRONIC BRONCHITIS

Chronic bronchitis is an inflammatory airway disease characterized by the presence of a daily cough for greater than 2 months. Neutrophilic or eosinophilic infiltration of bronchial mucosa results in production of proteases, elastases, and oxidizing products. Inflammatory cell products and oxidant injury cause increased epithelial permeability, cellular injury, and mucus hypersecretion. Histologically, chronic bronchitis is characterized by hypertrophy and hyperplasia of mucus glands and goblet cells, smooth muscle hypertrophy, fibrosis of the lamina propria, and epithelial erosion with squamous metaplasia. These changes result in obstruction to airflow and clinical signs of cough and exercise intolerance.

214.1.1 Presentation

Bronchitis affects middle-aged to older dogs. Although classically considered a disease of small breed dogs, bronchitis often affects larger breed dogs.[1] The primary clinical complaint is a harsh productive or nonproductive cough. Many affected dogs have a history of exercise intolerance, and some develop collapse or cough syncope.

On physical examination, dogs with chronic bronchitis appear in good health, are often overweight, and may pant excessively. Tracheal sensitivity is usually present, and auscultation reveals coarse, inspiratory crackles and expiratory wheezes. Dogs with significant bronchitis display prolonged expiration and an expiratory push. Heart rate is normal to low in dogs with respiratory disease, and an exaggerated sinus arrhythmia may be present due to increased vagal tone.

214.1.2 Diagnostic Evaluation

Clinicopathologic abnormalities are typically absent in dogs with bronchitis. Thoracic radiography can establish the likelihood of chronic bronchitis although normal chest radiographs do not rule out chronic airway disease. Thickening of airway walls and increased numbers of visible airway walls are found more commonly in dogs with bronchitis than in age and breed-matched controls.[2] End-on bronchi (doughnuts) and airways seen in longitudinal section (tram lines) represent airway walls thickened by inflammation (Figure 214-1). Right-sided cardiomegaly may be seen in dogs with chronic airway disease that develop pulmonary hypertension and/or cor pulmonale.

Hypoxemia and abnormal distribution of ventilation on radioaerosol scans have been reported in dogs with bronchitis.[1] Tidal breathing flow volume loops in dogs with chronic bronchitis demonstrate reduced expiratory flow and loop shapes similar to those seen in humans with chronic bronchitis.[1]

Collection of airway samples by tracheal wash or bronchoscopy characterizes the cellular infiltrate in the airways and rules out infectious causes of cough. Bronchoscopy is particularly useful in dogs that lack significant radiographic indications of bronchitis since virtually all dogs with chronic bronchitis have rough, hyperemic airway mucosa and mucoid or purulent secretions lining the airways. In animals with long-standing bronchitis, fibrous nodules can be seen protruding into the bronchial lumen. Cytologically, chronic bronchitis is characterized by a preponderance of nondegenerate neutrophils[1] (Figure 214-2), although some dogs have predominantly eosinophils in airway washings. Increased mucus and Curshman's spirals (bronchial casts of airway mucus) are sometimes noted.

Low numbers of bacteria ($<1.7 \times 10^3$ colony forming units per milliliter) can be found in airway samples from bronchitic dogs, and more than one species of bacteria may be isolated[3]; however, significant bacterial infection is not common in dogs with chronic bronchitis.[1,3] Bacteria can also be isolated from airways of healthy dogs (Box 214-1).

214.1.3 Treatment

214.1.3.1 Anti-inflammatories

Short-acting steroids such as prednisone or prednisolone are generally safe and effective in dogs with uncomplicated bronchitis. Remission of clinical signs can usually be achieved with initial doses of glucocorticoids that range from 0.5 to 1.0 mg/kg PO BID. The dosage should be decreased by half every 5 to 10 days, with the goal to achieve alternate day dosing to allow normalization of the pituitary-adrenal axis. If clinical signs recur, a return to the higher dose of glucocorticoid that controlled clinical signs is recommended. Many animals require lifelong therapy, whereas some may be successfully weaned off medication. In dogs with persistent or recurrent signs, concurrent treatment with a bronchodilator or antitussive is indicated.

1233 1234

Figure 214-1 Lateral chest radiograph of a dog with chronic bronchitis. Increased bronchial markings are apparent, primarily in the caudal lung fields.

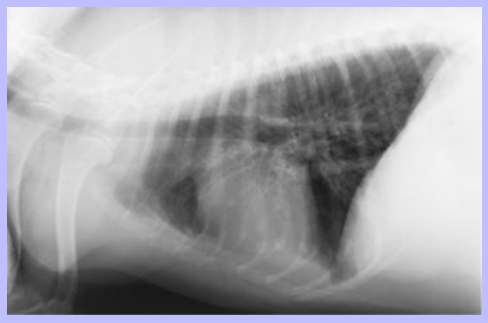

Figure 214-2 Cytology of BALF from a dog with chronic bronchitis demonstrating neutrophilic inflammation (>80% neutrophils on a differential cell count). In healthy dogs, BALF comprises predominantly macrophages (65% to 70%) and low numbers of inflammatory cells (6% to 9% each of neutrophils, eosinophils, and lymphocytes).

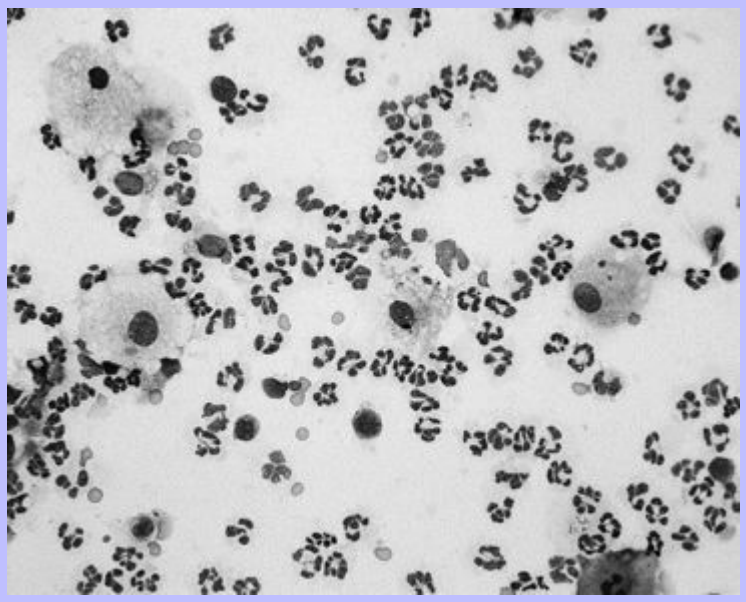

214.1.3.2 Bronchodilators

Use of bronchodilators can be associated with clinical improvement due to reduced pulmonary infiltrates or improved expiratory airflow.[1] A trial on a bronchodilator is indicated when a dog exhibits marked expiratory effort and persistent cough despite anti-inflammatory therapy. Bronchodilators can improve diaphragmatic contractility, reduce respiratory muscle fatigue, stimulate mucociliary clearance, and may reduce the dosage of glucocorticoid required.

The bronchodilators used most commonly in veterinary medicine are methylxanthine derivatives and beta-2 agonists. Methylxanthines are believed to act through antagonism of adenosine or effects on intracellular calcium handling, since therapeutic levels do not result in accumulation of cyclic AMP. Long-acting theophylline (Theochron®, Inwood Laboratories) at 10 mg/kg PO BID achieves plasma levels in dogs that approximate the human therapeutic range of 10 to 20 μg/mL.[4] Adverse effects of methylxanthines include gastrointestinal upset, sinus tachycardia, and hyperexcitability. When toxic signs are noted, drug therapy is discontinued and then reinstituted at half the initial dose. If clinical signs improve and the dog tolerates the drug, the dosage may be increased if needed. If no response is seen, an alternate class of bronchodilator is recommended.

214.1.3.2.1

Klebsiella spp.

Bordetella bronchiseptica

* Healthy dogs only, not cats.

Beta-2 adrenergic agonists (terbutaline or albuterol) have been used successfully in management of chronic bronchitis. Dosing of terbutaline is based on animal size, and small dogs receive 0.625 to 1.25 mg PO BID, medium-sized dogs may be given 1.25 to 2.5 mg PO BID, and larger dogs receive 2.5 to 5.0 mg PO BID. Albuterol is dosed at 50 µg/kg PO TID. Beta agonists may result in excitability or tremors during initial therapy but dogs usually become accustomed to the drug.

214.1.3.3

Antitussives

Dogs with bronchitis rely on a potent cough reflex to clear secretions from the airway, and suppression of cough prior to resolution of inflammation could trap mucus in the lower airway, perpetuate airway inflammation, and worsen pulmonary function and clinical signs. When inflammation has been effectively treated but cough persists, use of cough suppressants is warranted since chronic coughing causes repeated airway injury and may lead to syncope. Potent cough suppression can be achieved with narcotic agents such

as hydrocodone (0.2 mg/kg PO BID-QID) or butorphanol (0.05 to 0.12 mg/kg SQ BID-QID and 0.55 mg/kg PO BID-QID). These agents must be given at a frequent interval in order to suppress coughing without inducing excessive sedation.

214.1.3.4 Antibiotics

Airway infection is likely if greater than 3 intracellular bacteria per 50 high-power fields are seen on airway cytology,[3] and appropriate antibiotics are prescribed based on culture and susceptibility results.

214.1.3.5 Ancillary Therapy

Improvements in exercise tolerance and arterial oxygenation can be seen with weight loss alone since obesity decreases thoracic compliance, restricts expansion of the thorax, and worsens both clinical signs and gas exchange in dogs with chronic bronchitis. Exercise should be increased as tolerated. Dogs with concurrent tracheal collapse or marked tracheal sensitivity benefit from use of a harness instead of a collar. When stresses in the environment are encountered, such as cigarette smoke, pollutants, heat, or humidity, the animal should be removed to a cool, clean area.

Some animals may benefit from airway humidification to increase moisture in airway secretions and facilitate clearance. The most significant benefit can be achieved through nebulization with a pneumatic or ultrasonic nebulizer that creates small enough water particles to penetrate the airways. Standard vaporizers create larger water particles and are less effective. Nebulization can be performed two to four times daily for 10 to 30 minutes and should be followed by gentle exercise or coupage therapy to facilitate removal of secretions. Nebulization occasionally results in bronchospasm, overhydration, or distress to the animal. Some patients may benefit from administration of a bronchodilator immediately prior to therapy.

214.1.4 Prognosis

Bronchitis is a chronic disease that can often be controlled but never cured. The majority of patients have residual cough and exhibit clinical signs periodically throughout life. Goals of therapy are to control inflammation thus limiting clinical signs and to prevent worsening airway disease. When inadequately treated, long-standing bronchitis may lead to bronchiectasis or pulmonary hypertension due to chronic hypoxia and/or vascular remodeling. 1234 1235

214.2 BRONCHIECTASIS

Bronchiectasis is a focal or diffuse destructive lung condition characterized by irreversible dilatation of large cartilaginous airways, often with accumulation of pulmonary secretions. Dilatation results from destruction of muscular and elastic support structure of the airways by cytokines and proteolytic enzymes produced by inflammatory cells.[5] It can occur in association with primary ciliary dyskinesia (PCD), as a sequela to long-standing infectious or inflammatory pulmonary disease, secondary to smoke inhalation or airway obstruction, or as a complication of radiation-induced pneumonitis.[5] In cats, bronchiectasis is recognized as a histopathologic response to long-standing airway disease. Cocker spaniels seem predisposed to the disorder.[6]

214.2.1 Presentation

Dogs with bronchiectasis typically have a chronic history of a moist productive cough and frequent bouts of pneumonia that initially respond to antibiotics but then recur.[6,7] Hemoptysis may be present.

Physical examination is remarkable for moist crackles and expiratory wheezing. Loud bronchial sounds can sometimes be heard over dilated airways. Nasal discharge may be related to PCD or associated with pneumonia, when pulmonary secretions are expectorated into the nasal passages.

214.2.2 Diagnostic Evaluation

Nonspecific evidence of chronic infection includes neutrophilia, monocytosis, and hyperglobinemia due to chronic antigenic stimulation. Arterial blood gas analysis typically exhibits hypoxemia and a widened alveolar-arterial oxygen gradient.

Thoracic radiographs can demonstrate mixed bronchial, interstitial, or alveolar patterns with diffuse thickening of bronchial walls.[6] Although central or diffuse bronchial dilatation is classic for bronchiectasis, radiographs are relatively insensitive for the diagnosis. Dilated airways are more readily apparent when a severe pneumonic infiltrate is present. Computed tomography or bronchoscopy can provide evidence of bronchiectasis in dogs and cats. Classic bronchoscopic findings in bronchiectasis include dilatation of the airways with or without trapping of purulent secretions, loss of the cylindrical shape to airway lumens, and mucosal hyperemia and irregularity.

Bronchoalveolar lavage fluid (BALF) typically exhibits suppurative inflammation. Bacterial cultures for both aerobes and anaerobes are indicated since purulent secretions can favor the growth of anaerobic species. In dogs, cultures may fail to reveal bacterial growth[7] yet these cases often respond to antibiotic therapy.

214.2.3 Treatment

Dogs with lobar bronchiectasis or bronchial foreign bodies usually require lung lobectomy for management of disease. Dogs with pneumonia must be treated with broad-spectrum antibiotics that are efficacious against both aerobes and anaerobes. While cultures are pending, intravenous ampicillin (10 to 20 mg/kg IV q6-8h) and gentamicin (2 to 4 mg/kg q8-12h) or enrofloxacin (2.5 mg/kg IM q12h) can be used. Long-term use of antibiotics should be based on culture and susceptibility results. Animals that suffer recurrent infection due to bronchiectasis may be candidates for chronic suppressive antibiotic therapy or treatment with 1 week of antibiotics each month.

Bronchodilators can be beneficial, although animals typically have irreversible airflow limitation. Cough suppressants must be avoided since failure to remove infectious and inflammatory secretions will perpetuate disease. Maintenance of systemic and airway hydration through oral intake, intravenous fluids, and/or nebulization can be a critical factor in resolution of disease. Because dogs with bronchiectasis tend to pool secretions in lower airways, brisk coupage following nebulization is essential to assist in removal of airway secretions.

214.2.4 Prognosis

Owners should be aware of the likelihood of chronic recurrent infection in dogs with bronchiectasis. Resistance to antibiotic treatment may occur. Animals with significant hypoxemia and parenchymal changes may develop pulmonary hypertension or cor pulmonale. Some animals are at risk for sepsis.

214.2.5 Prevention

Bronchiectasis can be limited by use of appropriate antibiotic therapy in infectious lung disease, prompt recognition and removal of foreign bodies, and appropriate management of chronic bronchitis.

214.3 FELINE BRONCHIAL DISEASE

Feline bronchial disease describes a spectrum of inflammatory small airway diseases in the cat characterized by signs that range from chronic or intermittent coughing to life-threatening respiratory distress. Any age can be afflicted with bronchial disease, and Siamese cats seem to have an increased incidence of disease and may suffer from a more chronic form of bronchial disease.[8] Disease results from inflammation within the airways that induces reversible airflow obstruction through smooth muscle constriction and hypertrophy, bronchial wall edema, and hyperplasia of submucosal glands. Hyper-responsive airways and reversible airflow obstruction have been documented in some cases.[9] These conditions lead to a reduction in airway diameter and increased airway resistance, which cause clinical signs of cough and/or respiratory distress.[8,9]

Experimental models of feline bronchial disease that use antigen or allergen induction of airway hyper-reactivity describe generation of inflammatory and immunomodulatory cytokines and mediators within the airways.[10,11,12] Mast cell degranulation likely leads to recruitment and activation of T lymphocytes. Activated eosinophils release granule contents, and expose the epithelium to major basic protein (MBP), which causes ciliostasis and reduces mucociliary clearance. MBP also leads to epithelial cell lysis and desquamation.[13] Sloughing of pneumocytes exposes sensory and nerve endings to increased types and concentrations of allergens or irritants and may also result in a reduction of epithelial derived relaxant factor. Thus inflammatory damage can enhance neural responsiveness. Recent evidence suggests that inflammation can also induce oxidant stress that perpetuates airway injury.[14]

214.3.1 Presentation

The most frequent presenting complaints in cats with bronchial disease are coughing and abnormal respirations, such as wheezing, loud breathing, or respiratory difficulty.[9] Paroxysmal coughing is commonly reported, and the cough is often described as a dry, “hacking” cough or retch. Exercise intolerance or episodes of open-mouth breathing after exertion may be noted in some cats.

Cats with bronchial disease tend toward obesity given an inability to exercise. Bronchitic cats can appear normal at rest and exhibit normal pulmonary auscultation; however, increased tracheal sensitivity is usually present and post-tussive crackles are typically ausculted. Harsh lung sounds, crackles, or expiratory wheezes are evident in some affected cats, and the expiratory phase is prolonged.[9,15] An abdominal component to respiration may also be noted. Air trapping may occur distal to obstructed airways leading to decreased

thoracic compressibility and a barrel-shaped appearance to the chest. Auscultation in this area of the lung is quiet with increased resonance on percussion.

214.3.2 Diagnostic Evaluation

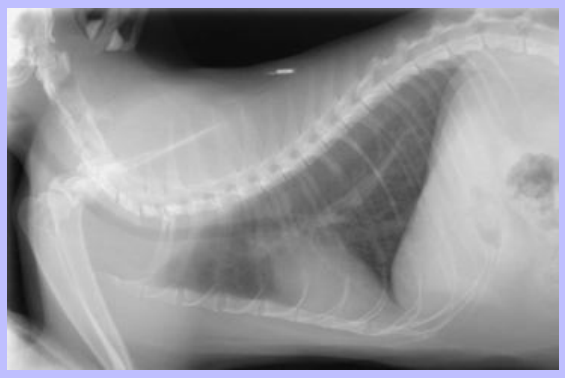
Cats with bronchial disease have nonspecific changes on blood work, and peripheral eosinophilia was reported in only 30% of affected cats.[9] Airway parasites should be ruled out as a cause of airway inflammation and subsequent bronchoconstriction. A sedimentation technique is used to detect the single-operculated egg of *Paragonimus* spp., whereas Baermann flotation is needed to detect *Aelurostrongylus* larvae. A routine fecal flotation can be used to identify *Capillaria* eggs. Heartworm antibody/antigen tests and echocardiography could be considered in cats presenting with cough or respiratory distress.[16]

A variety of interstitial, bronchial, and alveolar infiltrative patterns may be observed in cats with bronchial disease. The severity of the radiographic pattern may not match the degree of respiratory embarrassment in cats with acute bronchoconstriction, and normal chest radiographs do not rule out the diagnosis of bronchial disease. Cats without obvious pulmonary infiltrates may show other radiographic signs compatible with bronchoconstriction, such as air trapping, flattening of the diaphragm, or hyperinflation of the lungs. The hallmark of feline bronchial disease is peribronchial cuffing caused by infiltration of inflammatory cells around the airways (Figure 214-3). Excessive mucus production and obstruction of larger airways can cause alveolar infiltrates, consolidating lesions, or atelectasis.

In the stable cat with airway disease, a transoral tracheal wash or bronchoscopy can be performed to obtain airway specimens for cytology and culture. Substantial elevation of eosinophil and/or neutrophil percentages in airway specimens correlates with the severity of clinical disease[9] and so airway cytology can be used as a guide to therapy. However, normal cats may have up to 25% eosinophils in BALF cells.[17]

Bacterial culture and susceptibility testing should be performed in all cats; however, bacteria can be isolated from a large proportion of healthy cats[9] (Box 214-1). Detection of intracellular bacteria is supportive of a true bacterial infection. *Mycoplasma* species have been isolated from tracheobronchial lavage samples in 21% to 44% of cats with respiratory disease[8,18] but not from bronchoalveolar lavage samples from healthy cats,[17,18] and specific *Mycoplasma* culture on BALF should be considered in cats with respiratory disease.

Figure 214-3 Lateral chest radiograph of a cat with chronic bronchial disease. Airway walls are thickened by peribronchial infiltrates.



Measurement of airway resistance and lung compliance can be performed (in anesthetized cats) at some referral institutions. Cats with bronchial disease can exhibit high lung resistance due to bronchoconstriction. Cats with bronchial disease may also exhibit airway hyper-responsiveness to a nonspecific aerosol stimulant as evidenced by a reduction in the dosage of methacholine required to increase lung resistance.[9] Whole body plethysmography can be used to study airway reactivity in awake, spontaneously breathing cats by measurement of box-pressure signals (expiratory time, peak inspiratory and expiratory flows) and calculation of enhanced pause (PENH), a variable that correlates with airway resistance.[19] Plethysmography is technically challenging, and measured variables are influenced by respiratory rate and the animal's age.

Tidal breathing flow volume loops (TBFVL) have also been evaluated in spontaneously breathing cats with bronchial disease. The cat breathes through a facemask attached to a pneumotachograph and pulmonary mechanics analyzer. Pressure measured at the pneumotachograph is proportional to flow through the mask, and signals are integrated over time to determine volume at each cycle of respiration. Significant findings in cats with bronchial disease include increased expiratory: inspiratory time, decreased peak expiratory flow rate, and decreased tidal breathing expiratory volume.[15]

214.3.3 Treatment

214.3.3.1 Acute Therapy

In the cat with cyanosis and open mouth breathing, diagnostic tests are kept to a minimum initially. Stabilization can be achieved by providing an oxygen enriched environment and using parenteral administration of the beta-2 agonist terbutaline at 0.01 mg/kg IV, IM, or SC.[9] Epinephrine, a sympathomimetic agent, is a potent bronchodilator but should be used only when cardiac disease has been excluded since alpha and beta-1 adrenergic stimulation can result in adverse side effects of cardiac arrhythmias, vasoconstriction, and systemic hypertension. Aminophylline is a weak bronchodilator and its use in an emergency situation may not be justified since terbutaline is more likely to be effective.

Respiratory rate and effort are monitored visually in the first hour of observation to determine therapeutic response. If the cat does not respond to terbutaline initially, use of a short-acting corticosteroid often results in rapid alleviation of airway obstruction. However, use of corticosteroids will affect further diagnostic testing by decreasing migration of inflammatory cells into the airway. Failure to respond to terbutaline and corticosteroids indicates that other causes for respiratory distress should be investigated.

214.3.3.2 Chronic Management

214.3.3.2.1 Anti-inflammatories

Corticosteroids control airway inflammation by inhibition of phospholipase A, the enzyme responsible for initial metabolism of arachidonic acid into inflammatory agents. Corticosteroids also decrease migration of inflammatory cells into the airway, which decreases the concentration of toxic granulocyte products.

The initial dose and duration of corticosteroid therapy depends on the degree and chronicity of respiratory embarrassment, the severity of pulmonary infiltrates, and the level of inflammation detected on cytology. Initially, prednisolone is administered at 1 mg/kg PO BID for 1 to 2 weeks, and the dosage

is decreased to 0.5 mg/kg BID if a good therapeutic response is seen. If the cat remains stable, the dosage can be slowly decreased to once daily and then every other day. Recurrent episodes of coughing or respiratory distress necessitate a return to a higher dosage. Cats are relatively resistant to the side effects of corticosteroids; however, an attempt should be made to achieve the lowest dose of the drug that controls signs. Approximately one half of cats require lifelong medication. 1236 1237

Cats that cannot be orally medicated can be treated with intramuscular injection of a repositol corticosteroid (methylprednisolone acetate at 10 to 20 mg IM every 2 to 8 weeks), or use of inhaled steroids (fluticasone 110 µg) can be considered. Metered dose inhalers of steroid preparations can be attached to a spacer chamber and administered to the cat via facemask. Severely affected cats usually require concurrent oral prednisolone in the initial stages of therapy. Eventually some cats can be maintained with one actuation (and 8 to 10 breaths by the cat) twice daily.

Alternative anti-inflammatory drugs might be beneficial in some cats. In an experimental model of feline asthma, cyproheptadine, a serotonin-receptor blocker, attenuated airway smooth muscle in vitro constriction.[10] Serotonin levels have not been measured in naturally occurring feline bronchial disease; however, some cats may benefit from treatment with cyproheptadine at 1 to 2 mg/cat PO BID. Cyclosporine, an inhibitor of T-lymphocyte activation, may attenuate bronchoconstriction and limit airway remodeling in cats with chronic bronchial disease[11]; however, pharmacokinetics are unpredictable and blood levels must be measured weekly until the desired trough level is achieved. Currently there are no indications for use of anti-mediator drugs such as leukotriene antagonists or 5-lipoxygenase inhibitors in the management of feline bronchial disease.[10,12]

214.3.3.2.2 Bronchodilators

In some cases, bronchodilators may allow a reduction of the dose of steroids required to control clinical signs. Terbutaline can be administered at 0.625 mg PO BID. Inhaled preparations of beta agonists are also available. Theophylline may provide some relief of signs by prevention of acute attacks of bronchoconstriction in predisposed cats or by suppression of inflammation. Sustained-release theophylline can be administered once daily at a dosage of 10 mg/kg PO.

214.3.3.2.3 Antibiotics

Antibiotics should be prescribed based on culture/sensitivity and cytology results if airway infection contributes to bronchial inflammation and hyperresponsiveness. If *Mycoplasma* spp. infection is suspected, a clinical trial of doxycycline can be prescribed while cultures are pending.

214.3.4 Prevention

Because sympathetic tone is particularly important in achieving bronchodilation in the cat, beta-blockers such as propranolol and atenolol should be avoided if bronchial disease is suspected. Cigarette smoke, dusty litters, aerosol spray, and exposure to upper respiratory viruses may trigger clinical signs in susceptible cats.

214.3.5 Prognosis

Therapy with anti-inflammatories and bronchodilators alleviates acute clinical signs in most cases; however, a significant proportion of cats will suffer a recurrence of signs. Continual medical management should be anticipated for many cats diagnosed with bronchial disease.

214.4 PRIMARY CILIARY DYSKINESIA

Clearance of respiratory secretions is dependent on an intact mucociliary elevator. Ciliary ultrastructure is composed of two central microtubules, nine pairs of outer microtubules, dynein arms, and connecting proteins. Primary ciliary dyskinesia (PCD) is an inherited defect in microtubule formation affecting cilia of the respiratory tract, urogenital tract, and auditory canal.[20]

Ciliary dyskinesia can also be an acquired or secondary abnormality caused by chronic respiratory disease in animals with PCD. Clinical signs result from ineffectual movement of cilia and include rhinitis, bronchiectasis, dilatation of renal tubules, infertility, loss of hearing, and hydrocephalus. Kartagener's syndrome is a specific form of PCD characterized by the triad of situs inversus (right to left transposition of thoracic and abdominal organs), chronic rhinitis/sinusitis, and bronchiectasis.

214.4.1 Presentation

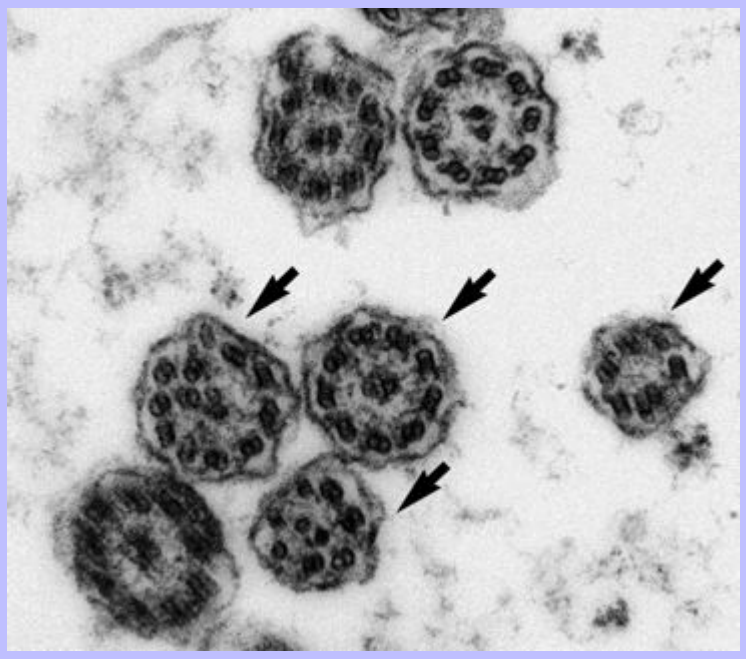
PCD is typically diagnosed in young purebred animals. A higher incidence is reported in the bichon frise, but mix-breed dogs and cats can also be affected. Clinical signs can be observed within the first few weeks of life, but mild clinical signs might not be recognized until later in life.[20] Respiratory findings include chronic serous to mucopurulent nasal discharge, productive cough, exercise intolerance, and respiratory distress. Typically signs do not totally resolve with antibiotic treatment or are recurrent in nature. Physical examination is remarkable for nasal discharge, a moist cough, tracheal sensitivity, or adventitious lung sounds.

214.4.2 Diagnostic Evaluation

Standard diagnostic tests reflect the severity of underlying respiratory infection or inflammation. Radiographic findings are variable and include bronchitis, bronchiectasis, and pneumonia. Consolidating lung lesions can develop in chronic cases. Growth of one or more microorganisms is common in dogs with PCD; therefore airway samples should always be cultured for aerobes, anaerobes, and *Mycoplasma* spp. to provide appropriate antibiotic therapy.

Diagnosis of PCD requires documentation of deficient tracheal mucociliary transport and abnormal ciliary structure. Assessment of functional ciliary transport is typically performed first with nuclear scintigraphy. Because *Mycoplasma* spp. infection, acquired ciliary defects, and exposure to cigarette smoke can delay transport, the diagnosis of PCD is confirmed with transmission electron microscopy of nasal or bronchial respiratory epithelium or seminal samples. Normal animals can have structural abnormalities in 2% to 5% of cilia; therefore both the extent and the quality of ultrastructural abnormalities must be examined (Figure 214-4). Typical findings in PCD include shortening or loss of dynein arms, atypical microtubular orientation, and duplication or deletion of central or outer microtubule doublets.[20,21]

Figure 214-4 Transmission electron micrograph displaying abnormal numbers of microtubules within respiratory cilia (*arrows*).



Culture techniques can be used to differentiate primary from secondary ciliary abnormalities. In cell culture, airway epithelial cells lose cilia as a monolayer develops. With resuspension and reculture, ciliogenesis occurs. In a patient with secondary ciliary defects, the regenerated cilia are normal, however abnormalities persist in the animal with PCD.[21]

214.4.3 Treatment

The primary goal of therapy is to control infection with appropriate antibiotics and to facilitate clearance of respiratory secretions. Use of cough suppressants is contraindicated in PCD since these drugs can enhance trapping of secretions in the lower airway and potentiate airway inflammation.

214.4.4 Prognosis

Control of respiratory infection is essential to prevent debilitating sequellae in dogs with PCD. Some dogs can achieve excellent quality of life despite defective ciliary transport.

214.4.5 Prevention

PCD is suspected to be inherited as an autosomal recessive trait; therefore clinically normal individuals could produce an offspring with PCD. Close relatives of affected animals should not be included in a breeding program.

214.5 BRONCHIAL NARROWING

Larger airways may be compressed by external mass lesions, by an enlarged left atrium, or by loss of cartilaginous support of large intrathoracic airways. Hilar lymphadenopathy due to fungal disease, granulomatous disease, or neoplasia typically causes dorsal compression of the airway at the carina. Left atrial enlargement associated with mitral regurgitation causes dynamic collapse of the left mainstem bronchus and can be a cause of cough in the absence of heart failure. However, the most common cause of airway narrowing appears to be related to failure of the cartilage to maintain the patency of the airways.

214.5.1 Presentation

Bronchial compression or collapse occurs more often in dogs than in cats. This obstructive lesion leads to a chronic, nonproductive cough, respiratory difficulty, or wheezing during inspiration and expiration. An end-expiratory snap may be heard as intrathoracic airways close and open during forced expiration. In dogs with left atrial enlargement and mitral regurgitation, a systolic murmur may be present.

214.5.2 Diagnostic Evaluation

Hilar mass lesions can usually be seen on static thoracic radiographs; however, collapse of the mainstem bronchi or intrathoracic airways often requires fluoroscopic or bronchoscopic examination. Echocardiography assists in the diagnosis of left atrial enlargement.

214.5.3 Treatment

Hilar lymphadenopathy due to active fungal infection usually resolves substantially with antifungal treatment. Rare cases may require steroid therapy or surgical debulking. Collapse of the left mainstem bronchus due to left atrial enlargement may be partially alleviated by therapy directed at reduction of left atrial volume; however, many cases have persistent collapse. Chronic cough associated with deficient cartilaginous support is challenging to control. Cough suppressants are used to alleviate clinical signs when infectious and inflammatory conditions are ruled out.

214.6 AIRWAY FOREIGN BODIES

Aspiration of plant material, sticks, toys, teeth, or stones occurs when the laryngeal reflex fails to prevent access of foreign objects into the trachea. Dogs that are involved in strenuous physical activity in rural environments are especially prone to aspiration. Animals with laryngeal paralysis may be more likely to aspirate due to a combination of poor laryngeal sensation and deficient laryngeal reflexes. Animals should be intubated during dental procedures to prevent aspiration of teeth or dental tartar.

214.6.1 Presentation

Bronchial foreign bodies cause an acute or chronic unrelenting cough, airway obstruction, and marked tracheal sensitivity. Within a variable period of time, consolidating pneumonia develops. A bronchial foreign body should be suspected when an animal has a recurrent cough that partially responds to antibiotic therapy, or when an animal has recurrent airway infection, particularly if anaerobic bacteria are involved.

214.6.2 Diagnostic Evaluation

Thoracic radiography will identify a radiodense foreign object; however, foreign bodies of plant origin are not always visible. Distal atelectasis or consolidation of a lung segment can be suggestive of foreign body obstruction, although a mass lesion, mucus plug, or pneumonic condition would appear similarly. Infection secondary to a foreign body can result in diffuse interstitial or alveolar infiltrates. A pulmonary abscess may be identifiable as a discrete fluid-filled cavity encased by fibrous tissue.

Definitive diagnosis can often be made by bronchoscopic evaluation of the airways. All airway segments must be evaluated in the search for foreign bodies, and objects can often be removed if there is an edge that can be grasped by biopsy or rat tooth forceps. Stones are a challenge to remove bronchoscopically, especially when they are wedged in a bronchus. In chronic cases of plant aspiration, the foreign body is often obscured by purulent exudate, and gentle lavage and suction of the area is required to identify foreign material.

Airway samples are cultured for both aerobes and anaerobes given the high likelihood of bacterial contamination. Animals should be followed closely after removal of the foreign body since bronchiectasis may develop distal to the obstruction.

214.6.3 Treatment

Animals with bronchial foreign bodies are at risk for pulmonary abscess, bronchoesophageal fistula, empyema, and bronchiectasis distal to the obstruction. Lung lobectomy is often required for unretrievable foreign bodies, or when lung abscessation, bronchiectasis, or fistulation has occurred. Pleural infection requires thoracic drainage and usually thoracotomy. Long-term antibiotic therapy is based on culture and sensitivity results.

214.7 BRONCHOESOPHAGEAL FISTULA

Bronchoesophageal fistula may be congenital, or acquired due to trauma, a penetrating esophageal foreign body, or a bronchial foreign body. Affected animals present with chronic cough and recurrent pneumonia related to aspiration of esophageal contents. In some cases, difficulty eating may be the predominant sign. Respiratory signs may be relatively mild, resulting in a marked delay in the diagnosis of a congenital lesion. The diagnosis should be suspected in a young animal with recurrent aspiration pneumonia or a focal, recurrent lung density. The diagnosis is confirmed by a contrast esophagram. Endoscopic examination via the airway or esophagus can occasionally detect a fistula. Surgical resection of the abnormal connection is required, and lung lobectomy is sometimes necessary due to adhesion formation or abscessation.

1238

1239

214.8 BRONCHIAL MINERALIZATION

Bronchial mineralization can occur secondary to any chronic inflammatory or infectious condition and is seen with bronchitis and bronchiectasis. Prominent mineralization of airways has also been reported in hyperadrenocorticism. The contribution of bronchial mineralization to respiratory dysfunction is unclear.

214.9 BRONCHIAL NEOPLASIA

Animals with bronchial neoplasia can present with cough, an obstructive breathing pattern, or panting. Respirations are typically loud, and harsh wheezing noises are heard over large airways compressed or occluded by mass lesions. Diagnosis and treatment is described under pulmonary neoplasia (see Chapter 127).

215 CHAPTER • 215 Pulmonary Parenchymal Disease

O. Lynne Nelson

Rance K. Sellon

215.1 OVERVIEW OF DIAGNOSTIC CONSIDERATIONS

Dogs and cats are susceptible to a wide variety of inflammatory and noninflammatory diseases of the pulmonary parenchyma. Animals with parenchymal disease may exhibit clinical signs typical of lower respiratory tract disease such as cough and respiratory difficulty, or show no clinical signs despite sometimes extensive pulmonary disease.

When clinical information is suggestive of pulmonary parenchymal disease, a relatively finite number of diagnostic tests become available to the clinician. Thoracic radiography will be the key diagnostic tool in the majority of cases. Collection of respiratory samples by wash techniques, needle aspiration, or biopsy will be appropriate in many cases. Ancillary diagnostic tests that are often employed in patients with respiratory disease include CBC, biochemical profile and urinalysis, fecal examinations, serologic assays, and microbial culture and sensitivity. The diagnostic approach to a given patient will be influenced by the list of likely differentials, costs associated with diagnostic tests, and the patient's status. Many patients will require initial empiric therapy and supportive measures (e.g., oxygen supplementation) for alleviation of respiratory distress and stabilization before proceeding with focused diagnostic tests. A more comprehensive discussion of the diagnostic tools used in the evaluation of the patient with respiratory disease is presented in Chapter 212.

An important diagnostic tool that is underused in small animal practice is blood gas analysis. The availability of portable bedside analyzers makes blood gas measurements accessible to most small animal practitioners. Blood gas analysis provides important information regarding two important functions of the respiratory system, alveolar ventilation and oxygenation of pulmonary arterial blood. Blood gas analysis is the only means to properly assess alveolar ventilation: the capacity of a patient to properly ventilate cannot be assessed by evaluation of respiratory rate or pattern or by thoracic radiographic abnormalities. Although many parenchymal diseases are associated with hyperventilation, some can be associated with hypoventilation, particularly as respiratory fatigue develops. Knowledge of the adequacy of alveolar ventilation has important treatment ramifications. Hypoventilating animals become candidates for ventilatory support depending on the cause of the hypoventilation. Untreated, severe hypoventilation can cause respiratory acidosis, which is associated with cardiac arrhythmias and central nervous system depression.

Blood gas analysis can also help the clinician determine the mechanism that drives the development of arterial hypoxemia. The most common mechanisms that cause arterial hypoxemia in small animal practice are hypoventilation, revealed by increased P_aCO_2, and ventilation-perfusion (V/Q) mismatches. Other mechanisms, such as right-to-left shunts, and diffusion barriers, are less common. Calculation of A-a differences can reveal underlying impairments in oxygenation coexistent with hypoventilation. Hypoxemia caused by V/Q mismatches or diffusion barriers are somewhat responsive to oxygen; hypoxemia caused by right to left shunting is poorly responsive to oxygen. A more complete discussion of blood gas interpretation is presented in Chapter 212.

There are many indications for oxygen supplementation. Animals with parenchymal or other diseases associated with arterial hypoxemia through any of the mechanisms noted above, or patients with diseases that alter hemoglobin affinity for oxygen (e.g., carbon monoxide poisoning) are candidates for oxygen supplementation.

Animals with clinical signs consistent with hypoxemia or tissue hypoxia, such as cyanosis, tachypnea, dyspnea, or central nervous system dysfunction are also potential candidates for oxygen supplementation. Interested readers are referred elsewhere for a more comprehensive review of the indications for oxygen supplementation.[1]

Oxygen may be administered to conscious patients via face masks, nasal oxygen catheters, intratracheal catheters, oxygen cages, or flow-by techniques.[1] The method of delivery selected will reflect availability, patient status, and patient tolerance. Increases in inspired oxygen concentration of 40% or greater can be achieved with these methods depending on flow rates. The risk of oxygen toxicity exists for patients supplemented with inspired oxygen concentrations of 50% for more than 24 hours, or 100% for more than 12 hours. If the patient's PaO_2 cannot be maintained at acceptable levels, generally 60 mm Hg or higher, on inspired oxygen concentrations less than 50% to 100%, ventilatory support may be needed. Humidification of oxygen is advised if oxygen is to be administered for more than a few hours to reduce complications associated with airway drying. Responses to oxygen supplementation can be made subjectively (changes in patient comfort, level of respiratory distress) or more objectively by repeat measurement of PaO_2 or oxygen saturation by pulse oximetry. The reader should be aware that patients monitored by pulse oximetry may still have clinically important hypoventilation and hypercarbia not detected by pulse oximetry when such patients are receiving supplemental oxygen.

1240

As noted, ventilatory support may be needed in some patients with parenchymal disease. Hypoventilation not readily corrected, as might occur with respiratory paralysis or fatigue, CNS disease, or others, is one indication for ventilatory support. Hypoxemia refractory to supplemental oxygen administration is another. There are many different strategies for providing ventilation, which have been reviewed elsewhere.[2] Short-term ventilatory support can be provided in most practices by use of an ambu bag or the reservoir bag on an anesthetic machine.

215.2 PULMONARY EDEMA

Fluid accumulation in the interstitium and alveoli of the lung is termed *pulmonary edema*. The causes of pulmonary edema are typically divided into four major mechanisms: (1) increased vascular hydrostatic pressure, (2) decreased plasma oncotic pressure, (3) increased vascular permeability, and (4) impaired lymphatic drainage. Occasionally, a fifth miscellaneous or idiopathic category is described if edema develops without any apparent association with the other four mechanisms. When increased pulmonary venous hydrostatic pressure and left-sided congestive heart failure (CHF) are responsible for edema, the term *cardiogenic pulmonary edema* is often used. *Noncardiogenic edema* describes edema from other, non-CHF causes induced by any of the additional mechanisms listed.

The pulmonary parenchyma is somewhat resistant to the development of edema. In general, the hydrostatic pressure in the pulmonary vascular bed is relatively low compared with vascular beds in other regions of the body. Normal pulmonary wedge pressures (an estimate of capillary hydrostatic pressure) are approximately 5 mm Hg. In addition, pulmonary lymphatic drainage is relatively high due to the continual pumping action of the lungs by respiration. The capacitance of the pulmonary lymphatic system is large, and the lymphatic volume can greatly expand to further increase the removal of fluid if necessary. Alveolar surfactant surface tension helps protect against the development of pulmonary edema by decreasing the tendency for fluid to be drawn into the alveoli. Because of these protective mechanisms, acute increases in pulmonary capillary hydrostatic pressures must exceed 20 mm Hg before edema develops.[3, 4] With more slowly developing increases in hydrostatic pressure, pressures in excess of 40 mm Hg have been documented without pulmonary edema.[4,5] In these instances, time allows for stretch and greater capacitance of the pulmonary vessels, as well as an increase in lymphatic drainage to remove interstitial fluid. When fluid translocates into the interstitial space and lymphatic drainage cannot match the rate of fluid influx, interstitial edema occurs. If the pathophysiologic process driving

the movement of fluid continues, the capacitance of the interstitial space is eventually overwhelmed and fluid accumulates in the alveoli. Gas exchange is impaired when airways become "flooded." Atelectasis, decreased lung compliance and airway compression, consequences of pulmonary edema, all increase pulmonary vascular resistance. The combination of impaired gas exchange and increased vascular resistance create ventilation-perfusion mismatches, which results in hypoxemia.

Left-sided CHF is the most common cause of pulmonary edema due to increased hydrostatic pressure (see Chapter 197). However, edema due to excessive fluid administration is not unusual, particularly in the setting of impaired fluid excretion as might be seen with oliguric or anuric renal failure. Pulmonary edema due to decreased plasma oncotic pressure is caused by hypoalbuminemia. Causes of hypoalbuminemia are listed on the inside cover of this book. Pleural effusions (transudative) are more common than pulmonary edema in patients with reduced oncotic pressure as a single driving mechanism. Pulmonary edema formation is not expected from hypoalbuminemia unless serum albumin concentrations are less than 1 g/dL. Even then, subcutaneous edema, pleural effusion or other sites of edema formation typically occur prior to pulmonary edema. Pulmonary edema may be seen in patients with higher serum albumin concentrations if there is vasculitis, or if hydrostatic pressures increase because of impaired ventricular filling or excessive administration of IV fluids.

Pulmonary edema due to increased vascular permeability can occur with a wide variety of pulmonary and systemic disorders. The edema in this case is termed *noncardiogenic* and is usually relatively proteinaceous.[6,7] Capillary wedge pressures are normal. Any septic or nonseptic inflammatory condition or any cause of vasculitis may promote vascular damage and leakage. Other diseases associated with noncardiogenic edema are acute respiratory distress syndrome (ARDS, see later discussion), acute upper airway obstruction, electric shock, neurogenic edema (often secondary to seizures or head trauma), and hepatic disease.[6,8] Although the pulmonary edema that develops in association with many of these conditions is suspected to result from increased capillary permeability, the exact mechanisms driving the formation of edema are for the most part unknown. Primary pulmonary lymphatic obstruction is an uncommon cause of pulmonary edema and when it occurs, is typically the result of a neoplastic process or lymphangitis.

215.2.1 Presentation

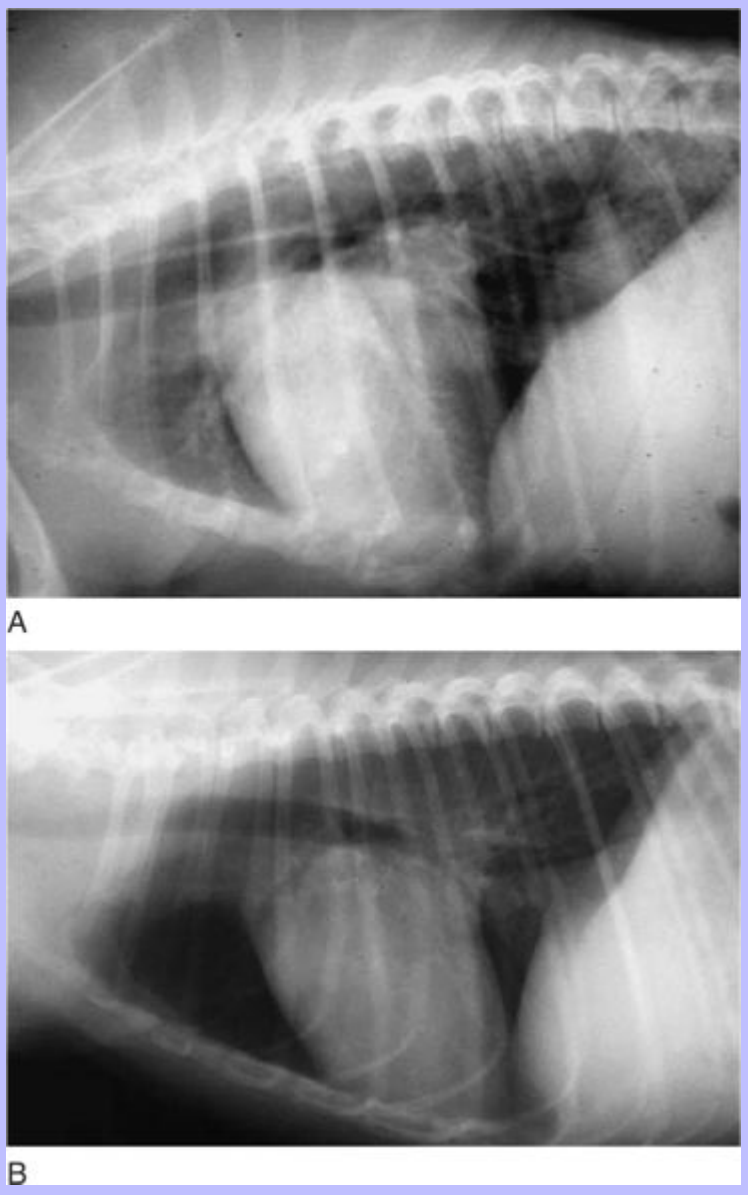
Most patients will present with tachypnea and cough, or respiratory distress and hypoxia if alveolar involvement is severe. Symptoms are directly related to the cause and severity of the edema. The character of respiration is usually that of increased effort noted during inspiration and expiration due to increased lung stiffness. Severe edema may cause coughing with expectoration of blood-tinged fluid. Several abnormalities may be heard during thoracic auscultation, classically in the dorsocaudal lung fields. Crackles heard on inspiration and especially end-expiration are common; however, crackles may be absent in early or mild edema. Lungs sounds may seem exceptionally quiet with very severe edema, particularly in cats. Additional changes reflecting underlying disease processes may be noted. Abnormalities of cardiac auscultation (murmurs, transient sounds, arrhythmias) may indicate the presence of heart disease, but their presence does not always indicate an etiology of cardiogenic edema. A patient with a heart murmur and coarse crackles during inspiration without sinus tachycardia should be carefully evaluated for pulmonary diseases other than cardiogenic pulmonary edema. Patients with CHF-induced pulmonary edema would be expected to have tachycardia as a result of increased sympathetic tone. Some patients with congestive heart failure will lack abnormal heart sounds, for example those with certain forms of cardiomyopathy.

215.2.2 Diagnostic Evaluation

Thoracic radiographs, combined with historical and physical findings, are often diagnostic. Cardiogenic edema is characterized radiographically by "fluffy" interstitial opacities that can rapidly progress to an alveolar pattern. In the dog, the opacities are most often distributed in the hilar and caudodorsal perivascular lung regions (see Figure 215-1). In the cat, these opacities are patchy and may be diffuse or focal. Pulmonary venous enlargement suggests pulmonary venous and left atrial hypertension consistent with left-sided CHF. Enlargement of the cardiac silhouette, particularly left chambers, is commonly present in patients with cardiogenic edema. Pulmonary edema caused by increased vascular permeability is also typically most severe in the caudodorsal lung lobes.[7] The absence of cardiac and pulmonary venous changes can, in most cases, distinguish such patients from those with cardiogenic edema. History and laboratory parameters are helpful in identifying underlying causes of noncardiogenic edema such as electrocution, sepsis, pancreatitis, and others. In many cases of noncardiogenic pulmonary edema, the edema is mild and not a part of the primary clinical complaint. Pulmonary edema resulting from decreased plasma oncotic pressure is typically characterized by generalized interstitial or mixed interstitial-alveolar pattern. Pleural effusion may also be present and vascular congestion is absent.

1240 1241

Figure 215-1 Lateral thoracic radiographs of a dog with cardiogenic pulmonary edema before and after treatment. Note the left atrial and ventricular enlargement and the engorged pulmonary veins, especially left cranial lobar vein. **(A)** There is an interstitial and alveolar pattern present in the pretreatment radiograph not evident in the post-treatment film **(B)**.



Arterial blood gas analysis typically documents hypoxemia, hypocapnia, and widened A-a gradient. Results of a CBC, serum biochemistries, and urinalysis may be helpful to determine underlying causes, particularly in noncardiogenic edema. Lung specimens obtained by respiratory washes or biopsy often do not yield a specific diagnosis unless primary pulmonary pathology is demonstrated.

215.2.3 Treatment

The primary therapeutic goal in the management of patients with pulmonary edema is improvement of oxygenation while stress is minimized. Minimizing stress is particularly important in severely distressed animals for which simple manipulations may lead to overt cardiopulmonary arrest. Oxygen may be administered through nasal cannula, face mask, or oxygen cage. Compromised patients may be best treated empirically based upon their initial clinical signs and presumptive diagnosis until deemed stable for additional tests, such as thoracic radiographs. Sedatives can be valuable to relieve anxiety and decrease unnecessary oxygen consumption. Morphine sulfate can be administered IV at a dosage of 0.1 to 1 mg/kg in dogs but is not suggested for use in cats. In addition to sedative benefits, mobilization of pulmonary edema has been attributed to morphine administration. Alternatively, acepromazine can be used in cats and dogs at 0.03 to 1.0 mg/kg IV, IM, or SQ. In critical cases, intubation and positive pressure ventilation may be necessary.

Narcotics and tranquilizers are likely to depress the respiratory center while severe hypoxia initiates significant anxiety. As with many medical states, an appropriate balance is sought.

Diuretic therapy is particularly effective for acute relief of pulmonary edema that develops from volume overload disorders such as CHF. Furosemide, 2 to 4 mg/kg IV every 4 to 12 hours, can be given for clinical pulmonary edema. Diuretics may be less beneficial for edema that develops secondary to increased vascular permeability disorders such as ARDS, and caution is advised when administering diuretics to patients with pre-existing hypovolemia.[9]

Bronchodilators such as the methylxanthines, aminophylline and theophylline may be beneficial to combat bronchospasm, enhance mucociliary function, and diminish diaphragmatic fatigue. Specific therapies should be also be directed at any underlying etiology such as hypoproteinemia (see Chapter 199) or cardiac disease.

215.2.4 Prognosis

Pulmonary function and cardiac disease, if present, are monitored often. Thoracic radiographs should be re-evaluated every 24 to 48 hours; the clinician should remember that radiographic changes often lag behind clinical response. The prognosis with treatment of pulmonary edema is variable and depends on the severity of edema and respiratory dysfunction, the nature of any underlying disorders, and aggressiveness of monitoring and therapy.

215.3 PULMONARY NEOPLASIA

215.3.1 Primary Pulmonary Neoplasia

Primary pulmonary tumors are not considered as common in dogs and cats as are metastatic tumors. Pulmonary neoplasia can be seen in animals of almost any age, although the majority of patients are middle-aged to older reflecting the general increase in prevalence of tumors in the pet population as it ages.

Primary lung neoplasia accounts for approximately 1% of all tumors in dogs, and fewer in cats.[10] Most primary tumors of the lung are carcinomas that arise from bronchial or alveolar epithelium, but occasionally squamous cell carcinomas can be seen.[10,11] Other less common primary lung tumors include osteosarcomas or other mesenchymal tumors.

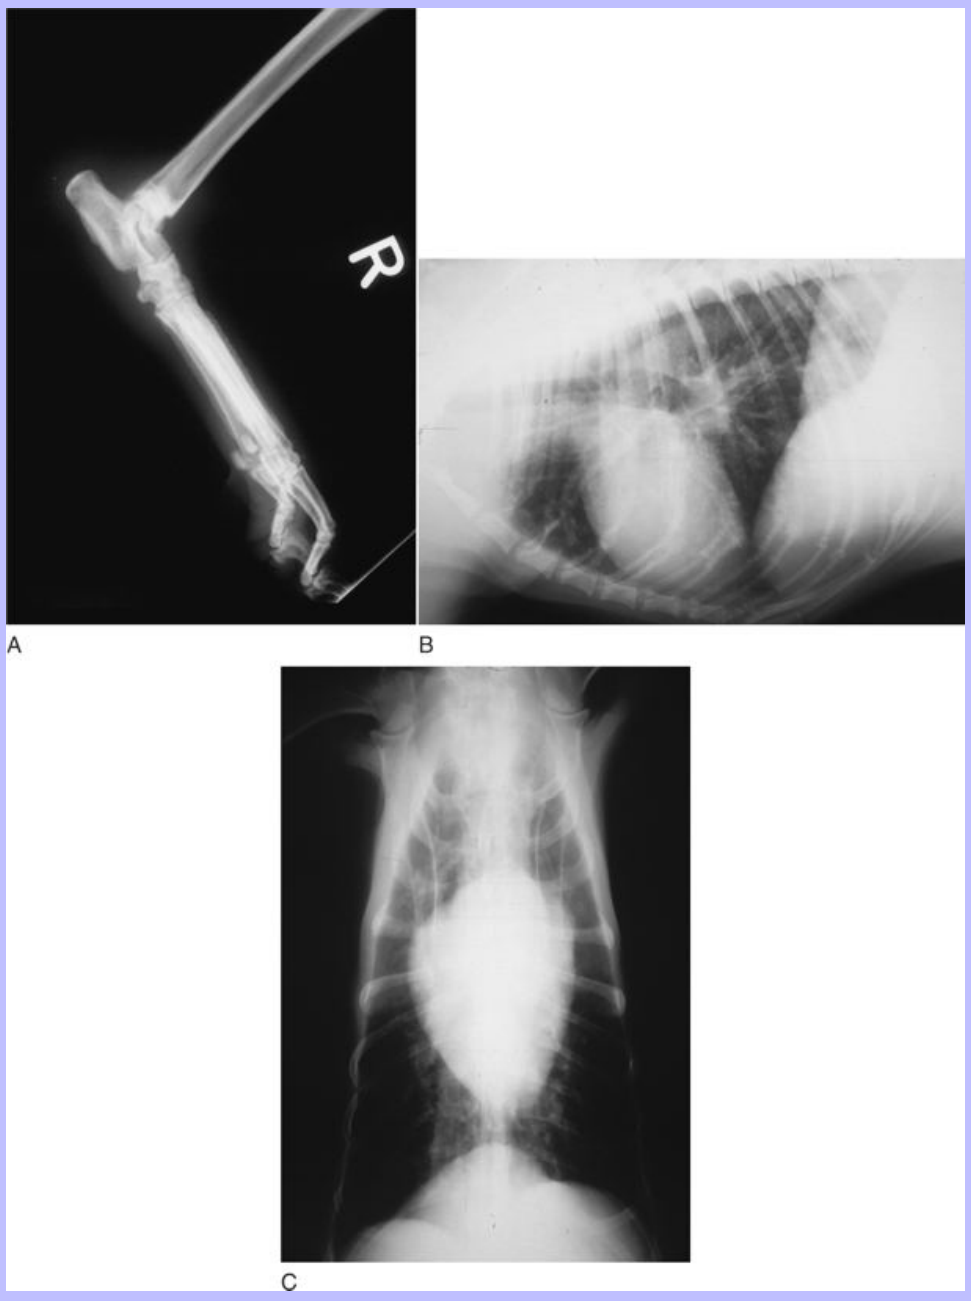
215.3.1.1 Presentation

The clinical presentation of patients with lung tumors can be variable and may or may not reflect signs referable to the respiratory system. Chronic cough that is unresponsive to antibiotics is seen most often in dogs. Exercise intolerance, tachypnea, or overt respiratory distress can occur. Respiratory distress can result from involvement of the pleural space with development of hemothorax, pneumothorax, or pleural effusion, intraluminal obstruction or extraluminal airway compression, or pulmonary artery obstructions (inflammatory or tumor thrombus) causing ventilation-perfusion mismatches.[13] Cats with primary lung tumors may exhibit lethargy, anorexia, weight loss, dyspnea and tachypnea, wheezes, and non-productive cough. A large proportion of cats with primary pulmonary neoplasia in one study had no clinical signs referable to the presence of the lung tumor.[11] Patients with primary pulmonary neoplasia can exhibit hemoptysis.[13]

1241 1242

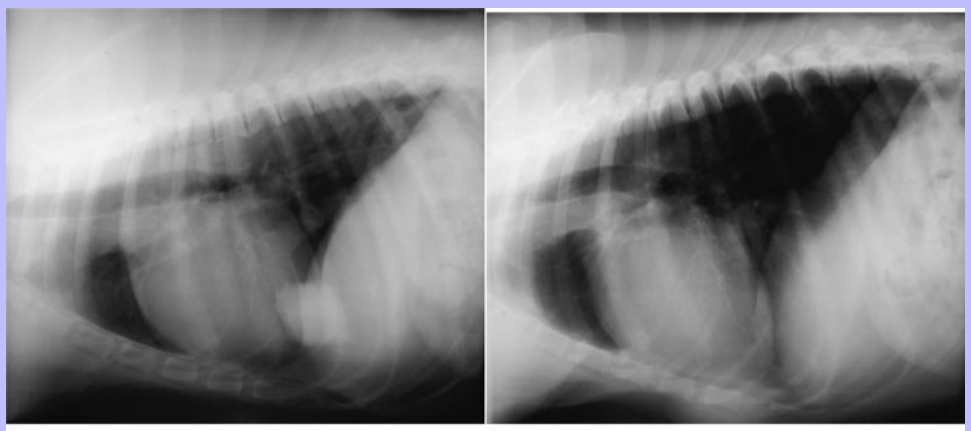
Although primary respiratory signs are expected in most patients with primary pulmonary tumors, some will have clinical signs that reflect metastasis of the lung tumor to extrathoracic organs, such as musculoskeletal structures, including the digits, abdominal organs, or brain. Clinical signs that develop from metastasis of lung tumors to other organs can thus include lameness, abdominal effusion, neurologic abnormalities, or others. Paraneoplastic syndromes that develop in conjunction with either primary or metastatic lung tumors may also be responsible for the development of clinical signs, such as lameness observed in animals with hypertrophic osteopathy (Figure 215-2).

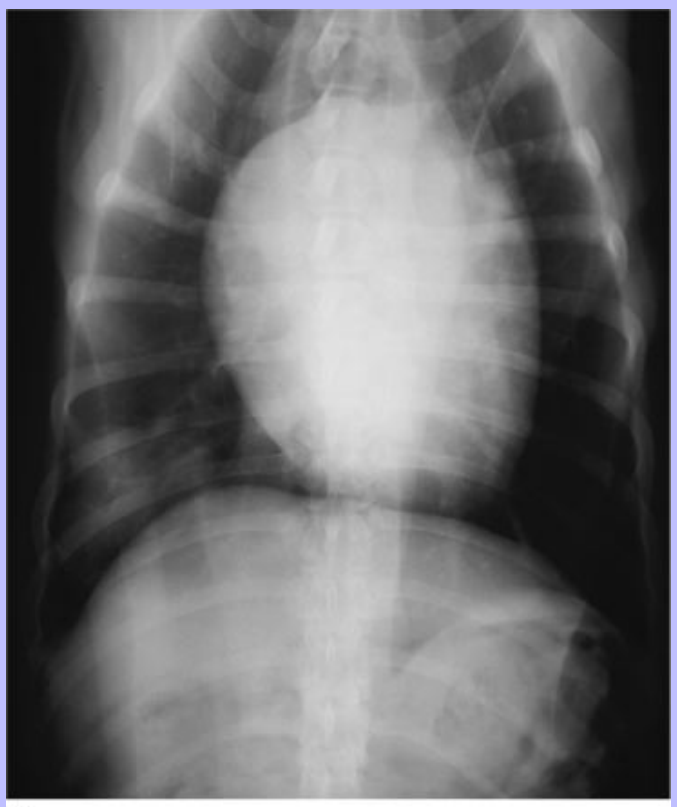
Figure 215-2 Hypertropic osteopathy in a dog with pulmonary metastatic disease. Note the extensive periosteal proliferation along the metatarsal bones.



1242

Figure 215-3 Right **(A)** and left **(B)** lateral and ventrodorsal **(C)** thoracic radiographs of a dog with a solitary lung mass best seen in only one radiographic projection.





215.3.1.2 Diagnostic Evaluation

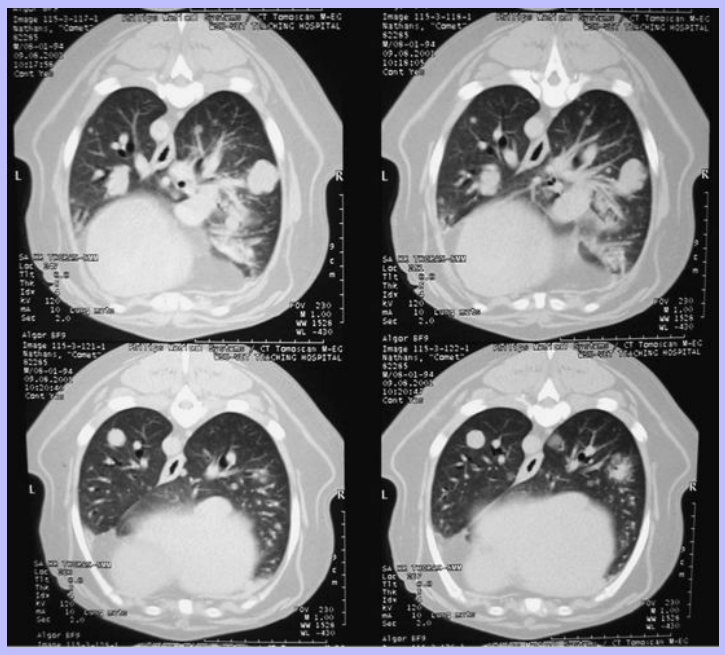
Thoracic radiographs are a key tool in the diagnostic approach to patients with pulmonary neoplasia. The radiographic appearance of primary pulmonary neoplasia varies. Abnormalities observed on thoracic radiographs can range from discrete nodules of varying size and number, to ill-defined interstitial patterns, to consolidated single lung lobes. Radiographic patterns can be focal or diffuse depending on the nature of the neoplasm and whether there has been pulmonary metastasis. Enlargement of hilar lymph nodes may also be seen.

When evaluating animals radiographically for which pulmonary neoplasia or other primary pulmonary disease is suspected, it may be useful to obtain three views of the thorax, right and left laterals, and either a ventrodorsal or dorsoventral image. Three radiographic views maximize the opportunities to see lesions that might be obscured by the heart, or if in caudal lung fields, the liver (Figure 215-3). Computed tomography (CT), available at many referral centers, can provide an extra degree of sensitivity in the characterization and localization of lung lesions, including small metastatic lesions (Figure 215-4).[14–16] The size of lesions detectable with CT is influenced by several factors, including the distance between slices, amount of overlap between slices, and the location of the lesion within the parenchyma, but detection of nodules less than 5 mm in size is possible. As with other imaging modalities, false positive and false negative results are encountered with CT. CT is more expensive as compared to plain thoracic radiographs, and general anesthesia is usually required for diagnostic CT images, which may be of concern in patients with respiratory embarrassment.

1243

1244

Figure 215-4 Computed tomographic scan of the thorax of a dog with pulmonary metastasis. Note the presence of numerous small densities in the lung periphery.



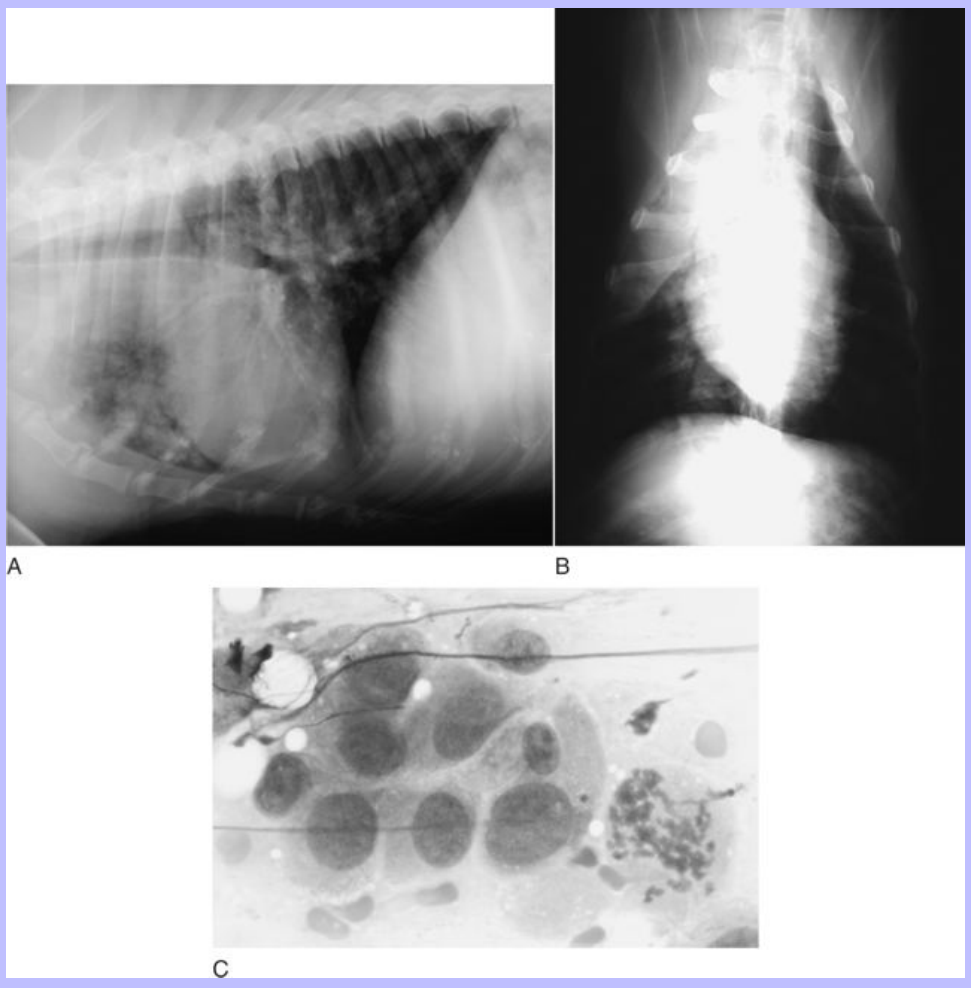
Thoracic radiographs cannot provide cytologic or histologic diagnoses, so the definitive diagnosis of primary pulmonary neoplasia hinges upon demonstration of neoplastic cells either cytologically or histopathologically. The location of lesions observed radiographically can be helpful in guiding the clinician toward appropriate sampling techniques. Some masses, particularly large masses adjacent to the thoracic wall, will be amenable to blind fine needle aspiration using anatomic landmarks observed on radiographs to guide needle placement (Figure 215-5). Smaller masses adjacent to the thoracic wall may be aspirated with ultrasound guidance; the more aerated lung around the mass, the less amenable to ultrasound-guided aspiration it will be. Techniques available at some referral centers for nonsurgical sampling of pulmonary masses include fluoroscopic and CT-guided aspiration (Figure 215-6). Respiratory wash techniques may be considered, but may have poor sensitivity for focal lesions. Bronchoscopy could be valuable to obtain brush cytology or biopsies of lesions extending into the bronchial lumen. Surgical approaches such as thoracotomy or thoracosopy can be both diagnostic and therapeutic.

The decision as to which diagnostic approach will be taken to define the origins of a pulmonary mass will be influenced by the features of the mass and by the client's willingness to tolerate expense, risk of complications, and the status of the patient. Transthoracic needle aspiration and tracheal wash are comparatively inexpensive and widely accessible because minimal equipment is needed to perform these techniques. The most common complication associated with transthoracic aspiration is pneumothorax (see Chapter 103), so the clinician should be prepared to manage the complications of needle aspiration. A key point to be considered when attempting to establish the etiology of a pulmonary mass is that false negative, or even misleading, results with any of the techniques are common. It is possible for samples collected from pulmonary neoplasms to appear as inflammatory or even infectious processes on aspiration cytology or bronchoalveolar lavage.[17] Thus a negative result does not at all exclude neoplasia or other diseases that cause pulmonary masses. A patient may be subjected to various nonsurgical attempts at a diagnosis and still in the end need a thoracotomy or thoracoscopy to establish a definitive diagnosis.[17]

215.3.1.3 Treatment and Prognosis

The treatment for primary pulmonary neoplasia is surgical resection. Patients with small focal lesions can have a good prognosis. The prognosis for dogs is considered better in those patients that have solitary, well-differentiated lesions less then 5 cm in diameter, no metastasis to regional lymph nodes, and no malignant pleural effusion.[10] Cats have been considered in general to have a poorer prognosis in the face of primary lung tumors, with the degree of differentiation of tumors being more predictive of survival.[18] Patients with adenocarcinomas are also considered to have a better prognosis than those with squamous cell carcinomas. Because the prognosis of patients with primary lung tumors is difficult to establish without histologic information (tumor type and degree of differentiation, hilar lymph node metastasis), surgical resection can be advocated early in the course of the diagnostic process as lung lobectomy will be diagnostic, provide prognostic information, and will be the first step in providing definitive therapy.

Figure 215-5 **A** and **B,** Thoracic radiographs (lateral, ventrodorsal) from a dog with primary pulmonary neoplasia. The affected lung lobe was sampled by ultrasound-guided needle aspiration. **C,** Photomicrograph of the carcinoma cells obtained by needle aspiration of the lung mass.



215.3.2 Metastatic Lung Disease

The respiratory system, owing to the key anatomic location of the pulmonary capillary bed, is a frequent site for the development of metastatic tumors of both carcinoma and sarcoma origin. Metastatic pulmonary neoplasia is the most common pulmonary neoplasia in dogs and cats. Although virtually any tumor can metastasize to the lungs, tumors with a high predilection for pulmonary metastasis include canine osteosarcomas, mammary carcinomas in dogs and cats, and oral and nail bed melanomas in dogs.

215.3.2.1 Presentation

Clinical signs observed in patients with pulmonary metastatic disease are widely variable and usually reflect the presence of the primary tumor. Clinical signs referable to the lower respiratory tract such as cough or exercise intolerance are frequently absent even in the face of large metastatic burdens (Figure 215-7). It is not unusual in the authors' experience to see patients with histories of lethargy, anorexia, weight loss, and unremarkable physical examinations that have radiographic lesions consistent with pulmonary metastatic disease. Because of the frequency with which vague clinical signs can be observed in dogs and cats with neoplasia that is not detectable by physical examination, a three-view thoracic radiograph is a recommended component of the initial diagnostic plan for such patients.

215.3.2.2 Diagnostic Evaluation

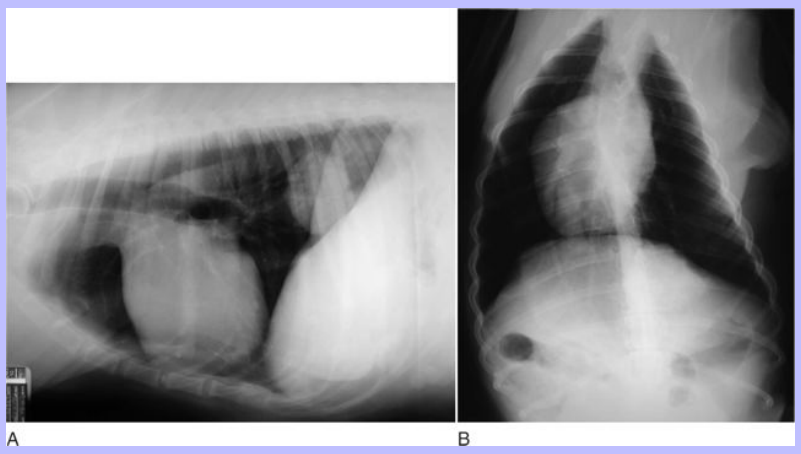
The diagnosis of metastatic neoplasia is often presumptive based on compatible thoracic radiographic abnormalities in a patient with a history of a histologically confirmed malignancy. Radiographically, pulmonary metastasis can be surprisingly variable in appearance and can run the gamut from multiple, well-defined interstitial nodules, to ill-defined interstitial patterns to alveolar patterns.[19] Many of these patients will not have diagnostic tests performed to confirm that observed lesions are metastatic lesions.

1245

However, the clinician has to be careful in assuming that observed radiographic lesions are neoplastic lesions, particularly in the patient that has not had a primary tumor identified. Pitfalls in such thinking include the fact that other diseases, such as the systemic fungal infections, occasional bacterial and mycobacterial infections, or hypersensitivity disorders (e.g., eosinophilic granuloma) can mimic the clinical disease and radiographic appearance of metastatic pulmonary disease. In addition, patients with one malignancy can develop other tumors that have no relationship to previously diagnosed tumors, and for which diagnostic and therapeutic intervention would be of benefit. Definitive diagnosis of metastasis can be made using the techniques described above in the diagnostic approach to primary lung tumors.

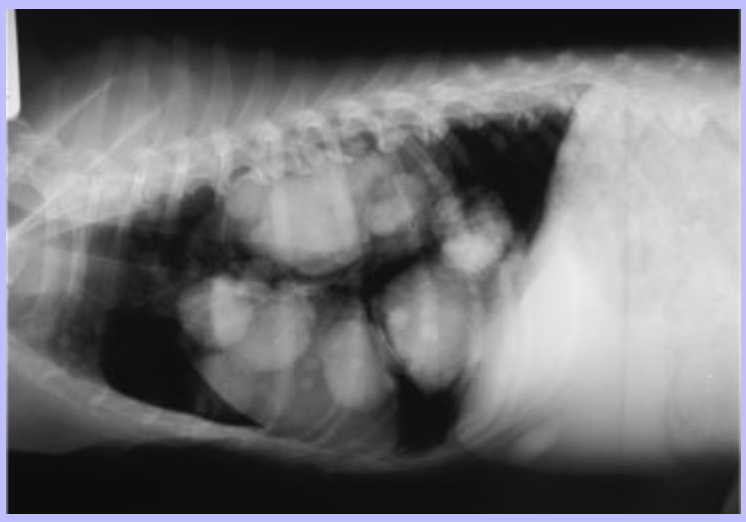
1246

Figure 215-6 Thoracic radiographs (lateral **[A],** ventrodorsal **[B]**) of a dog with a solitary lung mass deep in the thoracic cavity. This mass was successfully aspirated with fluoroscopic guidance.



Treatment of metastatic lung disease is often unrewarding but could be of short-term benefit in patients that exhibit clinical signs referable to their pulmonary lesions. The decision to treat obviously will be weighed against other factors, such as rapidity of disease progression, quality of life concerns, owner wishes, and owner willingness to tolerate expense and complications of treatment. Treatment of metastatic lesions could require surgical resection, best for few lesions, or chemotherapy if not already administered for the patient's primary tumor. Recently, some positive responses have been observed in dogs with metastatic pulmonary disease treated with chemotherapeutic agents or interleukin-2 via inhalation.[20,21] Such an approach offers the potential of treating pulmonary metastatic disease with fewer adverse effects as can occur with systemic administration of such agents.

Figure 215-7 Lateral thoracic radiograph of a dog with extensive pulmonary metastasis. This dog exhibited no clinical signs of respiratory disease. (Courtesy Dan Brown, Moscow, ID.)



215.3.3 Lymphosarcoma

The respiratory tract is frequently affected in dogs with lymphosarcoma, although not all dogs will have clinical signs of respiratory disease. Radiographically, lymphosarcoma can assume a variety of radiographic patters from interstitial to alveolar to mixed patterns (Figure 215-8). The diagnosis of lymphosarcoma is usually made based on assessment of other organs, but the similarities of the radiographic abnormalities to other pulmonary diseases should prompt consideration of other differentials for the respiratory component. Diagnosis of pulmonary lymphosarcoma is often readily accomplished from examination of respiratory wash specimens or needle aspiration. Treatment of lymphosarcoma is addressed in Chapter 181.

215.3.4 Lymphomatoid Granulomatosis

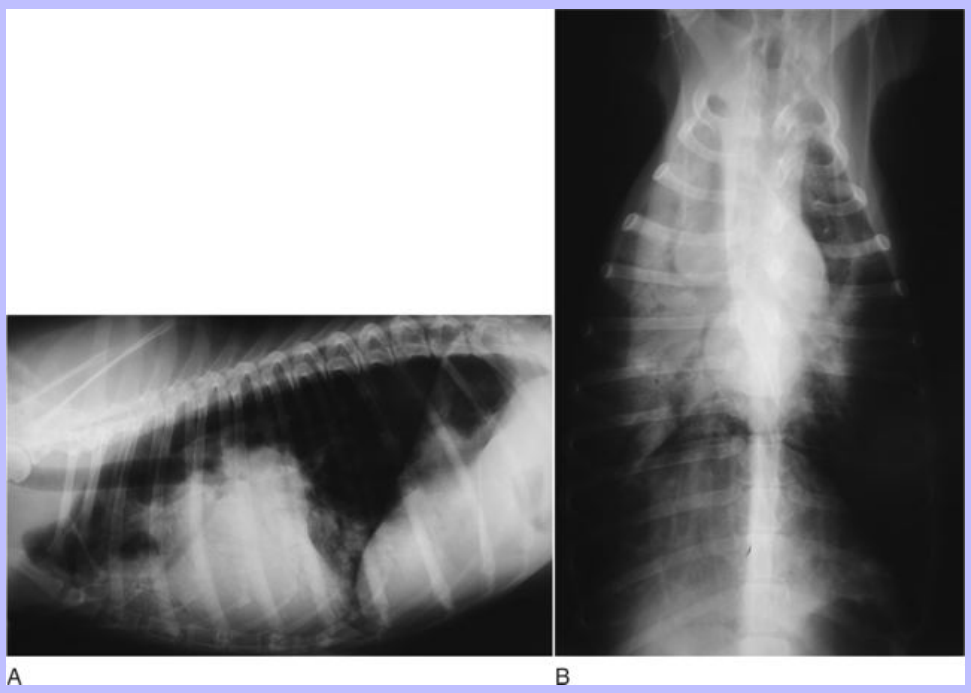
Lymphomatoid granulomatosis is characterized by infiltration around, and invasion of, pulmonary blood vessels with pleomorphic lymphoreticular and plasmacytoid cells. Eosinophils, neutrophils, and small

lymphocytes are also present.[22,23] Lymphomatoid granulomatosis was once considered an immune-mediated vasculitis, but evidence in people and dogs now supports the classification of this disease as a low-grade lymphoma (see Chapter 181).[24,25] Thrombosis, necrosis, and granuloma formation are common. Intrathoracic lymph nodes are also involved.

215.3.4.1 Presentation

This disease has only been described in people and dogs. There is no obvious age or breed predilection.[23] 1246
Patients usually present with respiratory signs such as cough, tachypnea, or respiratory distress, although 1247
fever, anorexia, or weight loss may also be noted. Clinical signs are usually slowly progressive.

Figure 215-8 Thoracic radiographs (lateral **[A],** ventrodorsal **[B]**) of a dog with pulmonary lymphosarcoma. On the lateral view there is a marked alveolar (air bronchogram in cranial lung lobe) and interstitial pattern. On the ventrodorsal projection, note the near consolidation of the right cranial lung lobe and enlarged hilar lymph node that is compressing the mainstem bronchus to the right caudal lung lobe.



215.3.4.2 Diagnostic Evaluation

Thoracic radiographs reveal a mixed nodular interstitial pattern. The pattern is typically generalized and the nodules ill-defined. Hilar and sternal lymph node enlargement may be present.[25] Consolidation of one or more lung lobes has been reported.

Cytology preparations of bronchial wash specimens or transthoracic lung aspirates often show a nonspecific mixed inflammatory response of lymphocytes, plasma cells, eosinophils, and mast cells. The radiographic and cytologic findings can be similar to those found in animals with eosinophilic pulmonary granulomatosis, neoplasia, fungal infection, or atypical mycobacterial infection.[22,26] Heartworm tests, fungal titers, and cultures are indicated to rule out other inflammatory diseases. Definitive diagnosis usually requires surgical biopsy and histopathologic evaluation.

215.3.4.3 Treatment

Chemotherapeutic protocols described for treatment of lymphoma are utilized for lymphomatoid granulomatosis (see Chapter 181). Administration of prednisone alone is often unrewarding.[22,26] Serial thoracic radiography is used to monitor resolution of disease.

215.3.4.4 Prognosis

Prognosis is typically guarded due to the variable individual clinical responses. The small numbers of cases reported hinders comparative assessment of the efficacy of different treatment modalities used in these patients.

215.3.5 Malignant Histiocytosis

Malignant histiocytosis was first recognized in Bernese mountain dogs but has since been recognized in other breeds such as golden retrievers and rottweilers.[23,27,28] In Bernese mountain dogs, malignant histiocytosis has a genetic basis with a polygenic mode of inheritance suspected.[29]

Most dogs are middle-aged and exhibit respiratory signs at the time of presentation. Lethargy, anorexia, and weight loss are also common clinical complaints as most dogs have widespread systemic disease at the time of diagnosis. Thoracic radiographs commonly show multiple pulmonary nodules, lymph node enlargement, and pleural effusion. The disease is characterized by infiltration of multiple visceral organs with atypical histiocytes. The brain and spinal cord may also be affected.[30, 31] Histopathologic examination of tissue is usually necessary for a definitive diagnosis. The prognosis has generally been poor with standard chemotherapy protocols; however, one report documented successful treatment in four dogs administered a human major histocompatibility complex nonrestricted cytotoxic T-cell line.[32]

215.4 INFECTIOUS DISEASES

215.4.1 Bacterial Disease

215.4.1.1 Bacterial Pneumonia

The development of bacterial pneumonia in dogs and cats is often viewed as a complication of a loss of one or more pulmonary defense mechanisms. Important mechanisms that protect the pulmonary parenchyma from infection include normal laryngeal function, cough reflex, the mucociliary escalator apparatus of the airways, an intact respiratory epithelial barrier with surface IgA, and in the alveoli, alveolar macrophages, and IgG. 1247 1248

Bacterial infection of the lung is a common complication of many diseases in dogs but is considered uncommon as a primary pulmonary disorder, which emphasizes the importance of careful assessment of patients with bacterial pneumonia for predisposing causes. Aspiration is considered the most common inciting cause, but other means of infection, such as hematogenous spread of infectious organisms, are also possible. Bacterial pneumonia may complicate viral respiratory infections following injury to the respiratory epithelium and disruption of the epithelial barrier, loss of mucociliary function, and local or systemic immune suppression.

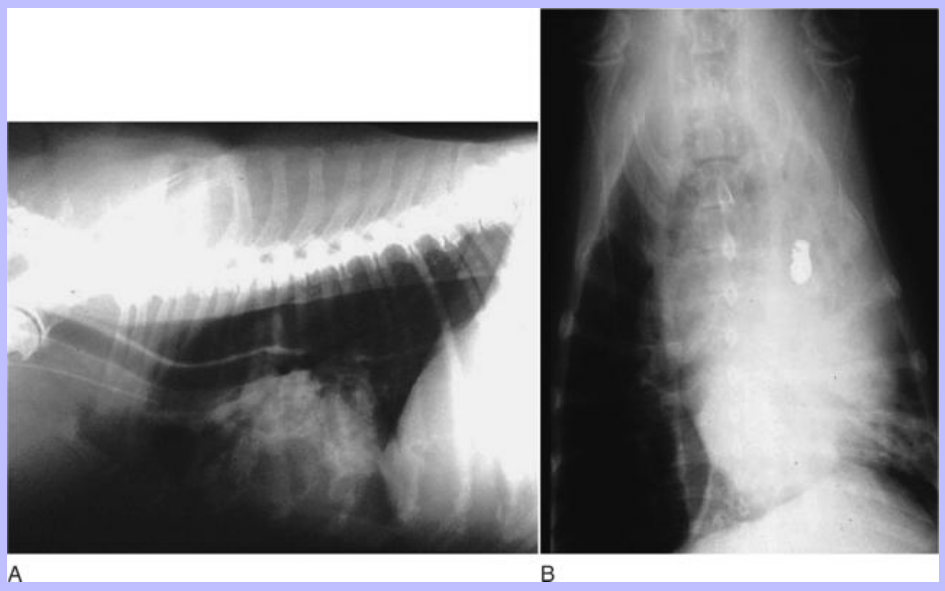
Nosocomial infections become a concern in patients that have been in the hospital for a number of days and have risk factors such as recumbency, regurgitation or vomiting, and prolonged endotracheal tubation as would be needed for patients on ventilators.[33,34] Bacterial pneumonia is considered a less common problem in cats as compared with dogs.

215.4.1.1.1 Presentation

Clinical signs of animals with bacterial pneumonia can be surprisingly variable. One aspect to recognize is that not all animals with pneumonia will exhibit clinical signs referable to the lower respiratory tract. Anorexia and lethargy are common but obviously nonspecific. Cough, which can be acute or chronic, tachypnea, and increased respiratory effort can be seen, with changes in respiratory character commonly reflecting the severity of underlying disease. Cough in cats with pneumonia occurs uncommonly. Some patients with bacterial pneumonia may have hemoptysis.[13] Exercise intolerance is seen in some animals. On physical examination, there may be fever, inducible cough, nasal discharge, increased lung sounds, and crackles or wheezes, but these features are not detected in every patient.

Other clinical signs in animals with pneumonia will reflect the primary diseases that put such patients at risk of bacterial pneumonia. Such patients may exhibit neurologic abnormalities, muscular weakness, gastrointestinal signs such as vomiting or regurgitation, or other signs.

Figure 215-9 Thoracic radiographs (lateral [**A**], ventrodorsal [**B**]) of a dog with focal bacterial pneumonia secondary to aspiration. Note the prominent air bronchogram in the cranioventral lung region on the lateral projection. Note that there is also megaesophagus.



215.4.1.1.2 Diagnostic evaluation

The diagnostic approach to a patient with bacterial pneumonia often involves some hematologic and biochemical assessment, and thoracic radiography, as first-line tests. Abnormalities of the CBC can be variable, and neutrophilia with or without a left shift and toxic changes will be expected in many but not all patients. Thrombocytopenia is associated with systemic inflammatory complications. There are no pathognomonic biochemical and urinalysis abnormalities for bacterial pneumonia, but these tests are often useful for comprehensive assessment of patient status and can give clues to diseases that are risk factors for pneumonia or other respiratory diseases. Abnormalities observed on biochemistries and urinalysis could be as much a reflection of underlying disease as of the pneumonia itself. Hypoalbuminemia reflecting increased pulmonary or systemic capillary permeability is not unusual, and animals that are clinically dehydrated may have azotemia. It is important to understand that animals with bacterial pneumonia may have normal laboratory data base results.

Although changes on arterial blood gas analysis will not be specific for bacterial pneumonia, blood gas results can be useful in the diagnostic assessment of patients with pneumonia. Arterial blood gas results will provide the clinician an indication of the adequacy of oxygenation (PaO_2) and the adequacy of ventilation ($PaCO_2$), which if severely compromised would suggest the need for ventilatory support. Evidence of ventilation-perfusion mismatches (hypoxemia, hypocarbia, widened A-a gradient) is expected in many patients.

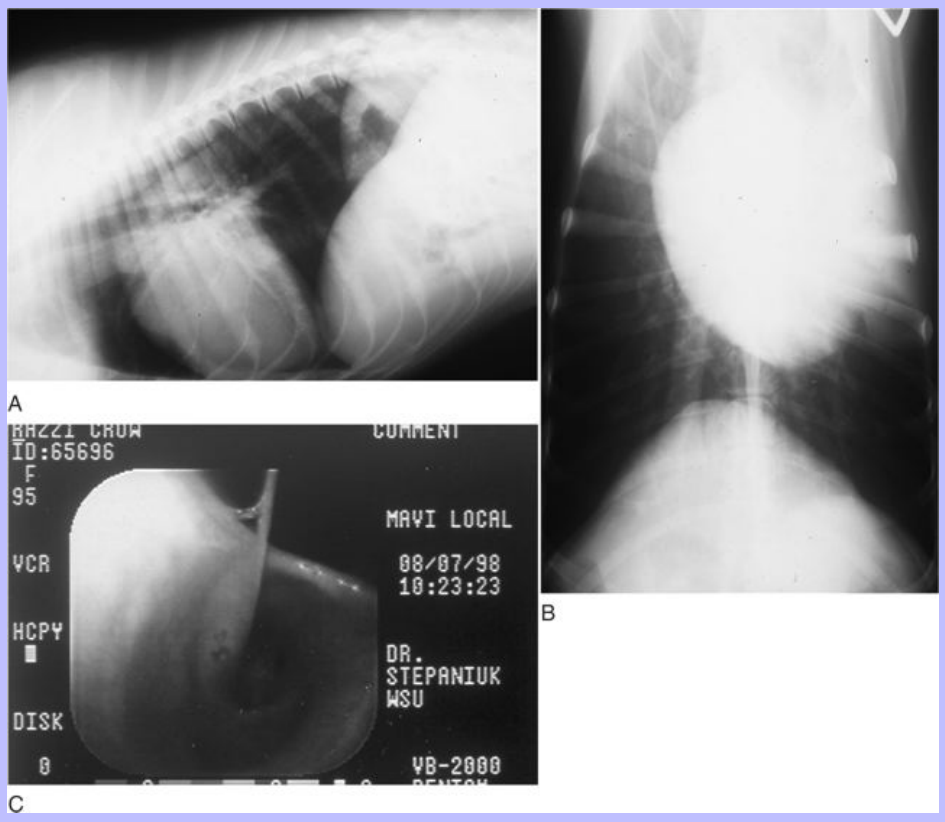
Thoracic radiographs are useful in the assessment of patients with bacterial pneumonia. The most common radiographic appearance seen in patients with bacterial pneumonia is an alveolar pattern (Figure 215-9) that may be focal or diffuse depending on the manner in which the respiratory tract was seeded with bacteria. Aspiration pneumonia (see below) is more often associated with radiographic abnormalities in the cranioventral lung regions, although not all patients will have this distribution. Depending on the causative organism, there may be pleural effusion, or soft tissue densities that reflect pulmonary abscesses. In severe cases, lobar consolidation may be apparent. Thoracic radiographs should be carefully scrutinized for other abnormalities that could suggest an underlying disorder that could predispose to bacterial pneumonia such as megaesophagus, bronchiectasis, or neoplasia.[34,35]

1248
1249

In some patients, extra effort may be required to demonstrate diseases that predispose to pneumonia. In a study of cats with esophageal disease, many were examined for signs of respira-tory disease and required contrast esophagrams to demonstrate abnormalities in esophageal motility.[36] Since bacterial pneumonia can accompany almost any other primary respiratory disease, repeating thoracic radiographs after resolution of pneumonia is important to help uncover other underlying primary diseases. Patients with recurrence of pneumonia confined to a single lung lobe should be suspected of diseases such as endobronchial foreign bodies, airway masses, or other causes of local disruption of pulmonary defense mechanisms (Figure 215-10).

Although a presumptive diagnosis of pneumonia is possible based on history, physical examination, and radiographic findings, definitive diagnosis is established from cytology and culture of material obtained from the respiratory tract by transtracheal washes or bronchoalveolar lavage. Cytologically, suppurative inflammation is expected, with signs of septic inflammation (intracellular bacteria, degenerative neutrophils) present in some, but not all, patients. Because not all patients with bacterial pneumonia have bacteria or septic features evident on cytology, it is important to culture samples for bacteria, including *Mycoplasma* spp. If thoracic radiographs are suggestive of abscessation, anaerobic cultures would also be appropriate. Ideally, samples should be obtained by transtracheal/endotracheal washes, bronchoalveolar lavage, or less commonly, needle aspiration, before administration of antibiotics if the patient's status will allow. Collection of samples by alveolar lavage is especially useful for focal disease, particularly if performed after bronchoscopic examination, which can identify predisposing diseases such as masses or foreign bodies. Fine-needle aspiration for cytology and culture may be considered if respiratory wash techniques do not provide an etiology, if there is lobar consolidation evident radiographically, or if other procedures are cost prohibitive.

Figure 215-10 **A,** Thoracic radiographs (lateral [**A**], ventrodorsal [**B**]) from a dog with recurring focal pneumonia. During bronchoscopy, grass awns **(C)** were found in airways of this lung lobe.



215.4.1.1.3

Treatment and prognosis

Treatment of bacterial pneumonia requires administration of antibiotics. The specific type of antibiotic and route of administration is ideally based upon results of culture and sensitivity of lower respiratory tract secretions or exudates, and in consideration of the clinical status of the patient. Certain situations, such as a patient in severe respiratory distress in which collection of samples by respiratory washes may be dangerous to the patient, may preclude sample collection. Some owners may not wish to incur the financial costs of sample collection and analysis. In such cases, antimicrobial therapy may be needed on an empiric basis.

1249

1250

Empiric selection of antibiotics for animals suspected of having bacterial pneumonia can be facilitated by knowledge of common bacterial isolates from dogs and cats with bacterial pneumonia. Organisms often isolated from the respiratory tract of dogs with bacterial pneumonia include *Escherichia coli*, *Pasteurella multocida*, *Klebsiella* spp., *Bordetella bronchiseptica*, *Acinetobacter* spp., *Pseudomonas aeruginosa*, *Moraxella* spp., and isolates of *Staphylococcus* and *Streptococcus*.[37,38] In cats, common

isolates include *P. multocida*, *Klebsiella* spp., *Proteus* spp., *Bordetella* spp., *E. coli,* and *Streptococci*.[38,39] *Mycoplasma* spp. are frequently cultured from dogs and cats with pneumonia. The role of *Mycoplasma* spp. as primary respiratory pathogens in both dogs and cats has been suggested, and recent reports are consistent with *Mycoplasma* spp. as a cause of pneumonia.[37,40,41] Less commonly, *Actinomyces* or *Nocardia* spp. can be a cause of pneumonia without pyothorax.

Initial empiric therapy can be further focused by morphologic assessment of observed organisms and gram-staining if available. Good empiric selections for canine and feline bacterial pneumonia are presented in Table 215-1. Good initial combinations would be a beta lactam such as ampicillin or first-generation cephalosporin and an aminoglycoside or fluoroquinolone. An empirically treated patient that shows no clinical improvement, or exhibits clinical deterioration, during the first 24 to 48 hours after initiation of treatment should be thoroughly re-evaluated, and another consideration given to collection of samples for analysis. A change in antimicrobial therapy could be warranted at this point, but selection becomes more difficult in the absence of sensitivity results. The patient exhibiting a positive clinical response should be treated at least 1 week beyond clinical and radiographic resolution of pneumonia as radiographic improvement may lag several days behind clinical improvement.

Table • 215-1 Antibiotic Selections for Empiric Treatment of Bacterial Pneumonia[1]

ANTIBIOTIC	ANTIMICROBIAL SPECTRUM	DOSAGE, ROUTE, FREQUENCY
Ampicillin	Gram-positive aerobes (staphylococci, streptococci), *Pasteurella multocida,* some *E. coli* Anaerobes	10–30 mg/kg IV, IM, PO q8-12h
Cefazolin (or other first-generation cephalosporin)	Gram-positive aerobes (staphylococci, streptococci), *Pasteurella multocida, Bordetella bronchiseptica*, some *E. coli* and *Klebsiella* spp.	10–30 mg/kg IV, IM, PO q8-12h
Gentamicin	Gram-negative aerobes (*E. coli*, *Proteus* spp., *Pasteurella multocida*, *Bordetella bronchiseptica*, some *Klebsiella* and *Pseudomonas* spp.), *Staphylococcus intermedius*	6–10 mg/kg IV q24h
Amikacin	Gram-negative aerobes (*E. coli*, *Pseudomonas* and *Klebsiella* spp., *Bordetella bronchiseptica*); *Staphylococcus intermedius*	10–15 mg/kg IV, IM, SQ q24h
Enrofloxacin	Gram-negative aerobes (*E. coli*, *Proteus* spp., *Pasteurella multocida*, *Bordetella bronchiseptica*, some *Pseudomonas* spp.); *Staphylococcus intermedius*	3–5 mg/kg PO, IV q24h (cat) 5–20 mg/kg PO, IV q24h (dog) 5–10 mg/kg PO, IV q12h
Doxycyline	*Mycoplasma* spp., *Bordetella bronchiseptica*	10–25 mg/kg PO q12h (cat)
Metronidazole	Anaerobes	15 mg/kg IV, PO q12h (dog)

1. Selection of drugs is based ideally on culture and sensitivity. Dosages may need to be altered in the face of concurrent renal or hepatic disease.

The route of administration of antimicrobials will, in most cases, be predicated by the patient's clinical status. Patients that are clinically stable and that have minimal clinical signs of respiratory disease are candidates for oral therapy administered at home. Patients that are clinically unstable will likely require

hospitalization for administration of intravenous antimicrobials, ancillary therapy such as intravenous fluids, and oxygen supplementation. Intravenous antibiotic therapy should be continued until the patient has become stabilized and can be safely discharged on oral medications. Patients with esophageal disease may need prolonged parenteral antimicrobials or gastrostomy tubes to ensure that adequate tissue concentrations of antimicrobials are attained and to provide nutritional support.

Administration of antimicrobials via nebulization may be considered in some patients, but the clinical implementation of this route of administration has some important limitations.[42] The efficacy of nebulized medications reflects a complex set of interactions between the drug administered, the formulation of the drug, the device used to deliver the drug, and patient factors such as the characteristics of the primary disease, breathing patterns, and tolerance of delivery systems. Nebulization of antimicrobials formulated for intravenous use may prove less effective because of an inability to achieve desirable particle size, or could be harmful because of changes in pH or other properties that, when administered as an aerosol, result in respiratory mucosal irritation or injury. The best products for nebulization are those medications that have been specifically formulated for administration via nebulizer. Unfortunately, few antimicrobials, other than aminoglycosides formulated for use in people with cystic fibrosis and *Pseudomonas* infection, are available for specific use in small animal patients.

Administration of bronchodilators to patients with pneumonia has been suggested but is not universally accepted. The most appropriate use of bronchodilators would be for patients with bronchoconstriction, which may be difficult to appreciate in some patients. Bronchoconstriction is not considered an important feature in dogs with pneumonia. In cats, however, inflammation is a potent stimulus for bronchoconstriction, which may contribute to clinical signs in cats. Bronchodilators have the potential to worsen oxygenation by contributing further to ventilation-perfusion mismatchings often present in patients with pneumonia.

1250

1251

Coupage may help some patients with pneumonia by helping loosen mucus secretions for expectoration to clear airways. Saline nebulization to keep respiratory secretions moist can be beneficial in facilitating clearance of respiratory secretions. Limited periods of exercise in the clinically stable patient that can tolerate activity may accomplish the same purpose.

Occasionally, lung lobectomy may be necessary to treat an animal with bacterial pneumonia. There are no specific criteria that have been established for determination of which patients should receive surgery. Some candidates for lobectomy include patients that have focal disease that has not demonstrated improvement or clinical response to medical therapy, patients that have focally recurring pneumonia, or patients for which less-invasive methods have failed to establish a diagnosis and empiric therapy has failed. Retrospective studies of lobectomies for pneumonia in dogs and cats suggest that the value of surgery may lie as much in its diagnostic value as its therapeutic value. In addition to its therapeutic potential in animals with severe focal pneumonia, surgery may also help rule out other concurrent diseases such as foreign bodies, fungal infection, or neoplasms. The best prognoses reported with lobectomy for pneumonia are associated with foreign body pneumonia, and focal pneumonia, including animals with lobar consolidation, for which no etiology is discovered.[43,44] A poorer prognosis can be expected for dogs with fungal or bacterial pneumonia, or the resection of large amounts of lung tissue.

215.4.1.2 Zoonotic Respiratory Pathogens

215.4.1.2.1 Mycobacteria

Mycobacteria spp. are an important cause of pneumonia in dogs and cats, not necessarily because of the frequency with which they are seen, but because mycobacterial infections can mimic other diseases such as neoplasia, systemic fungal infections, and severe bacterial pneumonia. Additionally, some *Mycobacteria* spp. are potential human health hazards. The clinical presentation of dogs and cats with mycobacterial infection is typically one of chronic cough progressing to more severe signs of respiratory disease such as tachypnea and increased respiratory effort. Radiographically, infected animals can have interstitial nodules of various numbers and sizes, or have prominent interstitial markings. Enlargement of hilar lymph nodes, lung lobe consolidation, and pleural and pericardial effusions may also be seen. As with other pulmonary parenchymal diseases, occasional animals will have hypertrophic osteopathy. Diagnosis of mycobacterial infection is made by demonstration of organisms, which are usually found in the cytoplasm of macrophages in samples collected via tracheal wash, bronchoalveolar lavage, lung aspirate, or biopsy. Mycobacterial nucleic acid can be detected in samples by the polymerase chain reaction[45] and would support a diagnosis in a patient with appropriate clinical signs and radiographic abnormalities.

215.4.1.2.2 Yersinia pestis and Francisella tularensis

Animals in the southwestern and western United States live in areas of endemic plague (*Yersinia pestis*) and tularemia (*Francisella tularensis*). Cats are particularly susceptible to development of clinical plague, with the bubonic form most common. However, pneumonic forms of plague are seen with some regularity in endemic areas and would pose the greatest threat to people.[46] Cats infected with tularemia do not commonly show signs of respiratory disease despite often extensive lesions in the lungs.[47] The diagnosis of these diseases can be established with fluorescent antibody assays performed on aspirates of lymph nodes or bone marrow.

215.4.2 Viral Diseases

215.4.2.1 Canine Distemper Virus

Canine distemper virus (CDV) infection can be associated with parenchymal disease. In CDV-infected dogs, viral infection may lead to secondary bacterial pneumonias. See Chapter 169.

215.4.2.2 Canine Adenovirus (CAV)-2, Parainfluenza (PI)

CAV-2 and canine PI are not typically a cause of parenchymal disease, although severe cases might be associated with secondary bacterial pneumonia. CAV-2 as a sole pathogen has been incriminated as a cause of pneumonia in rare instances.[48]

215.4.2.3 Feline Calicivirus

Feline calicivirus is more often a cause of upper respiratory disease in cats, but has been associated with interstitial pneumonia (see Chapter 173).[49]

215.4.2.4 Feline Infectious Peritonitis

Most cases of respiratory disease caused by feline infectious peritonitis (FIP) are associated with pleural effusion. Although pyogranulomatous pulmonary lesions are often seen in the setting of noneffusive FIP, most cats with non-effusive FIP exhibit signs referable to the eyes, CNS or liver, kidneys, or GI tract and are not commonly examined for respiratory disease.[50] Other clinical features and the diagnostic approach to cats suspected of having FIP are presented in Chapter 172.

215.4.2.5 Feline Immunodeficiency Virus and Feline Leukemia Virus

The feline retroviruses are not considered primary respiratory tract pathogens. Clinically affected cats, however, may develop parenchymal disease as a result of opportunistic infections or development of pulmonary neoplasia. Interstitial inflammation and alveolitis have been described in FIV-infected cats.[51] Diagnosis of underlying causes of respiratory disease in retroviral-infected cats will rely on the principles and techniques presented in Chapter 171, with treatment decisions based on diagnosis as well as the clinical status of the cat. FIV-positive cats may survive for long periods of time with appropriate veterinary care, so treatment decisions for such cats should not necessarily be based solely on the FIV status.

215.4.3 Rickettsial Disease

The primary rickettsial diseases of dogs and cats are infections caused by species in the genus *Ehrlichia* and *Rickettsia rickettsii*, the causative agent of Rocky Mountain Spotted Fever (RMSF) in dogs. RMSF causes a systemic vasculitis, and thus dysfunction of any organ system, including the respiratory tract, may cause clinical signs in affected dogs. Although not a common manifestation of infection, respiratory signs of RMSF that have been described in dogs include cough, tachypnea, and dyspnea.[52,53] Physical examination abnormalities referable to the respiratory tract can include nasal discharge and increased lung sounds. Thoracic radiographs may have an interstitial pattern, or alveolar patterns if vascular leakage secondary to pulmonary vascular inflammation is severe. Diagnosis is based on seroconversion or detection of organisms by immunohistochemical methods, and treatment involves administration of tetracycline family drugs (see Chapter 166). The canine and feline ehrlichioses are uncommon causes of respiratory tract disease despite the systemic nature of the infections.

215.4.4 Protozoal Disease

215.4.4.1 Toxoplasmosis and Neosporosis

Pulmonary disease in cats with *Toxoplasma gondii* infection is common. In a retrospective study of feline toxoplasmosis, fever, dyspnea, and tachypnea were common clinical signs, and pulmonary lesions were identified in approximately 25% of cats necropsied.[54] Pulmonary toxoplasmosis can be an acute, fulminant,

and fatal disease. Physical examination abnormalities can reflect the multisystemic nature of the disease with increases in bronchial sounds or crackles during thoracic auscultation in cats with a respiratory component. Radiographic features of respiratory toxoplasmosis in cats may vary. Patterns reflect diffuse alveolar and interstitial disease, and areas of emphysema can create a patchy appearance to the lungs. There are no pathognomic laboratory abnormalities in affected cats.

Diagnosis is supported by serologic results (increased IgM or increases in IgG in an animal with compatible clinical disease) or established definitively with demonstration of organisms in tissues. *T. gondii* tachyzoites can be detected in bronchoalveolar washings of affected cats and should be a useful technique for cats with respiratory signs and radiographic lesions.[55] Alternatively, lung fine-needle aspiration cytology can be attempted to examine samples for tachyzoites. Toxoplasmosis in cats is discussed in further detail in Chapter 168.

Canine toxoplasmosis is not as common as feline toxoplasmosis and can involve the lungs with similar clinical signs and radiographic features as described in cats. The diagnostic approach would be similar to that for cats.

Pneumonia attributable to *Neospora caninum* infection has been described in a dog that was evaluated for persistent cough, fever, and diffuse interstitial and focal alveolar lung disease.[56] An antemortem diagnosis was established by observation of tachyzoites in a lung fine-needle aspirate and confirmed on necropsy with immunohistochemistry. There were no obvious predisposing factors (concurrent lung disease, immunosuppressive disease) apparent in this dog. Pulmonary neosporosis appears to be an uncommon manifestation of *N. caninum* infection.

215.5 FUNGAL DISEASE

215.5.1 Systemic Fungal Infections

The systemic fungal organisms *Blastomyces dermatitidis*, *Histoplasma capsulatum*, *Coccidiodes immitis*, and *Cryptococcus neoformans* are notorious respiratory pathogens. Clinical signs of parenchymal disease are a common reason for infected animals to be evaluated, especially dogs with blastomycosis and cats with histoplasmosis. Clinical signs of cryptococcal pulmonary parenchymal disease are less common as compared with the other systemic fungal organisms. Coccidioidmycosis is rare in cats, and blastomycosis is less common in cats than cryptococcosis or histoplasmosis. Recognition of the contributions of the systemic fungal infections to small animal respiratory disease is important because the clinical signs and radiographic features can be similar to other diseases such as metastatic neoplasia. The systemic fungal infections are easily overlooked if the clinician fails to consider recent travel history of ill patients, particularly those patients that reside in areas where the disease is not endemic. More details of the systemic fungal infections are found in Chapter 174.

Generally, infection with systemic fungi occurs primarily after inhalation of organisms present in the environment. Local infection in the respiratory tract generally precedes systemic spread, although clinical signs of respiratory disease such as tachypnea and dyspnea may not be apparent until after systemic dissemination has occurred. Most affected animals have a history that suggests slowly progressive clinical signs of multisystemic disease; poor response to antibiotic treatment is often a component of the clinical history of animals with systemic fungal infections.

Most animals with clinical signs of respiratory disease will have abnormalities evident on thoracic radiographs, although some animals can have radiographically evident pulmonary disease in the absence of clinical signs of respiratory dysfunction. Although the radiographic appearance of the systemic fungal infections can be quite variable, typical changes on thoracic radiographs include diffuse interstitial patterns that can organize into small nodules (Figure 215-11), or larger, more ill-defined interstitial nodules (Figure 215-12). Some animals will have evidence of alveolar patterns, lobar consolidation (Figure 215-13) or peribronchiolar disease. Hilar lymph node enlargement can be seen in affected animals, and may occur independent of parenchymal lesions, especially with canine histoplasmosis. Hilar lymph node enlargement is also a common feature of canine coccidioidomycosis.[57] Occasionally, calcification of pulmonary nodules can occur with histoplasmosis. Pleural effusion can be a feature of any of these infections.

For all the systemic fungi, definitive diagnosis is often accomplished by demonstration of organisms in exudates, fluid washings, and needle aspirates or tissue biopsies of affected organs. The exception is cryptococcosis, the diagnosis of which can also be made by demonstration of circulating antigen with serologic methods. The cytologic and histologic diagnosis of coccidioidomycosis can be difficult in some cases due to few numbers of organism present in material examined. Most organisms will have to be identified within a cytologic background of inflammation characterized by the presence of neutrophils, macrophages, and depending on the severity of inflammation and the method of sample collection, some evidence of hemorrhage. Samples obtained by tracheal wash, bronchoalveolar lavage, or lung needle aspiration can be negative for organisms necessitating repeating the procedures or choosing an alternative approach, including lung biopsy, to establish a definitive diagnosis. If sufficient material is obtained during sample collection, and the samples do not contain organisms cytologically, consideration can be given to submission of the material for fungal culture. Serologic detection of antibodies, particularly in suspected cases of coccidioidomycosis, can add support to the diagnosis. As with many antibody tests, positive results indicate exposure but do not necessarily confirm clinical disease. Antibody tests can remain positive in animals that have had resolution of clinical disease.

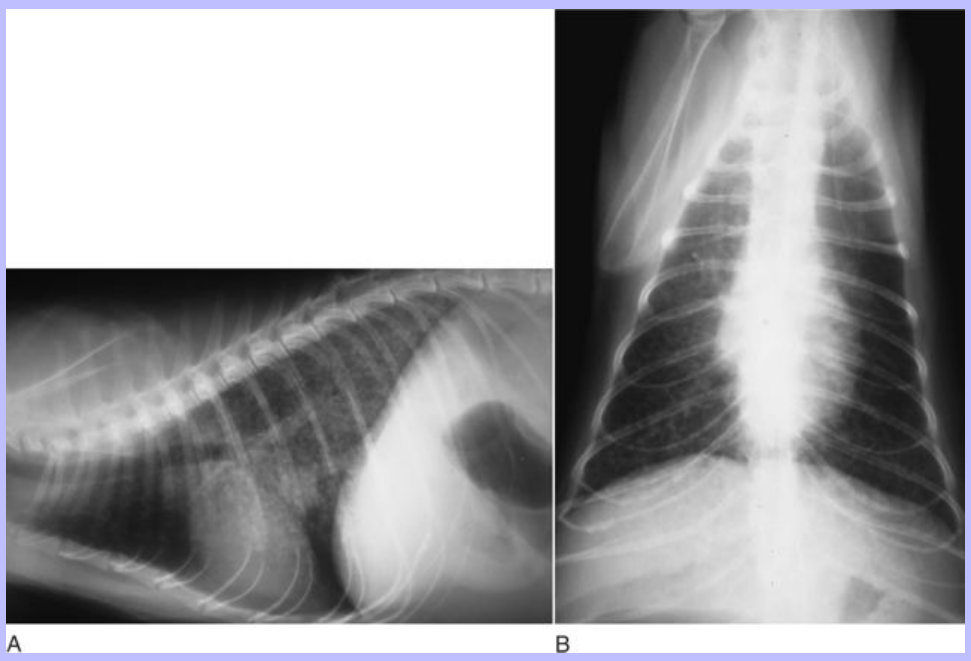
Treatment of the systemic fungal infections centers around administration of antifungal drugs in the azole category (ketoconazole, itraconazole, fluconazole) or amphotericin B. Although not proven in prospective studies, the concurrent administration of anti-inflammatory doses of glucocorticoids to animals with severe disease has been advocated to limit clinical deterioration associated with inflammation secondary to the death of large numbers of fungal organisms. Extension of antifungal therapy for an additional 2 to 4 weeks beyond typical treatment times is suggested if glucocorticoids are used.[58] The prognosis is favorable in animals diagnosed and treated early. The presence of severe respiratory signs worsens the prognosis. The reader is directed to Chapter 174 for additional details regarding the treatment of these infections.

215.5.1.1 Pneumocystosis

Pneumocystis carinii is a fungal organism that can be found in the alveoli of normal animals but can cause clinical disease in animals with immune system dysfunction. Most reported cases in dogs have been in young (<1 year) miniature dachsunds, although dogs of other breeds have also been described with the infection.[59,60] Affected dogs are evaluated for respira-tory difficulty and exercise intolerance, weight loss, and skin diseases (demodicosis, bacterial pyoderma) that also reflect systemic immune system dysfunction.[61] Physical examina-tion abnormalities include poor body condition, tachypnea, dyspnea, increased lung sounds, and skin and hair coat changes that reflect the secondary skin disease. Abnormalities on thoracic radiographs can vary from diffuse, mild, interstitial, or bronchial patterns to more severe interstitial and alveolar patterns. Laboratory assessment is consistent with chronic inflammation

(leukocytosis, thrombocytosis, monocytosis), except affected animals usually have low gamma globulin concentrations.

Figure 215-11 Thoracic radiographs (lateral [**A**], ventrodorsal [**B**]) of a cat with pulmonary histoplasmosis. Note the typical nodular, miliary interstitial pattern that is frequently seen with this infection. (Courtesy Dru Forrester, Blacksburg, Va.)



Definitive diagnosis is made by observation of organisms in respiratory washes, lung needle aspiration cytology, or histologic examination of lung tissue. Additional support for the diagnosis can come from immunohistochemical techniques, or polymerase chain reaction (PCR) performed on tissues from animals with compatible clinical signs. Treatment may be attempted with trimethoprim sulfa combinations (30 mg/kg PO q12h for 3 weeks) or a number of other chemotherapeutic agents including pentamidine isethionate and clindamycin/primaquine, but relapses are common. The long-term prognosis is considered guarded because relapses are common.

1253
1254

Figure 215-12 Thoracic radiographs (lateral [**A**], ventrodorsal [**B**]) of a dog with pulmonary blastomycosis. Note the larger, more ill-defined interstitial densities.

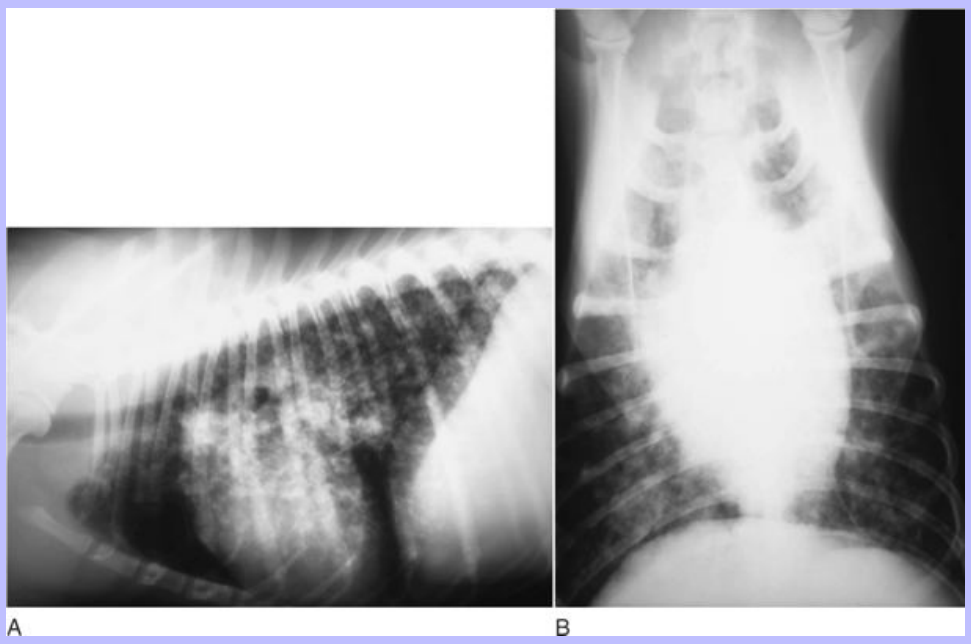


Figure 215-13 Thoracic radiographs (right [**A**] and left [**B**] lateral, ventrodorsal [**C**]) of a dog with *Coccidioides immitis* infection in a single lung lobe. The definitive diagnosis in this dog required lung lobectomy and histology.

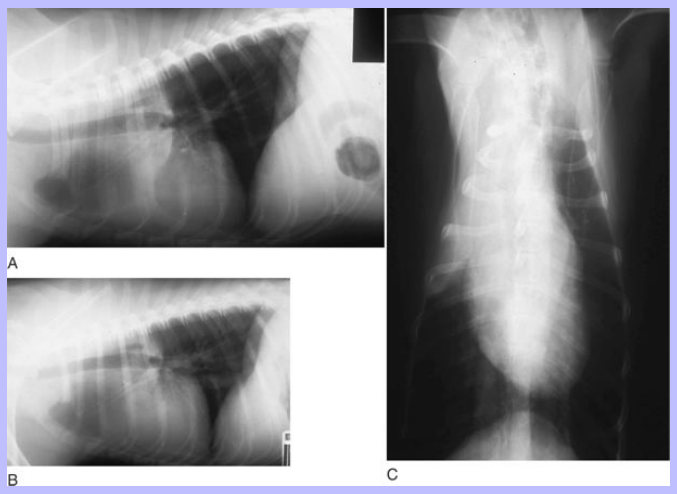


215.5.1.2 Aspergillosis

Aspergillus infections are most commonly a cause of nasal cavity disease in dogs. However, systemic aspergillus infection can occasionally be seen, and when it occurs, is usually caused by *Aspergillus terreus*. Rarely *Aspergillus fumigatus*, the cause of nasal aspergillosis, can cause systemic infection.[62] Systemic aspergillosis has been described most often in German shepherds, which commonly present with signs of neurologic disease from diskospondylitis. These dogs may also exhibit cough, dyspnea, and tachypnea as a consequence of pulmonary parenchymal infection. Diagnosis requires demonstration of fungal hyphae in tissues by cytologic examination of needle aspirates, biopsies, or respiratory washes. Treatment requires administration of systemic antifungals as described for the systemic fungal infections. The prognosis is considered poor.

215.6 PARASITIC DISEASES

The respiratory tract is the site of infection with a number of parasitic organisms, both flukes and helminths. As a whole, respiratory parasites are considered an uncommon cause of clinical respiratory disease in dogs and cats. The importance of the respiratory parasites is that they can cause radiographic lesions that can mimic other diseases such as metastatic neoplasia or systemic fungal infections. The eosinophilic pulmonary infiltrates caused by parasitic pneumonia require differentiation from other causes of eosinophilic pulmonary diseases.

When apparent, clinical signs from parasitic infection are usually mild, with some exceptions that can be associated with severe and life-threatening, presentations. The most common clinical sign of respiratory parasitism is cough, which can be acute or chronic. Other clinical signs that can be seen include wheezing, tachypnea, and respiratory distress in severe cases. The pathogenesis of clinical signs can reflect either the direct presence of the parasite or the immunologic response to the parasite.

As with most animals that present with clinical signs of respiratory disease, thoracic radiographs play a role in the diagnosis of respiratory parasites. Radiographic features common to most of the respiratory parasites include peribronchiolar infiltrates, interstitial patterns that can have a nodular appearance, and occasionally alveolar patterns. Other unique radiographic features of parasite infection are discussed below with the specific parasite.

The diagnosis of most of the respiratory parasites is made by detection of eggs or larvae in tracheal wash or bronchoalveolar lavage fluid, or by demonstration of larvae in stool samples, typically by the Baermann technique. Individual exceptions exist as noted below. Cytologic examination of respiratory samples typically reveals a mix of inflammatory cells, with neutrophils and eosinophils present in varying proportions but usually representing the majority of cells present. Peripheral eosinophilia is an inconsistent, although common, hematologic abnormality and its absence should not lessen the consideration of respiratory parasites as a differential diagnosis of respiratory disease if other aspects of the patient are consistent. Unique features of each of the important lower respiratory tract parasites are noted below.

215.6.1 Paragonimus kellicotti

Paragonimus kellicotti is the lung fluke of dogs and cats. Animals at risk of infection live primarily in the southern, midwestern, and Great Lakes regions of the United States, although infections have been seen in other parts of the world. Animals become infected following ingestion of a freshwater snail or crayfish, which serve as intermediate hosts. The fluke leaves the intestine and migrates to the lungs, where it lives in a cyst or bulla within the pulmonary parenchyma. Eggs from adult flukes are coughed, swallowed, and passed in feces

to infect intermediate hosts. Animals with *P. kellicotti* may be clinically normal or be presented for coughing, which results from inflammatory reactions to adult flukes or ova in the parenchyma and airways. Of the respiratory parasites, *P. kellicotti* has potential to cause life-threatening problems to the affected patient if cysts rupture to cause pneumothorax (Figure 215-14). The physical examination can reflect crackles or wheezes, or if a pneumothorax is present, the restrictive breathing pattern and decreased lung sounds typical of pneumothorax. In cats, wheezing may be seen from inflammatory-mediator induced airway constriction.

The suspicion of paragonamiasis is raised by the observation of cystic or bullous lesions on thoracic radiographs, which may or may not be accompanied by pneumothorax. Other radiographic abnormalities that can be seen are common to other respiratory parasites. The diagnosis of paragonamiasis is made by demonstration of fluke ova in feces by sedimentation techniques, which are preferred for examination of feces. Intermittent shedding of ova dictates a need in some patients for multiple fecal examinations to establish a definitive diagnosis. Ova may also be recovered in tracheal wash or bronchoalveolar lavage fluid; the cytologic picture of such samples is characterized by mixed populations of inflammatory cells, including neutrophils, eosinophils, and macrophages.

Drugs recommended for treatment of paragonamiasis are praziquantel (25 mg/kg PO q8h for 3 days) and fenbendazole (25 to 50 mg/kg PO q12h for 14 days); treatment may need to be repeated if fecal examinations remain posi-tive for ova. Animals with pneumothorax may require thoracocentesis, or thoracostomy tubes if repeated thoracocentesis is required.

Figure 215-14 Ova of *Paragonimus kellicotti*. (Courtesy Bill Foreyt, WSU.)

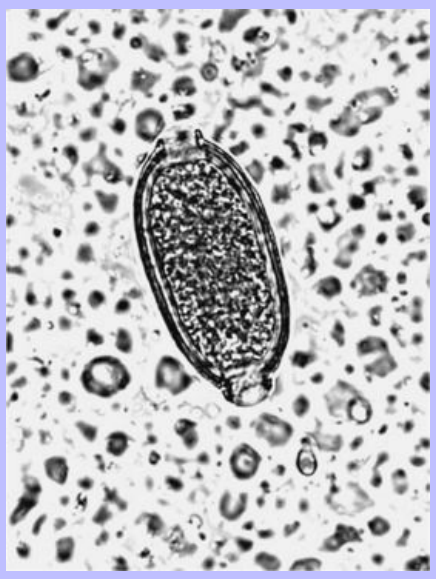
215.6.2 Filaroides hirthi

Filaroides hirthi infects dogs. Adults live in the terminal bronchioles and alveolar spaces. The parasite has a direct life cycle, and larvae can develop within the primary host and contribute to cycles of autoinfection that have the potential to create large worm burdens. Most infected dogs are asymptomatic, and as with other parasitic infections, cough is a common sign. Clinically affected dogs may have conditions associated with immune system compromise. The development of widespread granulomatous inflammation and destruction of respiratory bronchioles and alveolar units is capable of inducing respiratory distress in occasional animals from loss of gas exchange regions of the lung.[63] Interstitial infiltrates, which can appear nodular, as well as alveolar infiltrates, are features of thoracic radiographs that have been described.[63] Definitive diagnosis is made by detection of larvae or larvated eggs in respiratory washes, or in fecal samples by Baermann or zinc sulfate flotation. Administration of fenbendazole (50 mg/kg PO q24h for 14 days) or albendazole (50 mg/kg PO q12h for 5 days, repeat in 3 weeks) can be given to infected dogs, but there is a risk of exacerbation of clinical signs, possibly secondary to reactions to dying worms.[63]

215.6.3 Capillaria aerophila

Capillaria aerophila parasitizes dogs and cats. Adults reside primarily in the trachea and bronchi. Adults deposit eggs, which are coughed, swallowed, and shed in feces. Most parasitized animals are asymptomatic; animals with clinical disease most often cough. Radiographic abnormalities are as described generally above. The diagnosis of *C. aerophila* is made by detection of ova in respiratory washes or fecal flotation. The ova have an operculum at each end and are similar, though smaller, in appearance to the ova of the whipworm *Trichuris vulpis* (Figure 215-15). As with other of the respiratory parasites, intermittent shedding of ova can cause false negative results. Administration of fendbendazole (25 to 50 mg/kg PO q12h for 14 days) is recommended.

Figure 215-15 Ova of *Capillaria aerophila*. (Courtesy Bill Foreyt, WSU.)



215.6.4 Aelurostrongylus abstrusus

Cats are the principle hosts of *Aelurostrongylus abstrusus*. Adult worms live in the bronchioles, where larvae are deposited, coughed, swallowed, and shed in feces to infect a snail or slug intermediate host, which is eaten to complete the transmission cycle. Many cats are parasitized, and most are clinically normal. Clinical signs, when they occur, are attributed to inflammatory reactions to the parasites. Clinical signs can include cough, wheezing, and overt respiratory distress. Because of the overlap in clinical features, cats with a presumptive diagnosis of "asthma" should be considered candidates for *A. abstrusus* infection. Diffuse interstitial nodules are characteristic on thoracic radiographs, and peribronchiolar and alveolar patterns may also be present. Diagnosis is established by detection of larvae in respiratory washes, or in feces by Baermann technique (Figure 215-16).

Clinically symptomatic animals may be treated with fenbendazole (25 to 50 mg/kg PO q24h for 10 to 14 days) or ivermectin (400 ug/kg SC). Administration of bronchodilators and glucocorticoids has been advocated to help address the inflammation-induced bronchoconstriction that can contribute to clinical signs.[64]

215.6.5 Oslerus osleri

Though not a primary lower respiratory tract parasite, *Oslerus osleri* infection has been associated with secondary bacterial pneumonia, likely through disruption of normal pulmonary defenses caused by nodules in the airways. This parasite is discussed more completely in Chapter 213.

215.6.6 Crenosoma vulpis

C. vulpis is a lungworm that infects domestic and wild canids. Dogs acquire the parasite through ingestion of a mollusk like a slug or snail, the intermediate host that contains infective third stage larvae. Adult parasites live in the distal aspects of the bronchial tree where they produce larvated eggs that are coughed, swallowed and passed in feces. Infected dogs are seen primarily in the northeastern United States and eastern provinces of Canada.[65] Baermann techniques are the preferred method of examining feces for larvae, although centrifugal flotation techniques using zinc sulfate may also recover larvae or other parasites. Larvae and larvated eggs are usually readily recovered with airway washings. The preferred treatment is fenbendazole administered at a dosage of 50 mg/kg PO q24h for 3 days. Other anthelmintics such as ivermectin have also been suggested as effective.[65]

Figure 215-16 *Aleurostrongylus* larva. (Courtesy Bill Foreyt, WSU.)

215.6.7 Angiostrongylus vasorum

Sometimes referred to as the heartworm of France,[66] *Angiostrongylus vasorum* parasitizes the pulmonary arteries of dogs primarily in Europe, Africa, and Asia. Historically *A. vasorum* has not been considered a parasite of North American dogs; however, a recent report describes the first known infection of dogs in northeastern Canada.[67] Dogs are infected following ingestion of infected intermediate hosts such as snails and slugs. Adult worms shed eggs that are transported to the pulmonary capillaries where larvae penetrate the capillary wall to migrate into the alveolar spaces. Larvae are coughed, swallowed, and passed in feces.

Adult worms cause a thrombosing pulmonary arteritis, with inflammatory responses contributing to the development of interstitial pneumonia and pulmonary hypertension. Anaphylaxis and consumptive coagulopathies can develop in some infected animals. Clinical signs reflect the pathogenesis, and signs of right-sided heart failure including cough, exercise intolerance, abdominal effusion, and hepatomegaly are possible. Animals with coagulopathies may have evidence of bleeding (anemia, hemoptysis, melena, subcutaneous hemorrhage).

Radiographic abnormalities can include those described above for other respiratory parasites; when alveolar patterns are present, they are usually more prominent in peripheral regions. In addition, dogs with *A. vasorum*

may have right-sided cardiomegaly and pulmonary artery enlargement, ascites and hepatomegaly as can be seen in dogs with *Dirofilaria immitis* infection (see Chapter 206).

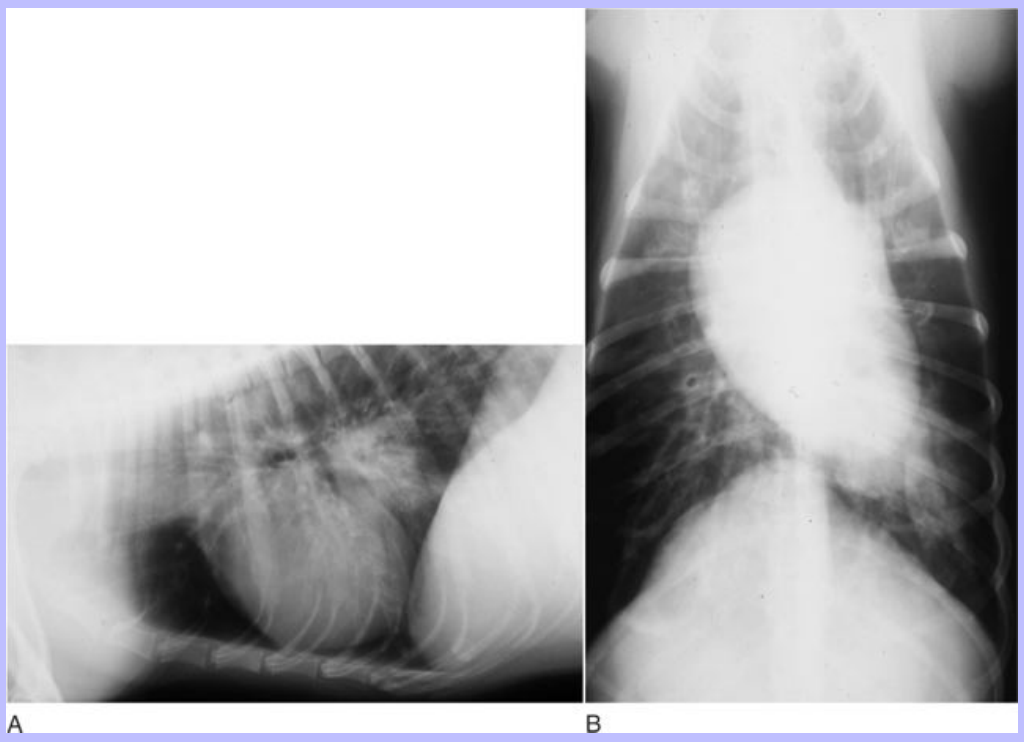
Detection of larvae can be accomplished by Baermann or fecal flotation. False negative results are possible as larvae are not continuously shed. Larvae may also be detected in respiratory washes. Levamisole (7.5 mg/kg PO q24h for 2 days followed by 10 mg/kg PO q24h on the next 2 days) is considered the standard treatment, but other anthelmintics, although known to stop fecal larval shedding, have not yet been adequately investigated for efficacy of killing adult worms.[66]

215.7 HYPERSENSITIVITY DISORDERS

A variety of eosinophilic disorders involving the lungs, either alone or in conjunction with infiltration of other organ systems, have been described in dogs and cats. The clinical spectrum reflects the extent of eosinophilic infiltration and ranges from disease limited to the respiratory tract to multisystemic disease involving not only the lungs, but liver, kidneys, heart, and gastrointestinal tracts. For many affected patients, the diseases are believed to be a manifestation of a hypersensitivity to an environmental or endogenous antigen. Identification of the offending antigen is infrequently accomplished.

Eosinophilic bronchopneumopathy (EB), formerly referred to as *pulmonary infiltrates with eosinophils* (PIE), is an inflammatory disease of unknown etiology that can be seen in dogs of all breeds, although a predisposition in Huskies has been reported.[68] Affected dogs can be of any age, though the majority of cases are seen in young to middle-aged dogs. The primary clinical manifestations of EB are cough, which is often accompanied by gagging, and difficulty breathing; mucopurulent or serous nasal discharge may also be seen. In the authors' experience, EB is frequently associated with coughing that results in expectoration of thick, greenish to greenish-yellow mucus. 1256
Occasionally, dogs may also exhibit lethargy and anorexia. Physical examination abnormalities are typically 1257
confined to the respiratory tract with evidence of nasal discharge, crackles, wheezes or generalized increase in lung sounds heard during thoracic auscultation. Auscultation can be normal in some dogs. Radiographically, EB is characterized by a variety of changes including diffuse bronchointerstitial, alveolar, peribronchio-lar, or some combination of these patterns (Figure 215-17); bronchiectasis may be a feature of some chronically affected dogs. There are no pathognomonic laboratory abnormalities, and peripheral eosinophilia, although common, is not present in all dogs.

Figure 215-17 Thoracic radiographs (lateral [**A**], ventrodorsal [**B**]) of a dog with eosinophilic broncho-pneumopathy. Note the pronounced interstitial and peribronchiolar markings.



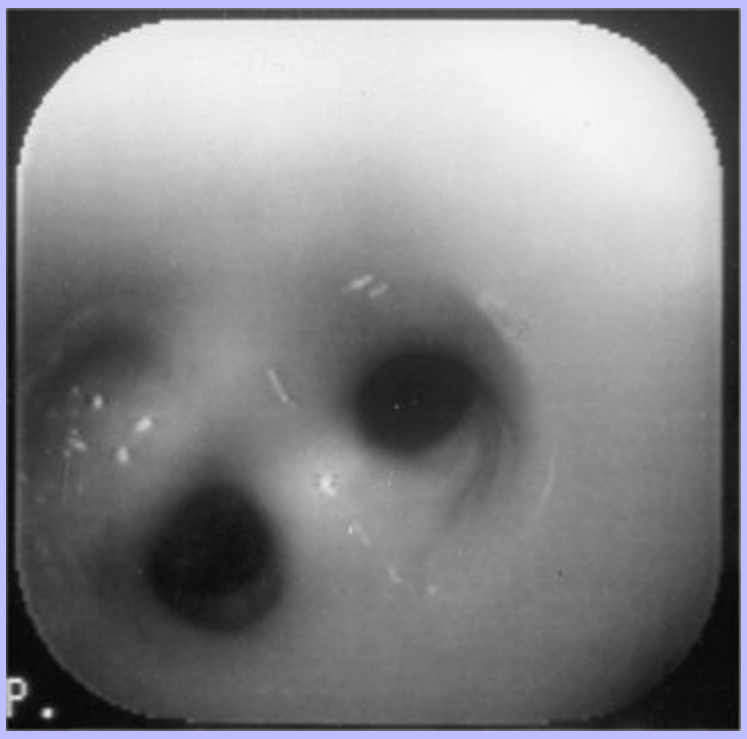
The diagnosis of EB is established by ruling out other causes of eosinophilic parenchymal disease such as respiratory or migrating parasites, bacterial or fungal respiratory infections, heartworm, and neoplasia. Thus fecal floats or Baermann examinations, heartworm testing, culture of respiratory washes or lavages, and bronchoscopic and cytologic examination of the respiratory tract all have a role in the diagnostic approach to EB. Bronchoscopic examination often shows evidence of green to green-yellow mucus adhered to airway walls or obstructing small airways (Figure 215-18). Airway mucosa may be thick to polypoid in appearance, and there may be airway collapse. Cytologic examination of material retrieved by transtracheal wash, bronchoalveolar lavage, or mucosal brushing typically reveals large numbers of eosinophils, but neutrophils and macrophages are also common inflammatory cells. Most dogs will have negative cultures for bacteria, but the role of bacteria in the disease in culture-positive dogs is not well defined.

1257

Administration of glucocorticoids at immunosuppressive dosages is the mainstay of therapy for EB, with treatment lasting weeks to months in most dogs. Many dogs can be maintained on lower doses once the inflammation is controlled, and many can also become steroid-independent. Allergy testing and hyposensitization have been attempted with limited success in reported dogs[68] but could still be a consideration to help lower glucocorticoid doses. The prognosis is generally good with adequate therapy given for appropriate lengths of time.

1258

Figure 215-18 Bronchoscopic image obtained during examination of the dog in Figure 215-17 showing airways partially occluded with eosinophilic exudate.



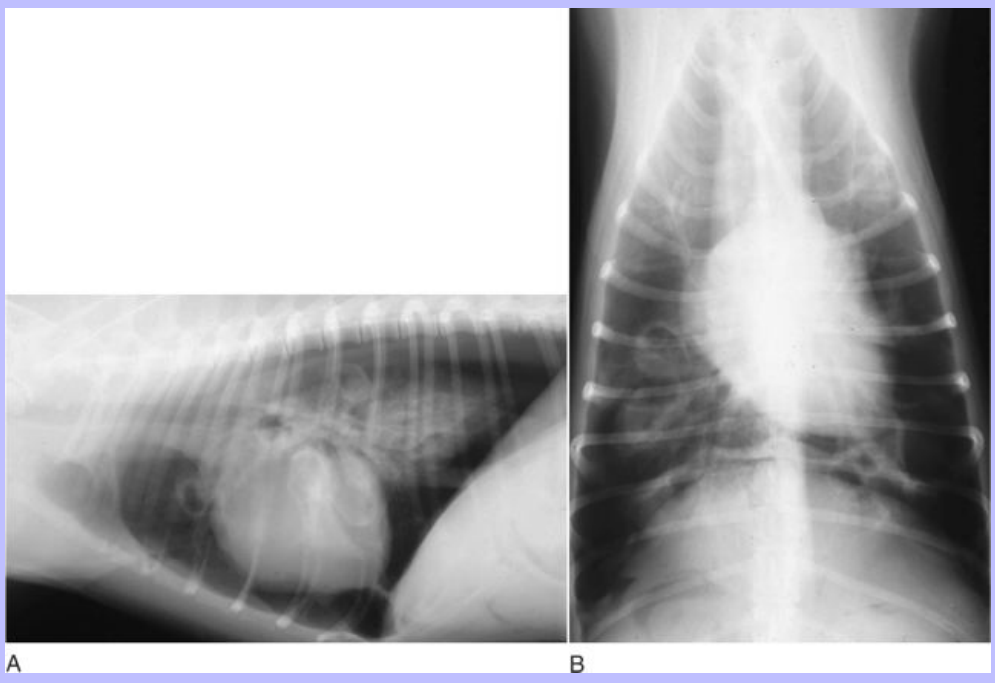
Eosinophilic granulomatosus, primarily a disease of dogs, is characterized by parenchymal infiltration with eosinophils. Unlike EB, the infiltrates of eosinophilic granulomatosis have a tendency to form distinct nodules or mass-like lesions, and the radiographic appearance is thus similar to that seen in patients with systemic fungal infections or pulmonary neoplasia (see above). Clinical signs include dyspnea and cough most commonly; affected patients may also exhibit anorexia, lethargy, and weight loss. Physical examination abnormalities can include abnormal lung sounds and fever. There are no pathognomonic laboratory features, and like EB, eosinophilia is often present, but can be absent in affected dogs. Thoracic radiographic abnormalities include pulmonary nodules of various sizes and numbers, hilar lymph node enlargement, and mixes of other patterns.[69] Some, but not all dogs with EB, will have evidence of heartworm infection.[70]

215.7.1 Vasculitides

Inflammatory vascular diseases of the lung are uncommon in dogs and cats. Reported cases have been associated with lymphoid granulomatosis and systemic-lupus erythematosis. Some patients have presumed pulmonary vasculitis for which a cause is not discovered, but which respond clinically to administration of immunosuppressive doses of glucocorticoids.[64] Clinical features of affected animals have been coughing, interstitial patterns on thoracic radiographs, and granulomatous inflammation on respiratory washes. Other

differentials for such patients include infectious or parasitic diseases that can have a vascular component (Rocky Mountain Spotted fever, FIP, heartworm), systemic fungal infections and neoplasia. Vasculitis has also been incriminated, though not proven, as a cause of thoracic radiograph abnormalities in dogs with leptosporosis.[71] Diagnosis is made by exclusion of other causes of clinical signs and radiographic lesions and by histopathology.

Figure 215-19 Thoracic radiographs (lateral [**A**], ventrodorsal [**B**]) of a dog with pneumothorax likely caused by rupture of a bulla. Multiple bullae remain evident in these projections. This dog had *P. kellicotti* infection.



215.7.2 Cystic-Bullous Lung Disease

Cystic-bullous lung disease is characterized by circumscribed regions of air or fluid occurring in the lung parenchyma. These lesions form as a result of cysts, bullae, or pneumatoceles. Cysts are fluid or air-filled lesions surrounded by respiratory epithelium and may be congenital or acquired.[72,73] Bullae are large areas of air accumulation formed by the loss of alveolar walls.[72,74,75] Pneumatoceles result from air entry into a necrotic lesion such as an abscess, granuloma, or tumor.

Bullae may occur as a result of emphysema (bullous emphysema), inflammation, trauma, or appear idiopathically. Emphysema results from enlargement and destruction of bronchial and alveolar walls due to obstructive pulmonary disease, such as some forms of chronic bronchitis.[76] The loss of radial traction on airway walls provided by alveoli contributes to airway collapse; alveoli may fill with air during inspiration, but negative intrathoracic pressures generated during expiration impair alveolar empyting from airway

collapse. Collagen defects may predispose some animals to the formation of these lesions.[76] *Paragonimus kellicotti* (the lung fluke) can cause bullae and granuloma/pneumatocele formation in dogs and cats (see above).[77] Any of the cystic or bullous lesions may rupture creating a pneumothorax (Figure 215-19). Depending upon the number and severity of lesions, large amounts of functional lung parenchyma may be lost. Large lesions may also compress airways.

1258

1259

215.7.2.1 Presentation

Symptoms and clinical complaints may relate to the primary disease processes such as chronic bronchitis or traumatic insult. Acute respiratory distress and tachypnea can occur when cysts or bullae rupture, which creates a pneumothorax. Occasionally, cystic-bullous lung disease is an incidental finding on thoracic radiographs in an animal with no clinical signs of respiratory disease.

215.7.2.2 Diagnostic Evaluation

Thoracic radiographs may reveal solitary nodules or the margins of cavitary lesions in the peripheral lung regions. Initially, these lesions may be obscured by soft tissue opacity related to primary disease processes, or by pneumothorax causing collapse of the lung tissue. Pneumothorax is commonly identified if a cavitary lesion has ruptured. Unfortunately, bullous emphysema is rarely as readily apparent per thoracic radiography as it often is during exploratory thoracotomy. Cytology from any specimens obtained via thoracocentesis (for fluid or air) may be helpful as *Paragonimus* ova might be found. Aspiration of a bullous lesion is not recommended due to the risk of inducing pneumothorax. Thoracotomy, excision, and histopathology can be required for definitive diagnosis and may also provide therapeutic benefits.

215.7.2.3 Treatment and Prognosis

Identification and treatment of acute pneumothorax is crucial (see Chapter 217). Surgical exploration and removal of cavitary lesions may be warranted in patients in which leakage of air into the pleural cavity persists in the face of conservative management (thoracocentesis or thoracostomy tubes), or for patients with recurrent episodes of pneumothorax. Removal of localized lesions carries the best long-term prognosis. Bullous emphysematous disease is difficult to correct surgically, as the bulla are numerous and the disorder is typically progressive. Pleurodesis may be considered to reduce episodes of pneumothorax.[75,76] Even though recurrence of lesions is common, survival post-surgery of greater than two years is reported.[76] When identified, successful treatment of underlying diseases, such as chronic bronchial disease or lung flukes, carries the greatest likelihood of resolution. Thoracic radiographs should be monitored frequently for the recurrence of bulla or cysts. If bullae are found radiographically, treatment is generally not advised unless the animal becomes symptomatic, for example develops pneumothorax.

215.8 TRAUMATIC LUNG DISEASE

215.8.1 Pulmonary Contusions

Pulmonary contusions are hemorrhages into the pulmonary parenchyma, most often caused by blunt thoracic trauma. Pulmonary contusions occur frequently in animals struck by motorized vehicles. Pulmonary hemorrhage can occur even when external thoracic damage is not detected. Hemorrhage occurs from traumatic

rupture of parenchymal vessels with bleeding into the interstitium and alveoli in the region of the insult. Flooding of large regions of alveoli with blood impairs normal gas exchange and may result in clinical signs.

215.8.1.1 Presentation

Acute tachypnea and respiratory distress may be noted with severe contusions. Tachypnea may also be the result of pain, pneumothorax, or cardiovascular shock, which are common in acute trauma patients. Crackles may be ausculted over the contused area. Decreased lung sounds are suggestive of lung consolidation or pleural space disease such as effusion or diaphragmatic herniation. Some patients have minimal clinical symptoms if only mild hemorrhage has occurred.

215.8.1.2 Diagnostic Evaluation

History and physical examination abnormalities, such as fractures or abrasions, may suggest a traumatic episode. Thoracic radiographs typically reveal regional, irregular patches of mixed interstitial-alveolar densities. However, radiographic changes may be delayed for up to 24 hours following trauma. Pneumothorax, lung consolidation, or rib fractures can sometimes be identified on thoracic radiographs.[78] Contra-coup radiographic signs may occur as a result of trauma to the opposite side of thoracic wall. The lung is violently moved across the thorax, injuring the lung opposite to the stricken side. Arterial blood gas results will often show hypoxemia, which may be worsened by hypoventilation if there are injuries to the thoracic bellows (ribs, intercostal muscles, diaphragm). Traumatic myocarditis is often concurrently found in thoracic trauma cases.[79] The ECG may reveal occasional to very frequent ventricular premature contractions or sustained ventricular tachycardia.

215.8.1.3 Treatment

When indicated by clinical signs or results of arterial blood gas analysis, oxygen supplementation can be provided with nasal catheters, face mask, oxygen cage, or other strategies. Ventilatory support may be needed if hypoventilation contributes to hypoxemia. Specific treatment for the contusions is not usually necessary. Treatment for the other trauma-related problems, for example, blood loss or circulatory shock, is often more critical. Antibiotics are recommended for patients with penetrating chest wounds but not for rou-tine prophylaxis of animals with contusions only.[80] Serial thoracic radiographs should be evaluated for the resolution of abnormalities.

215.8.1.4 Prognosis

Prognosis is excellent for recovery from pulmonary contusions, provided that other injuries sustained are stabilized and fluid therapy is monitored carefully. Improvement is usually noted within 24 to 48 hours. Secondary complications such as abscesses, lung consolidation, or the formation of cavitary lesions may occur but are unusual.

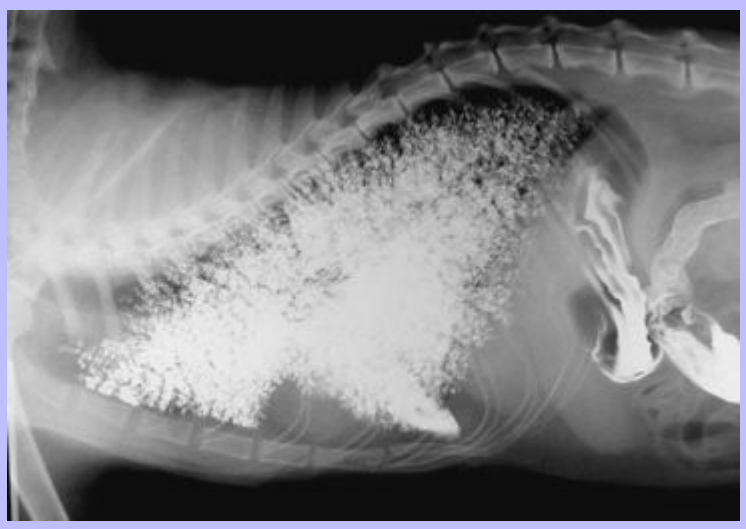
215.8.2 Aspiration Pneumonia

Inhalation of fluid or gastric contents, and bacteria from the oropharynx often results in profound pulmonary inflammation. Aspiration pneumonia can present as an acute fulminant illness, or a chronic and insidious process. The materials usually aspirated are acidic stomach contents and food.

Normal laryngeal and pharyngeal function typically prevent aspiration; however, certain diseases may alter normal laryngeal-pharyngeal function and predispose to aspiration events. Local or systemic neuromuscular disease, irritation and inflammation of the oropharynx secondary to chronic reflux or regurgita-tion (i.e., megaesophagus, esophageal obstruction, esophagitis, chronic vomiting), and anesthesia or depressed mental states resulting in prolonged recumbancy and reflux, are common causes of aspiration pneumonia.[78,81] Impaired oropharyngeal function and secondary aspiration has also been associated with brachycephalic airway conformation.[78,81] Aspiration pneumonia is a frequent complication of surgery for repair of laryngeal paralysis.[82] Accidental introduction of medications, food or contrast agents into the trachea, or lack of patient cooperation during administration of such products, can also result in aspiration pneumonia (Figure 215-20). Administration of mineral oil or similar agents by owners to prevent hair balls in cats is a particularly dangerous cause of inhalation pneumonia.

The severity of lung injury is related to various factors such as the volume of the aspirate, the pH of the aspirate (acidic stomach contents are especially damaging), and toxicity related to any particulate matter. 1259
Aspirated material may cause several reactions. Obstruction and collapse of alveoli, pulmonary hemorrhage and edema, influx of inflammatory cells, necrosis of airway epithelial cells, and reactive bronchoconstriction are common sequels to aspiration. Infection frequently develops due to aspiration of oropharyngeal bacteria or impairment of pulmonary defense mechanisms from lung injury (see Bacterial Pneumonia).[78,81] 1260

Figure 215-20 Lateral thoracic radiograph of a cat with severe barium aspiration.



215.8.2.1 Presentation

Patients are usually evaluated for an acute onset of respiratory distress, tachypnea, and cough, although some animals will die acutely from airway obstruction. There may be a sudden onset of coughing prior to respiratory distress. Some patients are evaluated for chronic, progressive respiratory signs. Systemic signs such as fever, inappetence, lethargy, and shock are common. Inspiratory and expiratory crackles and

wheezes are usually ausculted in the cranioventral lung lobes. Cats are especially prone to wheezes from bronchospasm secondary to airway inflammation.

215.8.2.2 Diagnostic Evaluation

A history of chronic vomiting, regurgitation, or medication administration that precedes the development of respiratory signs allows a presumptive diagnosis. Thoracic radiographs may support the diagnosis. Pulmonary opacities may be diffuse or focal, interstitial to alveolar. Increased alveolar opacities and consolidated regions are more common in the cranioventral and middle lung lobes (dependent areas) but can occur in any lung lobe, depending on the nature of the material aspirated and the position of the patient during the aspiration event. Nodular opacities may be noted in chronic cases or cases in which large solid particles have been aspirated. A miliary nodular pattern may be found in animals that have aspirated mineral oil mimicking neoplastic, fungal or parasitic disease. Depending on the material aspirated, evidence of aspiration may be inapparent initially on thoracic radiographs, but then pulmonary opacities develop over the ensuing 24 hours.

Respiratory secretions obtained by bronchoalveolar lavage or transtracheal wash are warranted in most patients and should be evaluated for cytology and submitted for microbial culture and sensitivity. Transthoracic aspirates may also be helpful, particularly when consolidated lesions are noted on thoracic radiographs. Cytology is typically characterized by a predominance of neutrophils and some hemorrhage. Bacteria may or may not be present. Particulate matter (e.g., food) may found in the wash materials. Bronchoscopy may be performed to examine airways and remove large pieces of foreign material.

A complete blood count often reveals an inflammatory leukogram. Blood gas measurements and electrolytes may be helpful in emergency management. Once the patient is stabilized, investigation for an underlying cause of aspiration should be sought.

215.8.2.3 Treatment

Patients presenting in respiratory distress will need immediate measures to improve pulmonary function. Oxygen may be administered via nasal cannula, face mask, or oxygen cage.

Intubation and positive pressure ventilation may be necessary to overcome severely increased lung compliance, which increases the work of respiration. Fluid therapy is often indicated to treat a shock-like state. Vascular volume, blood pressure, and pulmonary function should be carefully monitored. Respiratory compromise, due to exacerbation of pulmonary edema from increased pulmonary capillary permeability induced by inflammation in response to aspiration, may be worsened by aggressive fluid therapy. Bronchodilators may be beneficial in the acute management of patients with bronchospasm. Methylxanthines such as theophylline may be helpful to relax bronchioles, enhance mucociliary clearance, and decrease respiratory muscle fatigue.[83]

The use of corticosteroids in the management of aspiration pneumonia is controversial. Corticosteroids may be indicated in the deteriorating patient for treatment of shock. Corticosteriods decrease the inflammatory response and stabilize cell membranes but can also inhibit normal lung protective mechanisms. If given, routine use should not be continued for longer than 24 to 48 hours. There is no evidence in people to support prophylactic use of antibiotics in patients with aspiration pneumonia as aspirated gastric contents are typically sterile.[84] Although secondary bacterial infection is common, the development of resistant infections may be encouraged if antibiotics are used initially.[84] The benefits of prophylactic antibiotics

must be weighed against their potential risks. Antibiotic therapy ideally should be administered according to cytology or culture results obtained from wash or aspirate specimens. Attentive monitoring and serial radiographic, cytologic, and microbiologic analysis may be needed for some patients, particularly those with protracted illness or that exhibit clinical deterioration.

Measures should be taken to prevent further aspiration. Endotracheal intubation may be necessary to protect the airway if the patient is anesthetized or has an altered state of consciousness. Feeding tubes may need to be repositioned, or nasogastric or gastric tubes may need to be placed to facilitate removal of large volumes of gastrointestinal secretions. Institution of "upright" feeding for patients with esophageal or pharyngeal disorders may be beneficial, as may feeding through gastrostomy tubes.

215.8.2.4 Prognosis

Prognosis can vary widely depending upon the condition of the animal, the severity of lung injury, and the underlying cause of aspiration. Animals that aspirate a small amount of barium or mineral oil may have an excellent prognosis. Long-term complications may occur with aspiration pneumonia such as lung abscess, granuloma formation, or consolidation of lobes. Lung lobectomy may be indicated in these cases to eliminate sources of persistent or recurrent infections.

215.8.3 Near Drowning

Near drowning occurs with aspiration of water during submersion. Normal reflexes and input from higher neurologic centers cause cessation of ventilation under water; however, increased levels of carbon dioxide in the bloodstream eventually stimulate breathing efforts. Typically, only small volumes of water are typically aspirated resulting in severe pulmonary damage. Many mechanisms contribute to lung injury.[85,86] Aspiration of water dilutes surfactant, collapses alveoli, decreases lung compliance, and severely impairs oxygenation. Near drowning from inhalation of salt water exacerbates fluid flux into alveoli due to the hypertonicity of the solution.[85,86]

1260

1261

Laryngospasm occurs in about 10% of cases and prevents aspiration of water and "dry drowning" results.[85,86] Aspiration of bacteria or chemicals in the water or vomitus, may contribute further to pulmonary parenchymal injury and predispose to secondary pneumonia. Severe hypoxia may cause profound neurologic disturbances from cerebral edema or herniation. ARDS (see discussion below) can occur up to 24 to 48 hours after a near drowning episode.[85–87]

215.8.3.1 Presentation

Patients are classically presented following a rescue. A loss of consciousness and severe respiratory distress or arrest is typical. Cardiovascular shock and hypothermia are commonly noted and require prompt attention. Auscultation may reveal inspiratory and expiratory crackles and wheezes, or exceptionally quiet lung sounds may be noted. Neurologic abnormalities and altered mentation may signify cerebral edema.

215.8.3.2 Diagnostic Evaluation

Diagnosis is based on the history of rescuing the patient from the water. Thoracic radiographs reveal a generalized, mixed interstitial-alveolar pulmonary pattern. Radiographic changes may not be apparent until 24 to 48 hours after the near-drowning episode. The presence of radio-opaque material in the airways (sand

bronchograms) is a poor prognostic indicator.[86] Bronchial wash and cultures are indicated if there is suspicion of secondary bacterial infection.

215.8.3.3 Treatment

Ventilation is provided as soon as possible. CPR or mouth-to-muzzle resuscitation may be required during initial rescue. The Heimlich maneuver is not recommended due to the possibility of aspiration of stomach contents.[87] As soon as available, oxygen may be provided with a nasal cannula, face mask, or oxygen cage. Positive pressure ventilation is often required due to the profound decrease in lung compliance. If neurologic symptoms are present after metabolic stabi-lization, treatment for cerebral edema may be warranted (see Chapter 191). Animals that have been resuscitated should be observed in the hospital for up to 24 hours for the development of ARDS. Respiratory function and metabolic and neurologic status are followed closely.

215.8.3.4 Prognosis and Prevention

A poor prognosis is associated with coma, blood pH less than 7.0, the need for a CPR episode, and mechanical ventilation.[87] Educating clients as to the risks of allowing young dogs near the water is especially important; one study revealed that half the dogs presented for near drowning were 4 months old or younger.[87] Cold water and rapid currents are particularly exhausting.

215.8.4 Smoke Inhalation

Smoke inhalation causes direct injury to the airways and lung tissue due to heat, particulate matter, and combustion gases. Household fires are the most common cause of smoke inhalation injury in dogs and cats. A compounding factor in the pathogenesis of smoke inhalation is the secondary injury that occurs from the release of pulmonary inflammatory mediators.

In the acute phase (0 to 36 hours) of smoke inhalation, respiratory signs are caused by tissue injury, increased capillary permeability, mucosal edema, and tissue hypoxia. By 2 to 4 days post-injury, tissue edema begins to resolve. During this later phase, there is an increase in mucosal secretions, sloughing of epithelial cells, decreased mucociliary clearance, and secondary bacterial colonization leading to tracheobronchitis and pneumonia.[88] If thermal injury occurs, lesions are usually found rostral to the vocal cords because dry air has low heat carrying capacity. Carbon particulate matter can attach to airway surfaces, which results in impaired mucociliary function and contributes to bronchospasm. Numerous compounds of the gaseous by-products of combustion, when inhaled, are responsible for chemical injury, which contributes more to lung injury than does thermal injury.[88,89] Carbon monoxide inhibits oxygen binding to hemoglobin, reducing oxygen uptake in red blood cells, which results in severe tissue hypoxia. Hydrogen cyanide, hydrogen chloride, and aldehydes are irritants that cause profound airway edema and bronchospasm. In addition, hydrogen cyanide interferes with cellular aerobic metabolism compounding tissue hypoxia. Anaerobic metabolism and the generation of lactate and metabolic acidosis ensues.[90]

215.8.4.1 Presentation

Patients are classically presented following a rescue. Animals may have singed hair, and the presence of soot and smell of smoke on the fur. A loss of consciousness, and severe respiratory distress or arrest is

common. Upper airway stridor may be heard in patients with laryngeal edema. Ocular and nasal discharge, and corneal edema are often present. Mucous membranes may be bright red due to carboxyhemoglobin, or cyanotic. Some patients have minimal signs on presentation but may develop severe respiratory compromise 24 to 36 hours later due to laryngeal edema, release of inflammatory mediators, decreased mucociliary function, infection or ARDS.[90]

215.8.4.2 Diagnostic Evaluation

Thoracic radiographs may be normal initially but can progress to a patchy interstitial pattern and alveolar pattern. These changes correlate with the development of pulmonary edema and pneumonia. Likewise, arterial blood gas analysis may be normal in the acute phase of injury, but PaO_2 levels will drop as pulmonary injury progresses. PaO_2 must be interpreted cautiously in animals with carbon monoxide poisoning, as PaO_2 is a measure of the amount of oxygen dissolved in plasma. In patients with carbon monoxide poisoning, PaO_2 may be normal, but the patient may still manifest severe arterial hypoxemia because carbon monoxide interferes with oxygen saturation of hemoglogin decreasing the total carrying capacity of oxygen. It is important to remember that carboxyhemoglobin is not distinguished from oxyhemoglobin with pulse oximetry, which could give a falsely high impression of the degree of hemoglobin saturation.

Assessment of carbon monoxide toxicity can be accomplished using a co-oximeter, available at most human hospitals, to measure blood carboxyhemoglobin levels.[90] In the early stages of smoke inhalation, cytology from bronchial washings, and hemograms and biochemical profiles are unremarkable. These tests may become useful in chronically managed cases to screen for secondary bacterial infections and metabolic complications. Cardiac and neurologic status should also be carefully monitored in critical patients.

215.8.4.3 Treatment

As stated earlier, animals that are rescued from fire should be observed for at least 24 to 48 hours for progressive pulmonary injury. Patients that present with severe laryngeal edema and obstruction may require tracheostomies. Oxygen supplementation should begin as soon as possible. Carbon monoxide is eliminated by the lungs and elimination is greatly facilitated by 100% oxygen administration. The half-life of carboxy-hemoglobin is 4 hours in room air and 30 minutes in 100% oxygen. Oxygen should be administered until blood carboxyhemoglobin concentrations are less than 10%.[90] Positive pressure ventilation may be required in critical cases. Airway humidification and physiotherapy (chest coupage) may also be warranted.

1261

1262

Bronchodilators are sometimes used in the management of smoke inhalation. Ideally, antibiotic therapy should be based on documentation of infection by culture and sensitivity testing. Prophylactic therapy is generally not recommended because of predisposition to resistant infections.[90] Corticosteriods may be indicated in cases of acute cardiovascular shock; however, routine administration should be avoided due to their interference with tissue healing and protective mechanisms.

Fluid therapy is often indicated to restore lost circulatory volume and maintain tissue perfusion. Crystalloid or colloid solutions may be necessary to combat shock. If the animal has also suffered surface burns, aggressive fluid therapy will be needed. Fluids are administered with caution to smoke inhalation patients because pulmonary capillary leakage will predispose to pulmonary edema and worsening of respiratory function. Analgesics are indicated particularly if cutaneous burns coexist with smoke inhalation injury.

215.8.4.4 Prognosis

The prognosis ranges from good to grave depending upon the severity of the inhalant injury. In a study of 27 dogs with smoke exposure, 17 out of 17 dogs that had improvement or no change in respiratory signs during the first 24 to 48 hours after exposure were discharged from the hospital.[91] In this same study, dogs with deterioration in signs in the 24-to 48-hour period after hospitalization died or had prolonged stays in the hospital. The prognosis progressively worsens with severe respiratory disease requiring positive-pressure ventilation, the presence of neurologic signs, and cutaneous burns. Infection (pneumonia) and sepsis are common causes of death.

215.9 IDIOPATHIC AND MISCELLANEOUS LUNG DISORDERS

215.9.1 Acute Respiratory Distress Syndrome

Acute respiratory distress syndrome (ARDS) causes acute hypoxemic respiratory failure as a result of lung injury and increased pulmonary capillary permeability. ARDS is not a disease entity by itself, but rather a syndrome that develops secondary to numerous, usually critical, illnesses. Sepsis is the most common cause of ARDS in people, and has been identified as a common cause of ARDS in dogs.[8,92] Other well-described associations include aspiration of acidic substances (e.g., gastric secretions) or inhalation injury, multiple transfusions, shock, pancreatitis, microbial pneumonia, drug reaction or overdose, and major trauma or surgery.[8,92–95]

Although ARDS is a well-described syndrome, particularly in people, the pathogenesis of the syndrome is still poorly understood. Exudation of proteinaceous fluid into the interstitum in the early phase of ARDS occurs as a result of increased capillary permeability from either direct or indirect injury to the alveolar epithelium or pulmonary capillary endothelium.[96] The inflammatory response that accompanies such injuries can involve all lung parenchyma. In the later phases of ARDS (7 to 10 days post insult), increased numbers of inflammatory cells, hyaline membrane formation, and fibrosis with increased dead-space fraction are characteristic.[9,92] Severe hypoxemia that is characteristically refractory to oxygen supplementation is typical due to arteriovenous shunting and ventilation/perfusion irregularities. Pulmonary hypertension occurs as a result of hypoxic vasoconstriction and capillary obstruction from microembolization.[9]

215.9.1.1 Presentation

Most patients present with acute, severe respiratory distress and tachypnea within 24 hours of the precipitating cause, although delays of up to 3 days may occur. Tachycardia and extreme anxiety are commonly noted. Crackles and wheezes, particularly on end-inspiration and throughout expiration, are classically heard in the hilar and dorsocaudal lung fields. Sometimes lung sounds are quieter than normally expected, particularly if the patient is hypovolemic. There may be other physical examination abnormalities, such as fever or evidence of trauma, that reflect underlying causes.

215.9.1.2 Diagnostic Evaluation

ARDS is suspected when the patient demonstrates an onset of respiratory signs hours to days following a precipitating event. Thoracic radiographs usually reveal generalized interstitial or mixed patterns consistent

with noncardiogenic pulmonary edema. Left cardiac and pulmonary venous silhouettes are typically normal unless another (cardiac) disorder is present (Figure 215-21).

Echocardiography is a noninvasive tool that may provide information to help differentiate ARDS from other causes of pulmonary edema. Echocardiography can rule out left atrial and ventricular abnormalities that could be associated with high-pressure (cardiogenic) pulmonary edema, which is a common differential diagnosis. Echocardiographic evidence of acute pulmonary hypertension may support a diagnosis of ARDS. Expected findings include a poorly contracting right ventricle, tricuspid regurgitation (TR), which is often present secondary to acute geometric changes of the right chambers (dilation), and elevations in right ventricular systolic pressures. Tricuspid regurgitation velocities can estimate right ventricular systolic pressure, and thus pulmonary arterial systolic pressure, which is increased in ARDS. Leftward shifting of the interventricular septum is sometimes demonstrated. The main pulmonary artery may appear dilated. Pulmonary capillary wedge pressure, if measured, is low (<18 mm Hg) with ARDS, but elevated with cardiogenic pulmonary edema.

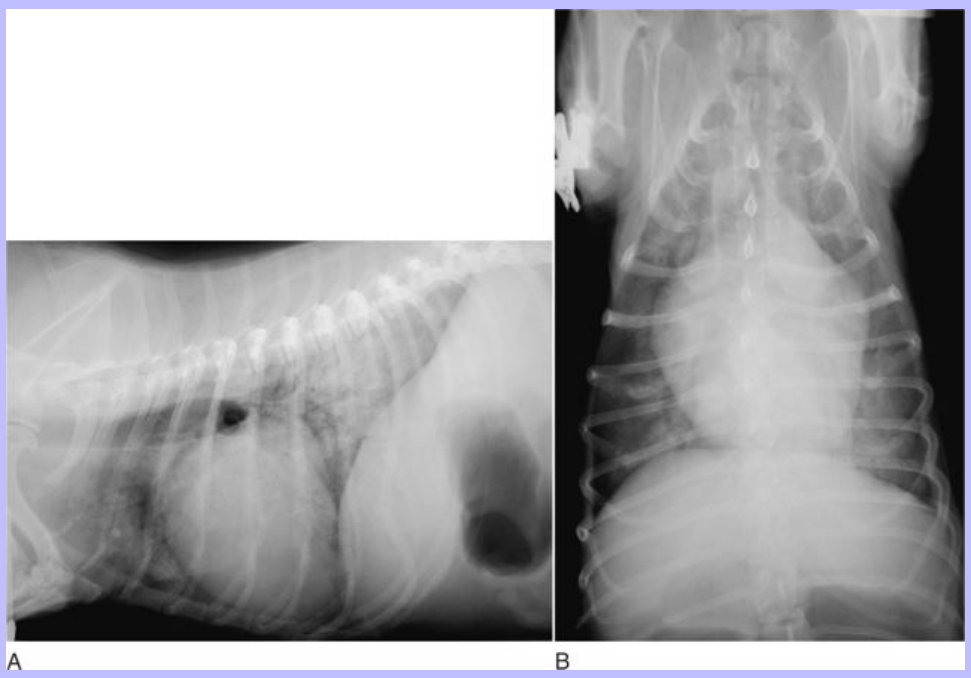
Edema fluid analysis may provide useful information in the early stages of ARDS. Fluid may be suctioned from the airways via tubing passed through an endotracheal tube. The ratio of protein content of the edema fluid (E) to the protein content in plasma (P) in ARDS is 79% to 90%, while the E/P ratio in cardiogenic edema is less than 50%.[97]

215.9.1.3 Treatment

The mainstay of ARDS treatment is addressing the underlying condition if known. Oxygen therapy is essential. Intubation and mechanical ventilation are quite appropriate and often needed for ARDS patients so that positive end-expiratory pressure (PEEP) can be delivered. PEEP can help prevent alveolar collapse in ARDS patient and relieves the patient of the work of respiration in the face of poorly compliant lungs. It also diminishes the need for high inspired oxygen concentrations to maintain acceptable levels of oxygen saturation, thus lowering the risk of oxygen toxicity.

A low-normal circulatory volume should be maintained with cautious fluid therapy. The smallest volume of fluids that maintains cardiac output and arterial blood pressure should be administered. Overzealous fluid therapy may worsen pulmonary edema and hypoxemia. A Swan-Ganz or other hemodynamic measuring catheter may be used to monitor cardiac output, and pulmonary capillary wedge and right heart pressures. Central venous pressures can be misleading as an estimate of volume status if significant pulmonary hypertension exists. Serial measures of arterial blood pressure, packed cell volume, total protein, electrolytes, BUN, and creatinine may be useful to monitor hydration status. Nutritional support and good nursing care, especially of recumbent animals, would also be crucial to successful therapy particularly for patients surviving the initial period of ARDS. Because of the demands these patients place on clinical staff, referral of these patients to tertiary care centers would be appropriate.

Figure 215-21 A left lateral [**A**] and dorsoventral [**B**] radiograph of a 10-year-old dachshund diagnosed with ARDS secondary to trauma. Note the severe, generalized interstitial opacities. This dog had a history of mitral valve endocardiosis, thus left-sided cardiomegaly is seen here. The pulmonary veins are not enlarged as would be expected with left-sided CHF and airway fluid aspiration revealed an E/P ratio of 86% consistent with ARDS. ARDS was confirmed on necropsy.



1262

1263

Corticosteriods are of unconfirmed benefit in ARDS patients. Diuretics may be helpful in the initial phase, but are of no benefit in the latter phase of ARDS (more than 5 to 7 days).[9,95] Careful attention to hydration status is required with diuretic therapy. Administration of nitric oxide as an endogenous mediator of vascular smooth muscle relaxation is under investigation.[97] Improvements in parameters of serial arterial blood gas analysis and thoracic radiographs may be helpful in the assessment of improving status.

215.9.1.4 Prognosis

ARDS patients typically progress rapidly and are notoriously fragile patients. Death can result from respiratory failure, or complications of ARDS and the underlying disease. The prognosis with severe or chronic ARDS (>3 days) is generally poor.

215.9.2 Lung Lobe Torsion

Lung lobe torsion is the rotation of a lung lobe around its long axis. The exact mechanism that results in increased mobility of a lung lobe is not known. Lung lobe torsion may be idiopathic, particularly in large, deep-chested breeds of dogs; however, toy breeds are sometimes affected.[44–46] Afghan hounds were overrepresented in one study.[98] Torsion can also be associated with several initiating events. Pleural effusion of various causes, thoracic surgery and manipulation of tissues, or trauma causing sudden lung lobe compression may predispose to rotation of a lung lobe.[72,99]

Rotation of the lung lobe at the hilus strangles the bronchus and vascular pedicle, which obstructs ventilation and venous drainage. Because the artery usually remains partially patent, progressive lobar engorgement with blood occurs and the lobe becomes an expansile mass. Increased hydrostatic pressure (venous congestion) causes exudation of bloody fluid into the pleural space. Pleural effusion may further impair tidal volume and respiratory performance. Mild blood loss anemia can be observed. Necrosis, fibrosis, and shrinkage of the lung lobe may eventually occur.

215.9.2.1 Presentation

Clinical signs of pre-existing pulmonary or pleural space disease may be present in the history. Clinical signs caused by the torsion are usually acute and progressive. Respiratory distress, tachypnea and cough, with or without hemoptysis, are common presenting complaints. Other systemic signs, such as hypotension, collapse, or fever and lethargy may be present.

215.9.2.2 Diagnostic Evaluation

Signalment may provide helpful clues, as deep-chested breeds such as sight-hounds appear to have an increased incidence of idiopathic lung lobe torsion. Physical examination abnormalities are compatible with pleural effusion (see Chapters 1, 54, 57). The appearance of thoracic radiographs may vary depending upon the stage of the disease. Pleural effusion usually obscures parenchymal detail. The pleural effusion may be removed and the thorax reradiographed, at which time lobar consolidation is typically noted. Air bronchograms may occur early, but air is reabsorbed with prolonged collapse. Rounding of the lung lobe edges is noted as the lung becomes engorged. The bronchus may lie in an improper anatomic plane. Pleural fluid analysis is consistent with a hemorrhagic modified transudate (see Chapter 57). Underlying conditions may be suggested by other laboratory abnormalities, for example hypoproteinemia associated with protein-losing enteropathy resulting in pleural effusion. Bronchoscopy is sometimes needed to verify rotation of the bronchus. Surgical exploration may be necessary to confirm the diagnosis in some cases. Histopathologic examination of the excised lung lobe should be performed to rule out underlying primary parenchymal disease such as pneumonia or neoplasia.

1263 1264

215.9.2.3 Treatment

Immediate improvement in tissue oxygenation is usually needed, thus supplemental oxygen is often indicated. Removal of excessive pleural fluid will enhance lung expansion and respiratory performance. Thoracostomy tubes may be warranted in some cases. Circulatory function can be supported with IV fluid therapy as needed to maintain hydration and systemic blood pressure. Surgical resection of the affected lobe is typically curative.

215.9.2.4 Prognosis

Prognosis is typically good with lobectomy, but underlying conditions may require additional therapy and monitoring. It has been suggested that the long-term prognosis may be poor in dogs that develop lung lobe torsions in association with chylothorax.[44]

215.9.3 Pulmonary Mineralization

Mineralization of the airways or pleura can occur in aged dogs of any breed and is often an incidental finding. Chondrodystrophic dogs may demonstrate airway mineralization at an earlier age.[47] Nodular pulmonary parenchymal mineralization of unknown etiology is occasionally misinterpreted as metastatic neoplasia. The nodules may be few or numerous and diffusely distributed (Figure 215-22). They are typically discrete and nonprogressive and are not associated with lung pathology.

Mineral opacities can also occur in areas of intense inflammation, or in necrotic lung lesions. The opacities usually occur in the center of mass lesions resulting from fungal infections, parasites, tuberculosis, or neoplastic disease.[100] Necrotic lymph nodes can also undergo mineralization and mineral-like opacities can be seen in regional lymph nodes from prior barium aspiration. Occasionally, systemic disease such as renal secondary hyperparathyroidism and hyperadrenocorticism can cause mineral deposition in lungs and other organs.

Figure 215-22 A right lateral radiograph of a dog with pulmonary mineralization. Note the multiple discrete opaque nodules, especially prominent over the cardiac silhouette.

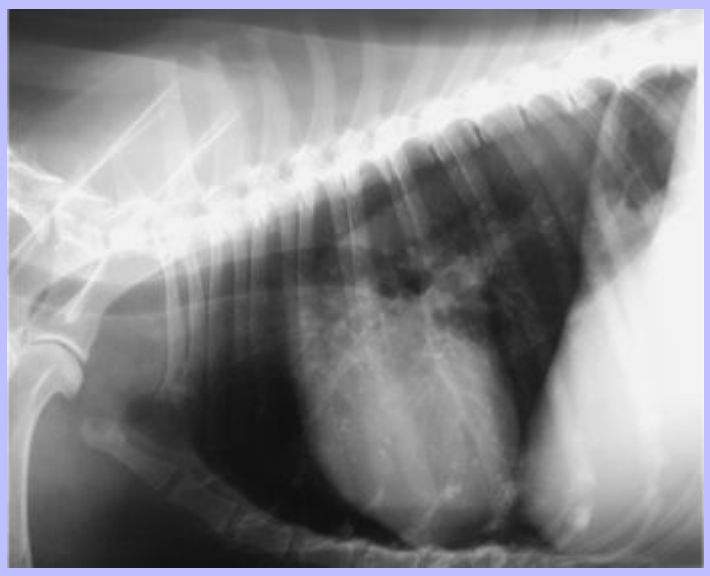


Figure 215-23 Left lateral [**A**] and dorsoventral [**B**] radiographs are shown of a 9-year-old West Highland White Terrier with idiopathic pulmonary fibrosis. Note the generalized bronchointerstitial pattern, especially prominent in the caudal lung regions. There is radiographic evidence of right heart enlargement and an enlarged caudal vena cava consistent with pulmonary hypertension.

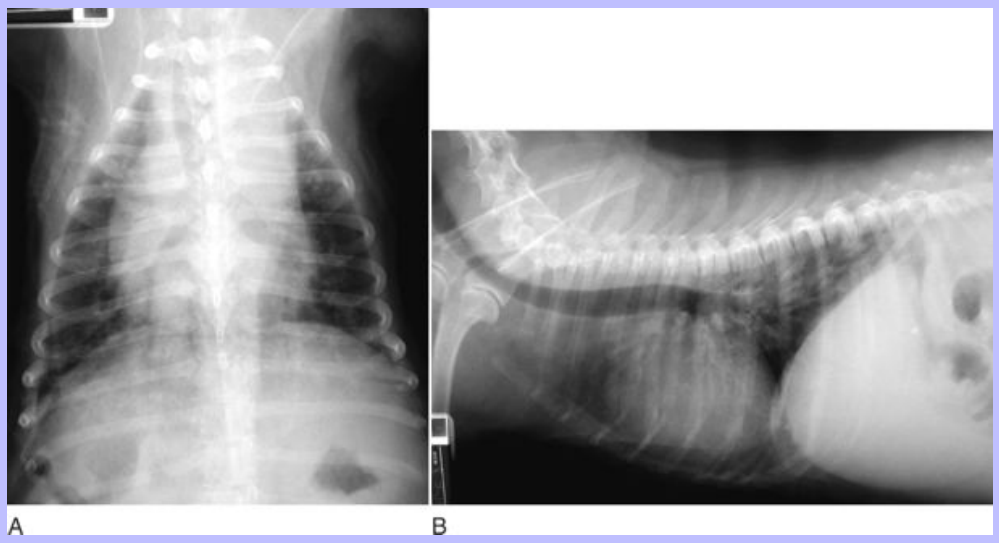


215.9.4 Pulmonary Fibrosis

Interstitial lung diseases are poorly characterized in veterinary patients. Pathologically, interstitial fibrosis is characterized by alveolar septal fibrosis, interstitial fibrosis, epithelial hyperplasia, and focal calcification. Inflammation (lymphocytes and macrophages) is a variable finding.[101–103] In humans, these findings can be the result of numerous types of pulmonary injury; however, in over 50% of cases, no cause is identified.[101,102] The term *idiopathic pulmonary fibrosis* is often used to describe this disease in animals.

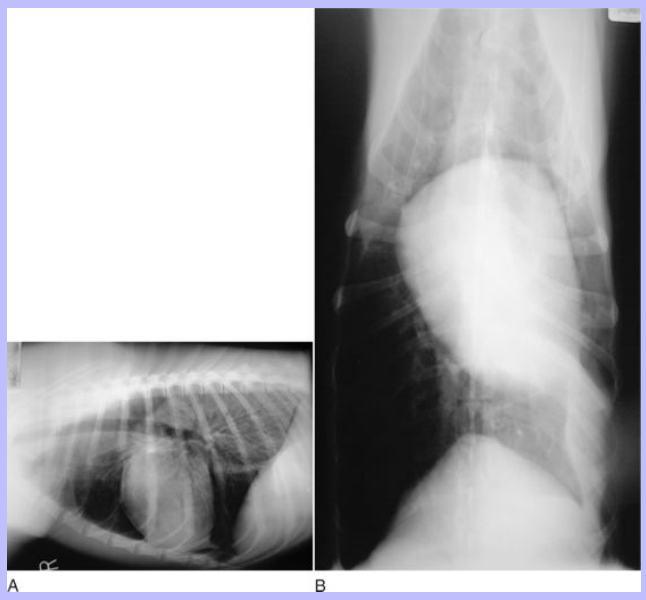
Idiopathic pulmonary fibrosis was first described in West Highland white terriers, but recent reports have suggested that other breeds of dogs may be affected, particularly Staffordshire bull terriers.[104–107] A form of idiopathic pulmonary fibrosis has now also been described in cats.[108] Dogs usually present with chronic and progressive pulmonary signs such as dyspnea and exercise intolerance. Cough is a variable finding.[104–107] Radiographically, there is a diffuse interstitial lung pattern with varying degrees of bronchial involvement (Figure 215-23).[104,106] Echocardiographic findings are usually indicative of moderate to severe pulmonary hypertension. A lung biopsy is generally necessary to confirm the diagnosis. The principal therapy for idiopathic pulmonary fibrosis is corticosteroids. Bronchodilators and azathioprine may be of benefit in some cases.[104,106] The prognosis for pulmonary fibrosis varies but is generally poor owing to the advanced nature of the disease at the time of diagnosis.

215.9.5 Obesity

Specific abnormalities of pulmonary function as a result of obesity have not been well characterized in veterinary patients. Increased oxygen consumption and myocardial work are noted in people with excess body mass with light activity. In humans, Pickwickian syndrome refers to a specific condition of obesity, lethargy, hypoventilation, and erythrocytosis. The syndrome is classically defined as elevations in $PaCO_2$ in the absence of pulmonary disease in patients who are extremely obese. A central neurological condition may be partially responsible for Pickwickian syndrome.[109] In addition, obesity is thought to worsen obstructive sleep apnea syndrome noted in humans and in English Bulldogs.[110, 111]

Excessive intrathoracic and intra-abdominal fat may interfere with lung function in numerous ways. Obese animals may have decreased thoracic wall compliance and thus have more difficulty expanding the thoracic cavity and lungs during inspiration. Hypoxia can result from decreased expansion and hypoventilation of peripheral lung regions.[109] Increased intrathoracic fat has often been suspected to worsen airway collapse in veterinary patients with redundant dorsal tracheal membrane and associated clinical signs. Even though specific obesity-related pulmonary dysfunction has not been reported in dogs and cats, weight reduction in animals with chronic airway or pulmonary disease can dramatically affect clinical signs.

Figure 215-24 A right lateral [**A**] and ventrodorsal [**B**] radiograph of a greyhound revealing consolidation of the left caudal lung lobe. Note the wedge-shaped soft tissue opacity in the left caudal thorax on the VD view and the consolidated caudal lung opacity with air bronchograms on the lateral view. Also notice the enlarged, spherical hilar lymph node dorsal to the heart and airways on the lateral projection. This dog had coccidiomyocosis.



215.9.6 Lobar Consolidation

Lung lobe consolidation can occur as a result of many pulmonary diseases. Lobar consolidation is not a disease entity itself but may occur secondary to processes such as aspiration pneumonia, granulomatous disease, contusions, lung lobe torsion, and neoplasia.[112] Fluid, exudates, or cellular infiltrates fill the alveoli and airways, which creates a wedge-shaped, homogenous soft tissue opacity on radiographs. In the early stages, a regionally diffuse interstitial pattern or an alveolar pattern may be recognized. As the disease process spreads, lesions coalesce, and the entire lung lobe becomes involved. Radiographically, lobar consolidation appears as a soft tissue opacity with visible lung lobe margins (Figure 215-24).[112] Ventilation-perfusion abnormalities occur as blood flow persists through unventilated lung tissue. If treatment of the primary disorder does not resolve the consolidation, surgical excision of the lung lobe may be necessary.

215.9.7 Pulmonary Alveolar Proteinosis

Pulmonary alveolar proteinosis (PAP) is a rare disorder of dogs characterized by the accumulation of protein-and lipid-rich fluid in alveoli.[113] Clinical signs described include chronic exercise intolerance and cough. Thoracic radiographs are characterized by increased interstitial markings. Tracheal or alveolar wash samples contain few cells and moderate amounts of proteinaceous fluid. Histologic examination of lung biopsies shows distension of alveoli with PAS-positive proteinaceous material, mucus granules, and intra-alveolar cholesterol clefts with only occasional inflammatory cells. Treatment requires intermittent lavage of affected lung lobes with 0.9% saline; clinical resolution of the disease has been documented with such an approach.

1265 1266

215.9.8 Endogenous Lipid Pneumonia

Endogenous lipid pneumonia (EnLP) is an uncommon disease of dogs and cats and is usually secondary to another respiratory or systemic disease process that injures alveolar epithelial cells. In cats, the most common clinical signs are lethargy, anorexia, and weight loss, which could reflect underlying diseases. Common signs referable to the respiratory tract include tachypnea, difficulty breathing, and cough.[114] Thoracic radiographic patterns associated with EnLP include pleural effusion, diffuse interstitial or bronchointerstitial markings, or pulmonary nodules. The cytologic features of the disease have not been well characterized. The most common underlying diseases associated with feline EnLP have been obstructive airway disease of various causes, or systemic diseases such as neoplasia, liver, kidney or heart disease, and pancreatitis. The diagnosis is not typically made antemortem, but is usually an incidental finding during necropsy, during which gross subpleural lesions are commonly found. Histologically, EnLP is characterized by alveoli filled with lipid-laden macrophages.

216 CHAPTER • 216 Mediastinal Disease

Lisa E. Moore

David S. Biller

216.1 ANATOMY

The mediastinum is a potential space centrally located between the right and left pleural cavities. The mediastinum is lined on each side by parietal pleura and contains and encloses the thymus, heart, aorta, trachea, esophagus, vagus nerves, lymph nodes, thoracic duct, vena cava, and other vessels and nerves that enter or leave the heart.[1] In the dog and cat, the tissue in the mediastinum is incomplete.[1,2] Therefore most unilateral pleural cavity diseases in the dog and cat ultimately become bilateral. The mediastinum is bordered dorsally by the spine, ventrally by the sternum, caudally by the diaphragm, and cranially by the thoracic inlet. The mediastinum also communicates cranially with facial planes of the neck and caudally with the retroperitoneal space through the aortic hiatus. These communications create pathways for spread of disease between the neck, thorax, and retroperitoneal areas.

Anatomic regions of the mediastinum can be subdivided to facilitate radiographic description of mediastinal disease. The mediastinum can be divided by frontal and transverse planes into five regions: craniodorsal, cranioventral, middle, caudodorsal, and caudoventral.

216.2 HISTORY AND CLINICAL SIGNS

The history and clinical signs will vary depending on the area of the mediastinum involved, the rapidity of onset, and the specific etiology of the disease process. Specific events that should prompt a clinician to consider mediastinal disease include trauma to the head, neck and/or thorax; foreign body ingestion; invasive diagnostic and/or therapeutic procedures that involve the trachea, esophagus, or cervical region. Clinical signs may include dysphagia, regurgitation, dyspnea, cough, and Horner's syndrome. Abnormal findings on physical examination that may indicate mediastinal involvement in the disease process include poor compressibility of the cranial thorax, decreased lung sounds, dyspnea, esophageal or thoracic pain, and edema of the head and/or neck. If mediastinal disease is a component of systemic disease, extrathoracic signs of illness may also be present and include, but are not limited to, peripheral lymphadenopathy, weight loss, and polyuria/polydipsia.

216.3 DIAGNOSTIC EVALUATION

The mediastinum is not easily accessible for clinical evaluation due to its location within the thorax. Noninvasive evaluation is therefore dependent upon the utilization of appropriate imaging techniques. Invasive techniques for evaluation of the mediastinum may then be pursued if necessary.

216.3.1 Survey Radiography

The normal mediastinum is difficult to evaluate radiographically due to the lack of contrasting tissue densities. All mediastinal structures, with the exception of the air-filled trachea, demonstrate soft tissue opacity. This results in border effacement, which causes the structures within the mediastinum to appear confluent and

prevents the structures from being visualized distinctly. The craniodorsal region is often more radiopaque than other areas of the mediastinum because of its greater thickness.

On dorsoventral (DV) and ventrodorsal (VD) projection radiographs, the craniodorsal and caudodorsal regions of the mediastinum appear as midline structures that are normally no more than two times the width of the spine. The craniodorsal region may appear wider in obese animals owing to accumulation of fat within in the mediastinum, but the boundaries remain smooth. The craniodorsal and cranioventral regions of the mediastinum are usually incompletely evaluated on DV or VD radiographs because of their superimposition on the sternum and spine. In young animals, the thymus may be visualized as a triangular, sail-shaped soft tissue dense structure in the cranioventral region along midline.

Survey radiography is the imaging modality of choice for localizing mediastinal disease. Survey radiography is used to assess the size, shape, opacity, and position of the mediastinum. Positional radiographs permit free fluid to move away from the mediastinum and may improve visualization of the mediastinum in animals with pleural effusion. Mediastinal disease can be seen radiographically as an abnormal position of the mediastinum (termed *mediastinal shift*), pneumomediastinum, or increased size and/or opacity of the mediastinum.

Abnormal positioning of the mediastinum is usually indicative of disease that originates in the lungs, bronchi, thoracic wall, or pleura. A mediastinal shift may result from the presence of an intrathoracic mass or from uneven inflation of the lungs associated with unilateral changes in lung volume. A mediastinal shift is identified by a difference in size between the right and left hemithoraces as assessed in a VD or DV view. In addition, lateral displacement of major mediastinal structures, such as the trachea or cardiac silhouette, may be apparent. Diaphragmatic asymmetry may also present with mediastinal shift.

Pneumomediastinum is characterized radiographically by visualization of mediastinal structures that are not normally seen, such as the esophagus and aorta, because the presence of air within the mediastinum provides excellent contrast to adjacent soft tissue structures (see Figure 216-1, *A*). Pneumomediastinum is usually not recognized on VD or DV radiographs. Pneumothorax, pulmonary overinflation, and deep-chested conformation in thin dogs can cause a radiographic appearance that may be mistaken for pneumomediastinum. Also, a gas-distended esophagus may drape over the trachea and rarely the great vessels, which creates a false impression of pneumomediastinum.

Increased mediastinal size is usually manifested radiographically as diffuse or focal widening of the mediastinum as assessed on a VD or DV view. Diffuse widening can be caused by mediastinal inflammation, hemorrhage, edema, or the accumulation of fluid within the mediastinum associated with pleural cavity disease. Positional radiography and ultrasonography are helpful in differentiating mediastinal fluid accumulation from other causes of diffuse mediastinal widening. Focal mediastinal widening is usually the result of a mass lesion. Pathologic widening of the mediastinum must be differentiated from diffuse widening caused by an accumulation of fat in obese animals. An accumulation of fat in the mediastinum is common in older dogs, especially brachycephalic breeds.

Contrast radiographic procedures are often helpful in further evaluation of structures within the mediastinum that cannot be adequately visualized on survey films. In the case of suspected esophageal perforation, the contrast medium of choice should be a water-soluble iodinated product.

216.3.2 Ultrasonography

Thoracic ultrasonography provides poor visualization of the normal mediastinum because air in adjacent lung lobes prevents transmission of the sound waves. Sonographic evaluation may provide useful information in

animals with pleural effusion or cranial mediastinal disease.[3,4] Ultrasonography allows visualization of most cranial mediastinal masses. Very large masses can be imaged from almost any location in the craniolateral thoracic wall. Placing the transducer in a parasternal position or using the heart as an acoustic window may be necessary for adequate evaluation of smaller masses. Ultrasonography also helps define the internal architecture of masses as solid or cystic. In addition, ultrasonography allows localization of vascular structures relative to the mass. Although ultrasonography alone usually does not allow identification of the tissue of origin, it can be used to direct needle placement for fine-needle aspirate (FNA) or tissue core biopsy.[3,5,6] Transesophageal ultrasonography provides excellent visualization of the heart base, major cranial mediastinal vessels, descending aorta, and part of the azygous vein.[7] Transesophageal ultrasonography eliminates imaging difficulties due to obesity, poor intercostal windows, and lung air interference.

216.3.3 Computed Tomography

Computed tomography (CT) provides the most detailed anatomic analysis of mediastinal structures.[8,9] It is valuable in defining the margins and size of mass lesions (see Figure 216-4, *C*) and can be used to guide placement of a needle or percutaneous biopsy instrument. Disadvantages of CT include an inability to distinguish mediastinal masses from adjacent collapsed lung lobes, limited availability in veterinary practice, and the need for anesthesia.

216.3.4 Further Diagnostic Evaluation

Thyroid scintigraphy using technetium 99m or iodine 131 can be used to identify ectopic or metastatic functional thyroid tissue within the mediastinum.[10,11] Technetium 99m sestamibi can be used for the detection of parathyroid secreting tissue, although the sensitivity and specificity of this method may be low.[12,13]

In humans, bronchoscopy with transbronchial needle aspiration of perihilar and other pulmonary masses has been shown to be useful in the diagnosis of various cancers.[14] Although not widely used nor reported in veterinary medicine, this technique holds promise in allowing relatively noninvasive needle aspiration of hilar and mediastinal lymph nodes. The author has performed this technique with no apparent complications.

Thoracoscopy is another technique that can be used to examine and biopsy mediastinal diseases and is a proce-dure that is becoming more commonly performed in veterinary medicine at referral practices and institutions.[15,16,17] Thoracoscopy allows examination of the parietal and visceral pleura, lungs, pericardium, and mediastinum. Biopsies and removal of diseased tissue can be performed with this minimally invasive technique.

216.4 DISEASES OF THE MEDIASTINUM

216.4.1 Pneumomediastinum

Pneumomediastinum is the presence of air within the mediastinum and can develop spontaneously, usually in animals with pre-existing respiratory disease, or as a result of damage to the esophagus, trachea, or lungs (Figure 216-1, *A*). This damage can be associated with cervical trauma, mechanical ventilation, transtracheal aspiration, tracheostomy, or central venous catheter placement.[18] Caudal extension of air from cervical fascial planes into the mediastinum and retroperitoneum may occur secondary to external trauma because of the

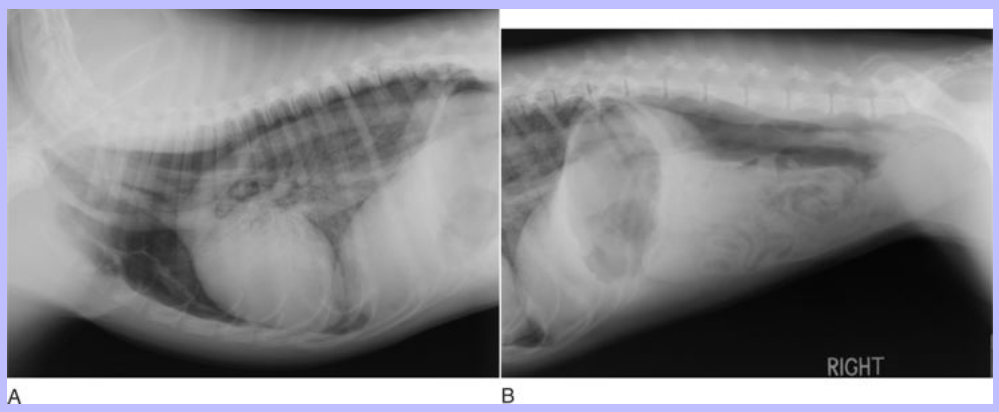
normal communication between the mediastinum, retroperitoneum, and fascial planes of the neck (Figure 216-1, *B*). Bronchial or alveolar rupture with subsequent dissection of air along perivascular or peribronchial spaces to the pulmonary hilus and into the mediastinum is thought to be the mechanism by which pneumomediastinum occurs secondary to mechanical ventilation and pulmonary trauma.[19] A less common, iatrogenic cause of pneumomediastinum is secondary to tracheal rupture due to overdistention of the endotracheal tube cuff.[20] Severe pulmonary pathology or pre-existing respiratory disease can lead to bronchial or alveolar rupture with subsequent pneumomediastinum.

Pneumomediastinum does not occur secondary to pneumothorax. However, pneumothorax can be secondary to pneumomediastinum and is caused either by rupture of the mediastinal pleura, allowing mediastinal air to leak into the pleural space or by airway or alveolar rupture asso-ciated with underlying pulmonary disease that allows air to extend into the lung interstitium and diffuse into the mediastinum and pleural space. Subcutaneous emphysema and pneumoretroperitoneum may also occur secondary to pneumomediastinum.

1267

1268

Figure 216-1 **A,** Lateral thoracic radiograph of a 9-month-old female Brittany Spaniel presented after being hit by a car. Numerous mediastinal structures, including the cranial vena cava, aorta, and serosal surface of the trachea, are well visualized as a result of pneumomediastinum. **B,** Lateral abdominal radiograph of the same dog. A large accumulation of air can be seen in the retroperitoneal space.



Pneumomediastinum alone is usually not associated with clinical signs. If the pneumomediastinum progresses to pneumothorax, tachypnea and dyspnea are often seen. The presence of subcutaneous emphysema may be uncomfortable for the animal. Animals with pneumomediastinum associated with esophageal rupture will present with signs associated with esophageal disease, such as regurgitation, pain, and dysphagia. Acute development of severe pneumomediastinum may cause signs of circulatory collapse secondary to decreased venous return resulting from compression of the vena cava and azygous vein.

The air trapped within the mediastinum does not require treatment and will spontaneously resolve within 2 weeks if there is no ongoing source of air leakage. Concurrent subcutaneous emphysema does not usually

require needle aspiration unless the volume is large enough to cause discomfort. Therapy should be aimed at resolution of any underlying disease process present.

216.4.2 Mediastinitis

Mediastinal inflammation is manifested radiographically as either focal or diffuse widening of the mediastinum. This may result from esophageal or tracheal perforation, deep cervical soft tissue infections extending along fascial planes into the mediastinum, or extension of infection from the pericardium, pulmonary parenchyma, or pleural space.[21,22,23,24] Chronic granulomatous mediastinitis may be caused by fungal organisms, such as *Histoplasma* or *Cryptococcus* spp., or bacterial organisms, such as *Actinomyces* or *Nocardia* spp.[24,25,26]

Mediastinitis has been documented secondary to spirocercosis in dogs.[27] Abscessation of the mediastinum may result from progression of chronic infectious or neoplastic mediastinal disorders.[23] Both mediastinal abscesses and granulomas typically appear on radiographs as mediastinal masses and thus may be mistaken for neoplasia.

Clinical signs associated with mediastinitis include tachypnea, likely related to thoracic pain, dyspnea, cough, head and/or neck edema, and regurgitation. Voice changes may occur secondary to recurrent laryngeal nerve involvement. Physical examination may reveal head and/or neck edema, tachypnea, dyspnea, fever, and decreased lung sounds if pneumothorax or pleural effusion are also present. Therapy involves resolving the underlying disorder. Esophageal perforation may require surgical repair and mediastinal masses may require surgical resection and/or drainage, along with appropriate antimicrobial therapy and supportive care.[23,26,28] Mediastinitis without a mass lesion may respond to antimicrobial therapy and supportive care alone. Thoracostomy tube placement may be necessary in animals with concurrent pyothorax or effusive mediastinitis.

216.4.3 Mediastinal Edema

Mediastinal edema can occur secondary to any disease that may result in edema in other areas of the body. The same pathophysiologic mechanisms apply. Although not recognized clinically very often, hypoproteinemia, lymphatic or venous obstruction, vasculitis, and heart failure may result in mediastinal edema. Edema in the mediastinum is often not clinically significant and may be overlooked due to accompanying pleural effusion.

216.4.4 Mediastinal Hemorrhage

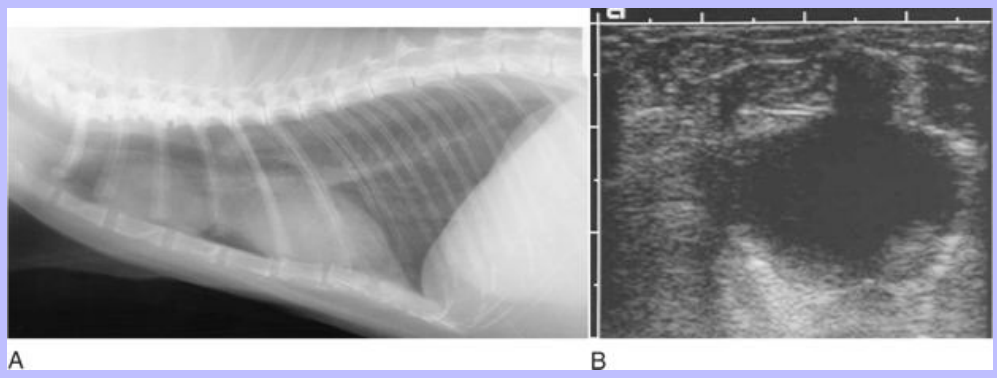
Hemorrhage into the mediastinum usually results from either trauma or coagulopathy but also may be associated with neoplastic erosion of mediastinal vessels.[29,30] The clinical signs associated with mediastinal hemorrhage are related to the effects of acute blood loss. Dyspnea may occur if mediastinal hemorrhage progresses to hemothorax. Treatment is aimed at resolution of the underlying cause, such as plasma and Vitamin K_1 therapy for anticoagulant rodenticide intoxication, along with supportive care. If hemothorax due to coagulopathy or trauma is also present, auto-transfusion may be performed. Mild mediastinal hemorrhage usually does not need specific treatment.

216.4.5 Mediastinal Cysts

Benign cysts of pleural, branchial, lymphatic, bronchogenic, or thymic origin occur infrequently in the mediastinum.[31,32,33] Most animals do not have clinical signs referable to the mediastinal cyst. Radiographically, a cyst can appear as a solid mass in the cranial mediastinum due to the fluid within the cyst (Figure 216-2, *A*). A cyst can be differentiated from a solid mass ultrasonographically (Figure 216-2, *B*). Solid neoplasms, abscesses, or granulomas may have cystic components and must be differentiated from a simple cyst. Fine-needle aspiration with ultrasound guidance is the diagnostic test of choice. Cytology and culture can be performed. Mediastinal cysts typically contain a clear, colorless fluid with low cellularity and protein content.[31,32,33]

1268 1269

Figure 216-2 **A,** Lateral thoracic radiograph of a 19-year-old castrated male cat who presented for chronic renal failure and a heart murmur. Radiographs demonstrate a smoothly marginated soft tissue mass cranial to the heart, which causes minimal displacement of the trachea dorsally. **B,** Ultrasound of the cranial mediastinal mass. The ultrasonogram demonstrates that the mass is thin walled and cystic. Fluid obtained via ultrasound guided FNA was clear with low cellularity and protein, consistent with a mediastinal cyst.



216.4.6 Non-Neoplastic Mediastinal Masses

Non-neoplastic mediastinal masses in dogs and cats and are usually infectious in origin. Fungal pyogranulomas, abscesses, lymphadenopathy, and hematomas have been described.[23–29] Lymphomatoid granulomatosis is a rare neoplastic/inflammatory disease of unknown etiology that causes hilar lymphadenopathy, pulmonary masses, and pleural effusion.[34] Lymphadenopathy may involve the cranial mediastinal, sternal, and tracheobronchial (hilar) lymph nodes. Cranial mediastinal lymph nodes lie along the major vascular structures and just ventral to the trachea. Sternal lymph nodes are just dorsal to the sternum, medial to the second costal cartilage, and cranioventral to the internal thoracic vessels. Sternal lymph nodes drain the abdomen, so enlargement often indicates intra-abdominal or multicentric disease.[19] The hilar lymph

nodes are found at the bifurcation of the trachea and proximal bronchi. None of these lymph nodes are visible in normal animals on survey radiographs. Other lesions that may appear to be a mass include esophageal foreign bodies, diaphragmatic hernias, and gastroesophageal intussusception.

Radiographically, mediastinal masses appear as thoracic opacities on or near the midline that frequently cause displacement of adjacent mediastinal or thoracic structures, such as the heart, esophagus, and trachea. The carina is normally located at the fifth or sixth intercostal space in the dog and the sixth intercostal space in the cat. It can be displaced caudally by cranial mediastinal masses. Esophageal masses usually cause ventral displacement of the trachea. Most other mediastinal masses displace the trachea dorsally and to the right. Other radiographic changes associated with mediastinal masses include increased opacity in the cranial thorax, widening of the mediastinum, tracheal compression, and loss of distinct, smooth, straight mediastinal borders. Masses that are in contact with a mediastinal structure may not have clearly defined borders. Enlarged sternal or hilar lymph nodes are most easily visualized on a lateral radiograph (Figure 216-3). Cranial mediastinal lymphadenopathy is better appreciated on a VD or DV view. Radiographic findings associated with enlargement of the hilar lymph nodes include separation of the main stem bronchi, elevation of the trachea cranial to the carina, and ventral deviation of the main caudal lobe bronchi caudal to the carina. Left atrial enlargement is the main differential diagnosis for this radiographic appearance. Mediastinal masses are frequently classified by location as cranioventral, craniodorsal, perihilar, caudoventral, or caudodorsal (Box 216-1).

Pleural effusion may imitate a mediastinal mass because of the associated tracheal elevation, which is caused by the dorsal displacement of the lungs.[35] Repeat radiographs obtained after removal of the pleural fluid are often helpful in distinguishing pleural effusion from a mediastinal mass. Other lesions that may be confused with a mediastinal mass include the normal thymus in young animals, mediastinal fat in obese animals, lung masses, especially those involving the accessory lobe or cranial tips of the left and right cranial lung lobes, very large right and left caudal pulmonary arteries, and perihilar edema. The presence of an air bronchogram within a suspected mediastinal mass indicates that it is actually a pulmonary lesion.

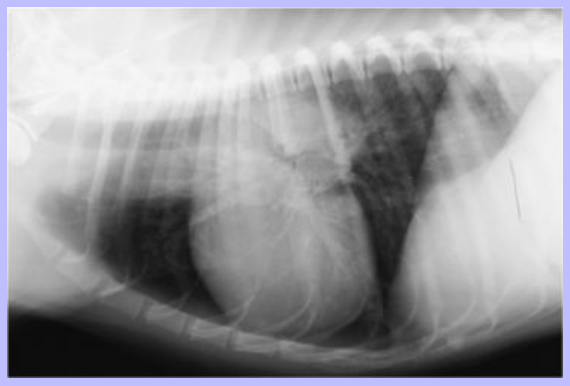
Figure 216-3 Lateral thoracic radiograph of a 3-year-old castrated male German Shorthaired Pointer presented for anorexia, weight loss, and fever. The radiographs demonstrate mass lesions and lymphadenopathy in the craniodorsal and hilar regions with displacement of the main stem bronchi ventrally. The final diagnosis was Nocardiosis.



216.4.6.1

Box • 216-1 Differential Diagnoses for Lesions Associated with Focal Mediastinal Enlargement

Region	Diseases
Cranioventral	Lymphadenopathy; abscess; thymic mass; ectopic thyroid; hematoma; granuloma; obesity; vascular mass (aorta, cranial vena cava); esophageal mass, foreign body, or dilatation; tracheal mass
Craniodorsal	Esophageal mass, foreign body, or dilatation; heart base mass; neurogenic tumor; paraspinal or spinal mass; hematoma; lymphadenopathy; aortic stenosis; patent ductus arteriosus; abscess; tracheal mass
Perihilar	Lymphadenopathy; left atrial enlargement; esophageal mass, foreign body, or dilatation; main pulmonary artery mass (post-stenotic dilatation); heart base or right atrial mass; spinal or paraspinal mass
Caudodorsal	Esophageal mass, foreign body, or dilatation; hiatal hernia; diaphragmatic hernia or mass; spirocercosis; spinal or paraspinal mass; aortic aneurysm; gastroesophageal intussusception
Caudoventral	Diaphragmatic hernia; peritoneopericardial diaphragmatic hernia; abscess; granuloma; hematoma

216.4.7

Mediastinal Neoplasia

Mediastinal tumors can originate from any structure within the mediastinum (lymph nodes, thymus, great vessels, trachea, esophagus, ectopic thyroid or parathyroid tissue) or from extension of neoplastic lesions in adjacent tissues.[36,37] Also, mediastinal neoplasms may be metastatic lesions or components of a multicentric neoplastic process.[38–44] Benign tumors have also been documented.[45]

Clinical signs associated with mediastinal tumors are usually caused by compression or invasion of structures such as the great vessels, thoracic duct, esophagus, and trachea. Signs include coughing, dyspnea, dysphagia, regurgitation, and edema of the head, neck, and/or forelimbs. Signs caused by peripheral nerve entrapment are less common and include laryngeal paralysis, vocalization changes, or Horner's syndrome. Signs associated with multicentric disease may reflect other sites of neoplastic involvement or may be related to paraneoplastic syndromes. These signs include anorexia, weight loss, vomiting, diarrhea, and polyuria/polydipsia.

Mediastinal lymphoma originates from either lymph node or thymic tissue in the cranial mediastinum. Mediastinal lymphoma is often associated with pleural effusion, which may initially obscure radiographic visualization of the mediastinal mass. The diagnosis of mediastinal lymphoma can often be confirmed by cytologic identification of neoplastic lymphocytes in either a sample of pleural fluid or a sample obtained directly from the mediastinal mass via FNA. In dogs, mediastinal lymphoma may be associated with hypercalcemia. The presence of a mediastinal mass is a poor prognostic indicator in dogs with lymphoma.[46] Less common lymphatic based tumors that can cause mediastinal masses include lymphangiosarcoma and lymphangioma.[37,45]

Chemodectomas, which are usually aortic or carotid body tumors, are most often identified as heart base masses.[47] Affected animals may be presented for dysphagia, dyspnea, heart failure, or cervical swelling. Because these tumors often invade and surround roots of the great vessels at the heart base, they result in a mediastinal mass effect.

216.5 DISEASES OF THE THYMUS

The thymus extends from the thoracic inlet caudally to the fifth rib in the dog and the sixth rib in the cat. Dorsally it lies next to the phrenic nerves and cranial lung lobes. Thymic involution in small animals occurs concurrently with the onset of sexual maturity and the loss of deciduous teeth.[48] The thymus atrophies and is gradually replaced by connective tissue and fat, but remnants persist into old age.[48] Thymic branchial cysts arise from remnants of branchial pouch epithelium and may occur in the cranial mediastinum of dogs and cats (also see above).[49]

216.5.1 Thymic Hemorrhage

An uncommon disease of spontaneous thymic hemorrhage has been described in dogs and one cat.[49–52] Although not uniformly fatal, most animals documented with this syndrome have died. Most animals affected have been less than 2 years of age, so it appears to be associated with thymic involution. Clinical signs include lethargy, signs of thoracic pain, increased respiratory effort, and dyspnea. Physical examination findings are attributable to acute blood loss/hypovolemia and pleural effusion. Signs include pale mucous membranes, prolonged capillary refill time, tachycardia, tachypnea, and muffled lung sounds. Thoracic radiographs demonstrate a mediastinal mass (hemorrhage, hematoma) usually associated with pleural effusion. Treatment is supportive in nature and involves volume support, blood replacement, and thoracocentesis as needed.

216.5.2 Thymoma

Thymomas are rare tumors in the dog and cat that arise from the epithelial cells of the thymus.[53–56] They appear radiographically as large, poorly defined soft tissue masses in the cranial mediastinum (Figure 216-4, *A* and *B*). Expansion and invasion into adjacent tissues are common, but in some cases the masses are well encapsulated and fairly noninvasive. Metastasis has been reported in dogs and cats.[53,56] Pleural effusion is a variable finding and may hinder visualization of the thymic mass. Sonographically, thymomas can appear as solid, cystic, or a combination. Cytologic examination of FNA samples reveals a variable number of mature lymphocytes, which makes cytologic differentiation of thymoma from mediastinal lymphoma difficult. Mast cells are also frequently identified in cytologic samples from thymomas. Surgical or ultrasound guided percutaneous biopsy is required for definitive diagnosis. Paraneoplastic syndromes are commonly associated with thymoma in both dogs and cats.[53,55] The most well described is myasthenia gravis, which is often associated with megaesophagus in dogs with thymoma.[53] Myasthenia gravis has also been reported in cats with thymoma, but is less common. Surgical resection is the treatment of choice for thymoma, but recurrence and metastasis have been reported.

Figure 216-4 Lateral **(A)** and dorsoventral **(B)** radiographs of a 10-year-old castrated male Labrador Retriever presented for collapse. Radiographs demonstrate deviation of the trachea to the right. The cranial border of the cardiac silhouette is effaced by a cranial mediastinal mass. **C,** Computed tomographic 3D reconstruction of the cranial mediastinal mass in the same dog. The mass was removed surgically. Final diagnosis was thymoma with hemorrhage.

217 CHAPTER • 217 Pleural and Extrapleural Diseases

Michelle M. Mertens

Theresa W. Fossum

Kristin A. MacDonald

217.1 DISORDERS OF THE DIAPHRAGM

217.1.1 Diaphragmatic Anatomy

The diaphragm is a musculotendinous structure that separates the abdominal and thoracic cavities and is covered by pleura on its convex (thoracic) surface, adjacent to the lungs. It aids in ventilation and movement of lymphatic fluid. The phrenic nerves, which in dogs are derived from C4 to C7, provide innervation.[1] In cats, the phrenic nerves arise from C4 to C6. Prior to reaching the diaphragm, the phrenic nerves traverse the mediastinum and pericardium and are therefore subject to disruption from infiltrative masses or surgical transection (during pericardectomy or mass removal).

217.2 DIAPHRAGMATIC DISPLACEMENT AND DYSFUNCTION

Cranial or caudal displacement of the diaphragm may be associated with certain conditions and can be unilateral or bilateral. Cranial displacement results from enlargement or gas distension of abdominal contents as would be seen with late-term pregnancy or gastric dilatation-volvulus, respectively. It may contribute to respiratory compromise in such circumstances. Removal of a lung lobe or pulmonary atelectasis or consolidation results in unilateral cranial advancement of the diaphragm. Caudal diaphragmatic displacement is associated with pleural cavity disease (e.g., pneumothorax, pleural effusion) or obstructive airway disease that causes air trapping and pulmonary hyperinflation. These displacements are typically bilateral and recognition may be difficult when pleural fluid obscures the diaphragmatic silhouette. Unilateral caudal displacements are uncommon and may occur with either unilateral pneumothorax or pleural effusion, particularly chylothorax or pyothorax.

Paralysis of the diaphragm may also be uni-or bilateral. Unilateral paralysis is unlikely to be associated with clinical evidence of respiratory abnormalities; however, bilateral paralysis can result in substantial impairment of respiration. Bilateral paralysis most commonly results from cervical spinal trauma or fracture. In such cases, cranial displacement of the diaphragm may be radiographically apparent. Lack of movement of the diaphragm during fluoroscopic evaluation increases suspicion of this condition.

217.2.1 Diaphragmatic Hernias

Diaphragmatic hernia (DH) is a term for disorders of the diaphragm that allow abdominal contents to enter the thoracic cavity, either within the pleural space (pleuroperitoneal hernias, hiatal hernias) or pericardial sac (peritoneopericardial diaphragmatic hernias). Diaphragmatic hernias are divided by etiology into traumatic and congenital hernias.

217.2.1.1 Traumatic Diaphragmatic Hernias

Traumatic DHs are more commonly recognized in small animal veterinary patients than are congenital hernias, with studies reporting between 77% and 85% of diaphragmatic hernias being traumatic in origin.[2–4] Traumatic DHs are frequently associated with motor vehicle accidents or other forceful blows to the thorax or abdomen.[3,5] A sudden increase in intra-abdominal pressure, with an open glottis, results in rapid deflation of the lungs. The position of the glottis may be unimportant provided there is the creation of an abrupt, substantial increase in pressure with an abdominal pressure gradient.[2] The large pressure gradient causes the diaphragm to tear at its weakest points (usually in the muscular portions). The location and size of the tear(s) depend on the position of the animal at the time of impact and location of the viscera.

217.2.1.1.1 Signalment and History

Young male dogs between the ages of 1 and 2 years are most commonly diagnosed with traumatic DH because of their propensity to roam and sustain vehicular trauma. Affected animals may present in shock and respiratory distress, depending on the size of the hernia, which viscera have herniated, and severity of other injuries. Concurrent injuries are common. Chronic diaphragmatic hernias are reported and respiratory embarrassment may not be immediately evident. In one study, 20% of animals with traumatic DH were not diagnosed until at least 4 weeks after the injury had occurred.[2] Clinical signs associated with chronic diaphragmatic hernias are generally confined to the respiratory or gastrointestinal system and may include dyspnea, exercise intolerance, anorexia, depression, vomiting, diarrhea, weight loss, and/or pain following ingestion of food.

217.2.1.1.2 Physical Examination

Physical examination findings vary with the acuteness of the trauma, concurrent injuries, and organs herniated. Hypoventilation is often present and is attributable to inadequate lung expansion, voluntary decrease in chest wall motion due to pain, fractures or flail segments causing chest wall dysfunction, or pulmonary atelectasis. Signs consistent with shock include pale or cyanotic mucous membranes, tachypnea, tachycardia with variable pulse pressure, and decreased mentation. Cardiac arrhythmias, attributable to traumatic myocarditis, may be present and if severe, are associated with significant morbidity. The liver is the organ most commonly herniated and is often associated with hydrothorax as a result of venous occlusion and capsular weeping. Extrahepatic biliary obstruction has been reported.[6] Herniation and entrapment of the stomach can lead to gaseous distension, which results in a rapidly declining clinical condition and fatal respiratory impairment. Gastric dilation-volvulus has been reported with DH and should be suspected in dogs and cats presenting with abdominal enlargement and dyspnea.[7]

217.2.1.1.3 Diagnosis

Diagnosis of DH is made either on thoracic radiographs (Figure 217-1) or by ultrasonography of the diaphragm and cranial abdomen. The presence of gas-filled viscera in the thoracic cavity is diagnostic of a DH; however, visualization of thoracic structures and the diaphragmatic silhouette may be obscured by the presence of pleural effusion. In such cases, thoracocentesis may be necessary prior to obtaining diagnostic radiographs. Ultrasound examination is most helpful in cases with herniation of the liver or when large volumes of pleural fluid are present. An upper GI barium study may identify portions of the

intestinal tract that have herniated into the thoracic cavity. Positive contrast celiography with a water-soluble contrast agent is occasionally used as a diagnostic aid but caution must be used when injecting radiographic contrast agents in dehydrated animals. Additionally, omental or fibrous adhesions may obscure diaphragmatic defects and result in false-negative studies.

Figure 217-1 Ventrodorsal thoracic radiograph of a dog with a traumatic diaphragmatic hernia. Notice the gas-filled loops of small intestine in the right hemithorax.

217.2.1.1.4 Management

Initial management should include oxygen therapy in dyspneic animals and treatment for shock, including fluids and administration of a broad-spectrum antibiotic (see Chapter 120, 124). Ventilation may be improved by positioning the animal in sternal recumbency with the front end elevated. Thoracocentesis should be performed if moderate to marked pleural fluid is present. Animals presenting with gastric distension should be considered surgical emergencies and operated on as soon as they can safely be anesthetized. Other animals with diaphragmatic hernias and associated trauma may benefit from stabilization prior to surgical intervention and definitive repair of the DH. However, these animals must be closely monitored for worsening respiratory compromise. Overall mortality rate for dogs and

cats undergoing diaphragmatic herniorrhaphy is cited at approximately 20%.[8–10] Readers are referred to a surgical textbook for details of surgical correction of DH.

217.2.1.2 Congenital Diaphragmatic Hernias

217.2.1.2.1 Signalment and History

Congenital pleuroperitoneal hernias can occur and result from improper development of the left pleuroperitoneal membrane. These hernias are infrequently recognized in dogs and cats as they generally result in death upon or shortly after birth.[11] Hernias involving the esophageal hiatus are typically congenital in nature and are known as *hiatal hernias*. (See Chapter 220.)

Peritoneopericardial diaphragmatic hernias (PPDHs) are the most common congenital pericardial and diaphragmatic anomalies in dogs and cats.[12] Herniation of abdominal viscera into the pericardial sac can result from abnormal development of the septum transversum or from failure of the lateral pleuroperitoneal folds and the ventromedial pars sternalis to unite. This defect likely occurs as a result of a teratogen, genetic defect, or prenatal injury.[13] A high incidence of right-and left-sided DH was induced when the embryotoxic herbicide nitrofen was given to rats during a critical period in gestation.[14] A teratogen was the suspected cause of PPDH and multiple cardiac defects in an entire litter of collies.[15] Unlike in humans, PPDHs are always congenital in dogs and cats because there is no direct communication between the peritoneal and pericardial cavities after birth in these species.

Cardiac abnormalities and sternal deformities often occur concomitantly with PPDHs. Reported concurrent anomalies include umbilical hernias, cranial midline abdominal wall hernias, malformed or absent sternebrae, pectus excavatum or intracardiac defects.[16,17] Polycystic kidneys have been reported in association with PPDH in a cat.[18] Although seldom noted in animals, pulmonary vascular abnormalities may occur in children with congenital DH; persistent pulmonary hypertension is thought to contribute to the morbidity and mortality associated with this condition in affected children.[19] A predisposition for PPDH has been suggested in Persian cats and Weimeraners.[17,20]

217.2.1.2.2 Clinical Signs and Physical Examination

As with other DH, clinical signs of affected animals may vary from none to severe respiratory embarrassment, depending on the organ(s) herniated and degree of compromise of that organ(s). Vomiting and anorexia are often observed. Physical examination may reveal muffled heart sounds and lack of normally palpable organs in the abdomen.

217.2.1.2.3 Diagnosis

Diagnosis of PPDH is usually made from thoracic radiographs and/or ultrasound and is frequently an incidental finding. Radiographic findings include apparent cardiomegaly, dorsal elevation of the trachea, and silhouetting of the heart and diaphragm; gas-filled viscera may be present. As with other diaphragmatic hernias, oral barium administration may be useful if the diagnosis is not readily apparent on radiographs or if ultrasound is unavailable.

217.2.1.2.4 Management

Initial management of the symptomatic animal with PPDH includes oxygen therapy if dyspneic and positioning the animal in sternal recumbency with the chest elevated. Surgical repair of PPDH is recommended in most cases and should be performed at as early an age as possible. Early surgical intervention may decrease the incidence of adhesions and risk of postoperative re-expansion pulmonary edema.

217.3 DISORDERS OF THE THORACIC WALL

217.3.1 Chest Wall Trauma

Damage to the thoracic wall may be due to blunt (motor vehicle accidents, being kicked) or penetrating (bite wounds, gun-shot wounds) injuries. Both blunt and penetrating trauma can cause extensive soft tissue damage of the thoracic wall. Although soft tissue damage is rarely the cause of major morbidity or mortality, it may be the only external evidence of severe thoracic trauma. Pain associated with thoracic wall trauma may lead to hypoventilation because the animal is unwilling to breathe; analgesics may improve ventilation. Similarly, isolated rib fractures, although unlikely to result in significant respiratory impairment, may result in decreased ventilation due to pain. Chest wall trauma alone (without pulmonary parenchymal damage) rarely leads to significant hypoventilation resulting in hypoxia.

1273 1274

A flail segment (flail chest) is produced when multiple segmental rib fractures produce a free segment of thoracic wall that has lost its continuity with the remainder of the thorax. Intrapleural pressure changes during respiration result in paradoxic segment movement; the segment moves inward during inspiration and outward during expiration. Flail chest segments can initially be stabilized by positioning the animal with the flail side down. Mechanical ventilation is the preferred treatment for people with flail segments. As this may not be practical in veterinary patients, surgical stabilization of the flail segment is thought to help decrease pain, improve ventilation, and prevent further damage to thoracic structures. A recent retrospective study of the medical records from five veterinary teaching hospitals investigating the clinical management of flail chest in dogs and cats reported that the majority of cases were treated without stabilization of the flail segment.[21] The study was not able to demonstrate a difference in outcome between surgically stabilized and conservatively managed cases. It was not possible to determine from the results of the study which animals would benefit from surgery. Readers are referred to a surgical text for more details of the surgical management of flail chest.

Subcutaneous emphysema can occur with both blunt and penetrating trauma and is usually of little clinical significance. It occurs when air dissects along fascial planes under the subcutaneous tissues. Air may enter the subcutaneous tissues from direct communication with an external wound, from disruption of the pleura and intercostals muscles, or as an extension of mediastinal emphysema. The condition is usually self-limiting; treatment should be directed at the underlying cause.

217.3.2 Pectus Excavatum

Pectus excavatum (PE) is a deformity of the costocartilages and sternum that result in a dorsoventral narrowing of the chest. Although the causes are unknown, several theories have been proposed. It has been suggested that there may be both congenital and acquired forms of PE in people.[22] Possible etiologies include shortening of the central tendon of the diaphragm, abnormalities of intrauterine pressure, congenital deficiency

of musculature in the cranial portion of the diaphragm, and abnormal respiratory gradients as may be present with upper airway obstruction.

217.3.2.1 Signalment and History

Sternal depressions are often noted early in the life of the animal and prompt owners to seek veterinary attention. The disease is progressive and the severity of the defect may increase as the animal matures. In humans, males appear to be predisposed, yet a gender predilection has not been clearly identified in animals. PE has been reported in dogs, cats, sheep, and calves. Brachycephalic dogs and Burmese cats are more commonly affected than other breeds.[23,24] PE has occurred in multiple animals of certain litters; therefore affected animals should not be used for breeding. PE can be associated with "swimmer's syndrome," a poorly characterized disease of neonatal dogs in which the legs splay to the sides.

217.3.2.2 Clinical Signs and Physical Examination

Animals with PE may be asymptomatic or may present with clinical signs associated with both respiratory and cardiovascular functional abnormalities. The sternal depression often causes malpositioning of the heart within the thoracic cavity and may result in kinking of the large veins, disturbance of venous return, restriction of ventricular filling, and decreased respiratory reserve. Direct compression of the heart may result in cardiac arrhythmias. Symptoms such as exercise intolerance, weight loss or failure to thrive, hyperpnea or dyspnea, cyanosis, recurrent respiratory infections, and vomiting may occur. A correlation between severity of clinical signs and severity of the abnormality has not been identified. Other abnormalities that may be noted on physical exam include cardiac murmurs and increased or harsh lung sounds. Concurrent cardiac abnormalities such as pulmonic stenosis and atrial septal defects have been reported; care must be taken to distinguish abnormalities caused by the position of the heart from those that result from cardiac disease.

Figure 217-2 A cat with pectus excavatum. Notice the palpable depression of the caudal sternum. (From Fossum TW et al: Pectus excavatum in 8 dogs and 6 cats, J Am Anim Hosp Assoc 25:595, 1989.)

217.3.2.3 Diagnosis

Diagnosis of PE is made on physical examination by palpation of a depression in the sternum (Figure 217-2). Thoracic radiographs show an abnormal elevation of the sternum. The heart is often shifted to one of the hemi-thoraces as insufficient room exists on midline. In this abnormal position, it may appear enlarged on thoracic radiographs. Echocardiography may be necessary to distinguish cardiac disease from this apparent enlargement. Classification of the sternal deformity as mild, moderate, or severe has been described and is based on the frontosaggital and vertebral indices obtained from thoracic radiographs[24] (Figure 217-3).

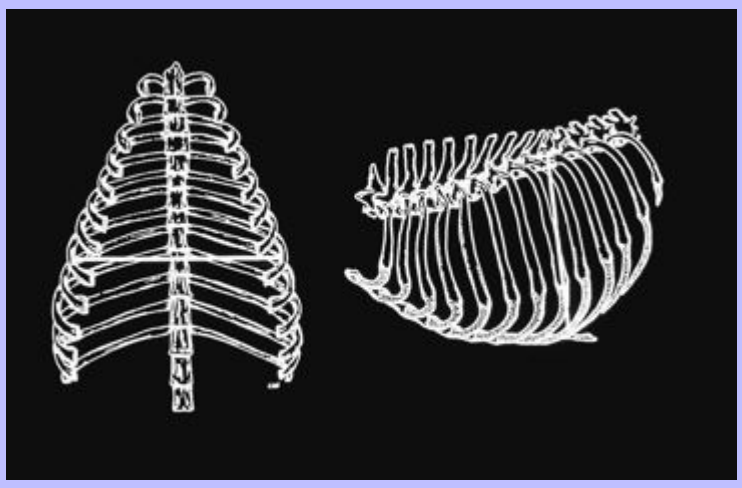
217.3.2.4 Management

Animals with mild PE or those with simply a flattened ventral thorax are unlikely to require surgery. Owners should be instructed to perform medial to lateral chest compressions in such cases. In young animals with moderate to severe disease, or those with clinical signs, application of a splint to the ventral aspect of the thorax is the most commonly used treatment. Older animals with less compliant thoracic and sternal walls may require a partial sternectomy to relieve their clinical signs.

217.3.3 Thoracic Wall and Sternal Neoplasia

Primary tumors of the rib are uncommon in the dog; however, these tumors are usually malignant and have a high metastatic rate. Some reports cite that they generally develop in young dogs, with a mean reported age in one study of 4.5 years[25], whereas others report median ages of between 7 and 9 years.[26,27] Osteosarcomas are the most common neoplasm of the canine rib, followed by chondrosarcoma; the costochondral junction is the usual site of origin of these tumors. Fibrosarcomas and hemangiosarcomas are less frequently reported.[25,28] Most rib tumors cause a localized swelling of the thoracic wall; however, pleural effusion without evidence of a thoracic mass has been reported in two dogs with primary rib tumors and metastatic pulmonary lesions.[29] Other clinical signs noted in two animals with rib tumors included weight loss and dyspnea.

Figure 217-3 The frontosagittal index is the ratio between the width of the chest at the tenth thoracic vertebra (a) and the distance between the center of the ventral surface of the tenth thoracic vertebral body and the nearest point on the sternum (b). The vertebral index is the ratio between the distance from the center of the dorsal surface of the tenth vertebral body to the nearest point on the sternum (b and c) and the dorsalventral diameter of the vertebral body at the same level (c). (From Fossum TW et al: J Am Anim Hosp Assoc 25:595, 1989.)



Neoplasms of the ribs or sternum should be differentiated from bacterial or fungal osteomyelitis. A tentative diagnosis of the tumor cell type can usually be made by fine-needle aspiration of the mass; however, definitive diagnosis requires histologic examination of a biopsy specimen. Although pleural effusion is common in dogs with rib tumors, identification of neoplastic cells in the fluid is very uncommon. Due to the high rate of pulmonary metastasis, the prognosis for dogs with rib tumors is poor. In one study of 15 dogs with primary rib tumors, greater than 90% of the dogs died or were euthanized within 4 months of the diagnosis.[29]

Although also rare, both metastatic and primary tumors of the sternum have been reported in dogs.[30] In humans, metastatic tumors involving the sternum are more frequently recognized than primary tumors. The distant primary site is most commonly in the thyroid, kidney, breast, testicle, lung, stomach, or rectum. Primary neoplasms of the bony chest account for 7% to 8% of all bone tumors in humans, and although primary rib tumors are frequently benign, tumors of the sternum are typically malignant. Similar generalizations are difficult to make in the dog due to the infrequency with which sternal tumors have been reported. However, chondrosarcomas and osteosarcomas involving the sternebrae have been reported in dogs.[31]

When a diagnosis of sternal neoplasia is made, the diseased bone as well as normal surrounding tissue should be removed. Unlike most bones in the body, the sternebrae can be removed with little compromise of

function.[32] Successful treatment of sternal osteomyelitis following resection of large portions of the sternebrae has been reported in dogs and human beings, and the procedure would likely benefit dogs with primary sternal neoplasia.

217.4 PLEURAL EFFUSION

217.4.1 Anatomy of the Pleural Space

The pleura consists of a single sheet of flattened mesothelial cells supported by a layer of elastic connective tissue containing vascular and lymphatic channels. The visceral pleura covers the lung surface; the parietal pleura lines the inner surface of the ribs, diaphragm, and mediastinum. The pleural space normally contains a small amount of fluid that aids in transmission of forces and provides lubrication of the lung surfaces during respiration. Pleural fluid in the normal animal is similar to that of a plasma filtrate with a low protein concentration and a cellular composition of mesothelial cells and monocytes. Differences in electrolyte composition between pleural fluid and blood suggest modification of the plasma filtrate by an active transport or selective diffusion mechanism.[33] Filtration rate and lymphatic drainage increase with animal size and age; larger animals have small pleural fluid volumes.

Theories concerning the regulation of pleural fluid turnover have been expanded greatly over the past few decades. In 1927 Neergard described the balance of fluid formation and resorption as an equilibrium between hydraulic and colloid osmotic pressures.[34] Although these concepts are still valid, additional mechanisms must be in place to explain the stable composition of interstitial and pleural fluids. Given the differential permeability of water and solutes, pleural fluid protein concentration would increase over time if pleural fluid exchange were based solely on the difference between hydrostatic and colloid osmotic pressures. Similarly, if fluid production occurred solely at the arteriolar end of the capillary bed and resorption at the venular end as previously described, then a progressive increase in interstitial protein should occur over time.

The formation of pleural fluid is thought to be the result of filtration of fluid into the pleural space via Starling forces. It is currently thought that the absorption of pleural fluid is controlled by several mechanisms. The pressure differential across the visceral pleura favors liquid absorption; however, this is believed to contribute to only a small amount of fluid absorption.[35,36] Some believe that the pleural lymphatics provide the majority of interstitial fluid drainage[34], including particles, cells, and albumin.[37] There is evidence that stomas that help to transport albumin and water exist between the mesothelial cells of the parietal pleura and endothelial cells of the pleural lymphatics.[34] However, some albumin and liquid are also transported outside of the stomas via transcytosis.[38] A subatmospheric pressure of approximately −10 cm H_2O is generated by pleural lymphatics[39], which allows them to act as a drainage mechanism in pleural fluid accumulation. Lymphatic flow rate can increase dramatically (twentyfold) in response to increased pleural fluid filtration. Lymphatic drainage is greatest in the ventral thoracic cavity, diaphragm, and mediastinum.

More recently, the role of mesothelial cells in active trans-serosal transport (electrolyte coupled liquid absorption) has been investigated[40]; direct and indirect evidence of this function has been provided.[41–43] Mesothelial cell permeability to water and solutes may be equivalent to that of the capillary endothelium and these cells appear to be involved in the active transport of solutes and liquid. Thus the volume and composition of pleural fluid in the normal animal is governed by lymphatic drainage, Starling forces through the mesothelium and capillaries of the connective tissue, and activity of mesothelial cells.

217.4.2 Etiology of Pleural Effusions

Pleural effusions develop when there is an alteration in the balance between fluid formation and fluid resorption. This can result from changes in hydrostatic and osmotic pressures, impaired lymphatic drainage, and increased vascular or lymphatic permeability.[40] Alterations in the pleural fluid protein content and cellularity can give some evidence as to the underlying disease process. Low protein effusions are generally caused by cardiac, renal, or hepatic disease and are known as *transudates*. Effusions with a high protein count (>3.0 g/dL) suggest increased vascular permeability, decreased lymphatic removal, or both and can be caused by inflammatory or neoplastic processes or by diseases of the lymphatic system.

1275

1276

Alterations in osmotic pressure result in low protein effusions as disruption of Starling forces allows fluid movement out of the vascular space and decreased absorption of fluid by the capillaries of the visceral pleura. Serum albumin concentrations of less than 1.5 g/dL may result in pleural or peritoneal effusions; edema of the extremities may also occur. Hypoalbuminemia can be secondary to decreased production as seen in liver disease or increased loss as in protein-losing enteropathy or nephropathy. Hepatic hydrothorax occurs when a marked pleural effusion occurs in a patient with hepatic cirrhosis in the absence of primary pulmonary or cardiac disease.[44] These effusions often recur and may be associated with diaphragmatic peritoneopleural communications or may occur via transdiaphragmatic lymphatic drainage of the cranial abdomen.

Increased systemic venous hydrostatic pressure is most commonly seen secondarily to congestive heart failure (CHF) and may result in pleural effusion. Left-sided CHF increases visceral capillary hydrostatic pressure and decreases fluid absorption, whereas right-sided CHF increases parietal capillary pressure and tends to favor increased pleural fluid formation.[45] Increased venous pressures also decrease lymphatic drainage within the pleural cavity and can result in a transudative or chylous effusion. Venous or lymphatic obstruction, as might be seen with a lung lobe torsion or incarceration of a liver lobe through a diaphragmatic hernia, can cause transudation of fluid through the organ capsule and result in pleural effusion. Other causes of increased venous pressures include pericardial effusion and cardiac tamponade, heartworm disease, and neoplasia.

Animals with fibrosing pleuritis or severe upper airway obstruction may develop increased negative pressure in the pleural space. In fibrosing pleuritis, the lungs are unable to re-expand despite absorption or removal of pleural fluid, which result in an increase in negative pressure.[33] This negative pressure promotes rapid accumulation of pleural fluid.

Alterations in vascular or lymphatic permeability or decreased lymphatic drainage cause effusions with increasing amounts of protein and fluid accumulation. Increased vascular permeability may be induced by vasculitis, which results from release of mediators such as histamine during inflammatory processes. Diseases that commonly result in vasculitis that may cause pleural effusion include feline infectious peritonitis (FIP), pancreatitis, uremia, and immune-mediated diseases such as systemic lupus erythematosus (SLE) and rheumatoid arthritis. Lymphatic drainage may be altered by neoplastic processes such as lymphangiosarcoma, mesothelioma, or metastatic mammary carcinoma.

217.4.3 Clinical Signs and Physical Examination

Clinical signs associated with pleural effusion can vary according to the etiology of the increased fluid volume, rapidity with which the fluid accumulated, and the volume of fluid present. With increased pleural fluid accumulation, compensatory mechanisms are overcome and clinical evidence of decreased lung

expansion and impaired gas exchange become evident. These signs are likely to have an insidious onset and substantial disease can be present before abnormalities are recognized.

Dyspnea is the most common clinical sign in animals presenting to the veterinarian with pleural effusion. Often the owner reports an acute onset. The dyspnea is usually marked by a forceful inspiration, with delayed expiration. Animals are often reluctant to lie down and may extend their heads and necks in an elevated position. Other clinical signs include tachypnea, open-mouth breathing, and cyanosis. Dogs and cats with chronic pleural effusion may present with coughing as the only clinical sign and should therefore be evaluated for pleural effusion when presenting with a persistent cough that does not respond to routine therapy. Coughing may be a result of irritation caused by the effusion, or related to an underlying disease process (e.g., cardiomyopathy). Other physical exam findings can include muffled heart and lung sounds and dullness on thoracic percussion. Additional findings that are related to the underlying cause of the pleural effusion can include fever, weight-loss, anorexia, depression, pale mucous membranes, heart murmurs or arrhythmias, ascites, pericardial effusion, or Horner's syndrome. Animals that remain dyspneic following pleural fluid removal should be suspected of having underlying pulmonary parenchymal or pleural disease such as pneumonia or fibrosing pleuritis, respectively.

Fibrosing pleuritis is a condition that has been associated with chylothorax in both dogs and cats.[46,47] Although the cause of the fibrosis is unknown, it apparently can develop subsequent to any prolonged exudative or blood-stained effusion. Exudates are characterized by a high rate of fibrin formation.[48] Fibrin formation probably increases because chronic inflammatory exudates, such as chylothorax and pyothorax, induce changes in mesothelial cell morphologic features, resulting in increased permeability, mesothelial cell desquamation, and triggering of both pathways of the coagulation cascade.[49] Desquamated mesothelial cells have also been shown to produce type III collagen in cell culture, and promote fibrosis.[50] Additionally, the chronic presence of pleural fluid might lead to an impairment in the mechanism of fibrin degradation.[51] Fibrinolysis may decrease because direct injury to mesothelial cells may reduce inherent fibrinolytic activity of the cells, and/or the increased fluid volume may dilute local plasminogen activator. Plasminogen activator converts the precursor plasminogen to its active form, plasmin. Fibrinolytic activity in mammals is attributable primarily to this serine protease.[52]

In animals with fibrosing pleuritis, the pleura is thickened by diffuse fibrous tissue that restricts normal pulmonary expansion (Figure 217-4, *A*). Animals with fibrosing pleuritis may be misdiagnosed as having large amounts of pleural effusion, when in fact the pleural effusion is minimal. Diagnosis of fibrosing pleuritis is difficult. The atelectatic lobes may be confused with metastatic or primary pulmonary neoplasia, lung lobe torsion, or hilar lymphadenopathy. Radiographic evidence of pulmonary parenchyma that fails to re-expand after removal of pleural fluid should be considered possible evidence of atelectasis with associated fibrosis (Figure 217-4, *B*). Fibrosing pleuritis should also be considered in animals with persistent dyspnea, yet minimal pleural fluid. In human beings, computerized tomography is occasionally helpful in differentiating pleural fibrosis from other abnormalities, such as neoplasia.[53,54]

217.4.4 Diagnosis

Animals suspected of having pleural effusion should be thoroughly evaluated for underlying cardiac or respiratory disease. Thoracic auscultation may reveal decreased heart and lung sounds ventrally. Thoracic percussion may demonstrate a fluid line with hyporesonant sounds ventrally and normal sounds dorsally. Murmurs may be auscultated in animals with underlying cardiac disease. Animals should be evaluated for the

presence of jugular pulses. In cats with cranial mediastinal masses, the cranial thorax may become less compressible. See below for radiographic and ultrasonographic findings in animals with pleural effusion.

217.4.5 Thoracocentesis

In addition to relieving respiratory difficulty, thoracocentesis also provides samples to aid evaluation and diagnosis. *In the dyspneic animal, thoracocentesis should be performed prior to thoracic radiographs.* Removal of even small amounts of fluid may substantially decrease the animal's ventilatory effort. The animal should be restrained in sternal recumbency with oxygen provided by mask if tolerated. Slight sedation may be required in fractious animals; general anesthetics should be avoided. Caution should be used when sedating dyspneic animals. Typically, the mediastinum in dogs and cats appears to be incomplete and fluid aspiration from either side will permit drainage of the entire thorax. However, due to chronic inflammation and thickening of the mediastinum, unilateral effusions may be noted with certain diseases such as chylothorax and pyothorax. Thoracocentesis techniques are described in Chapter 103.

1276

1277

Figure 217-4 **A,** Intra-operative photo of a cat with severe fibrosing pleuritis secondary to chronic chylothorax. Notice the small, consolidated lung lobes and the thickened pleura. Decortication of the fibrous pleural was performed in this cat. **B,** Lateral radiograph of the cat from **A**. Note the rounded appearance of the caudal lung lobes. Removal of the pleural fluid did not improve the expansion of the lung lobes.

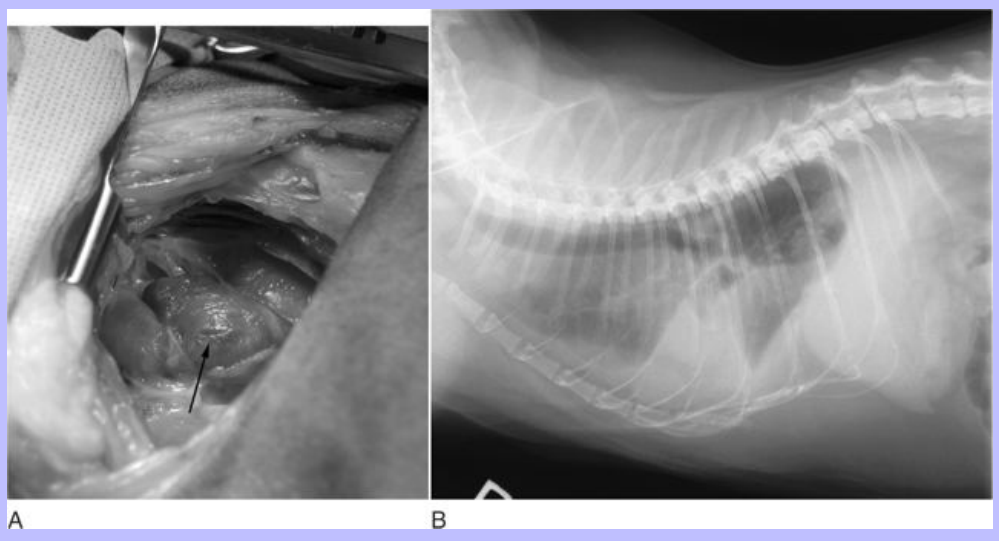


Figure 217-5 Lateral and dorsoventral radiographs of a dog with pleural effusion secondary to chylothorax. Note the loss of the cardiac and diaphragmatic silhouettes, and widened interlobar fissures.

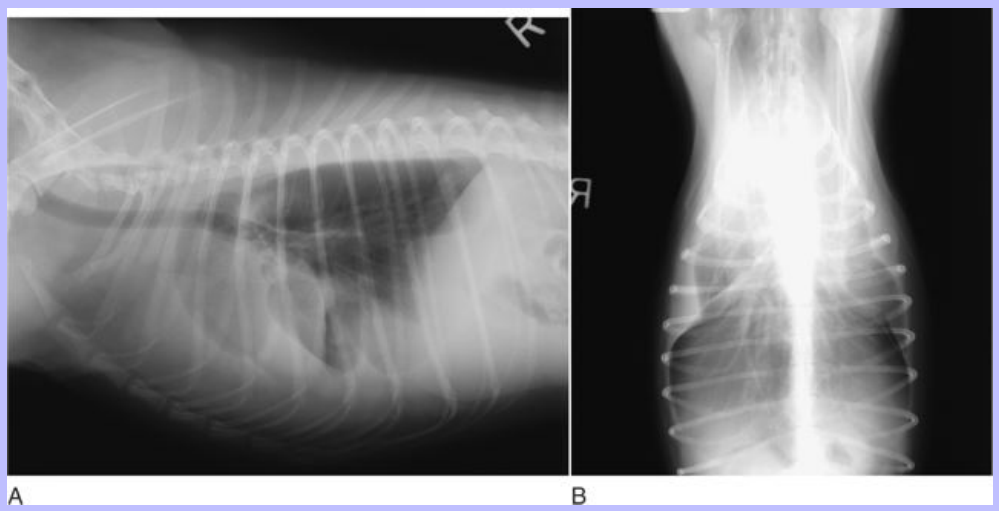


217.4.6 Radiography and Ultrasonography

If the animal is not dyspneic, thoracic radiographs should be obtained to confirm the diagnosis of pleural effusion and allow evaluation of thoracic and intra-thoracic structures (Figure 217-5). Dorsoventral (rather than ventrodorsal) and "standing lateral" views may cause less stress to a compromised animal. Handling should be minimized and supplemental oxygen provided.

1277

1278

Normal pleura is not generally radiographically visible. With pleural thickening, pleural lines may become visible and may be mistaken for pleural effusion. A horizontal beam radiograph will help differentiate the two. Roentgen signs associated with pleural effusion include widened interlobar fissures, retraction of the lung margins from the thoracic wall, rounding of the lung margins at the costophrenic angles, and obscuring of the diaphragmatic and cardiac silhouettes. Visualization of the cranial aspect of the cardiac silhouette in the presence of pleural effusion is occasionally possible with identification of the "pericardial fat stripe."[55] It is reported that a lucent line is occasionally evident at the cranial edge of the cardiac silhouette and represents the x-ray beam striking fat around the heart at a tangent. To permit more careful evaluation of intra-thoracic structures, radiographs should be repeated once the pleural fluid has been removed.

In the stable animal, ultrasonography should be performed prior to fluid removal as the fluid provides an "acoustic window" and may allow clearer visualization of intra-thoracic structures such as mediastinal masses. Ultrasonography can be used to diagnose cardiac functional and structural abnormalities and identify pericardial effusion. It may aid in location of encapsulated fluid and identification of the appropriate site for thoracocentesis.

217.4.7 Pleural Fluid Evaluation

Cytologic analysis of pleural fluid obtained via thoracocentesis is indicated. Identification of cell types and numbers, protein levels, and other physical characteristics and biochemical markers allow classification of pleural fluids into categories that aid in the identification of the underlying etiology. Fluids are generally divided into three types: transudates, modified transudates, and exudates. Additional sub-classifications include chylous, neoplastic, and hemorrhagic effusions.

Table • 217-1 Characteristics of Fluid Types

	TRANSUDATE	MODIFIED TRANSUDATE	EXUDATE	PYOTHORAX	CHYLOTHORAX	FIP
Protein content (g/dL)	<2.5	2.5–4	>3	>3.5	Variable	>5
TNCC* (cells/μL)	<1500	1000–7000	>7000	>7000	<10,000	<10,000
Color	Clear	Yellow, whitish-pink, red	White, amber, red	Amber to red or white	Usually white or pink	Straw to gold colored
Transparency	Colorless	Hazy to turbid	Opaque (usually) Turbid (rarely)	Turbid or opaque	Opaque	Hazy
Biochemical parameters			LDH >200 U/L	Glucose <10 mg/dL pH <6.9	Triglyceride >serum triglyceride	
Predominant cell types	Mesothelial cells, macrophages	Mesothelial cells, macrophages eosinophils, lymphocytes	Neutrophils (most common) Lymphocytes, macrophages, mesothelial cells, neoplastic cells	Degenerative neutrophils	Lymphocytes or neutrophils	Nondegenerative neutrophils

* *TNCC*, Total nucleated cell count.

217.4.7.1 Transudates and Modified Transudates

Pure transudates are clear, colorless fluids with a low total protein and low cellularity (Table 217-1). The primary cell type is mononuclear, with macrophages, and mesothelial cells most often present in small numbers; occasional lymphocytes or neutrophils can be seen. With chronicity, there is often a small increase in protein and cell numbers as a result of pleural irritation. Because of the low total nucleated cell count (TNCC), cytologic evaluation of a transudative fluid is most efficiently accomplished by concentrating cells with a cytospin preparation. Modified transudates develop from chronic transudates or they may result from increased vascular hydrostatic pressure or lymphatic leakage. In their initial stages, inflammatory processes may cause modified transudates to be produced. In addition to mesothelial cells and macrophages, neutrophils, and lymphocytes may be seen. Mast cells, eosinophils, and neoplastic cells are less commonly observed. A turbid sample may indicate a higher cell count, which allows cytologic evaluation to be performed from direct smears. A cytospin preparation may be used if there are not sufficient cells observed on direct smears. Diseases that may result in transudates and modified transudates include hypoalbuminemia, right-sided heart failure, pericardial disease, diaphragmatic hernia, and neoplasia.

217.4.7.2 Exudates

Exudates have a high protein concentration (see Table 217-1) and higher nucleated cell counts than transudates or modified transudates. They range in color from white to amber or red. The high TNCC of exudates allows accurate cytologic evaluation to be obtained from direct smears. The predominant nucleated cell typed depends on the cause of the exudate. Neutrophils are the most common cell type seen in inflammatory processes. Other nucleated cell types found in exudates include mesothelial cells, macrophages, lymphocytes, and neoplastic cells. A predominance of lymphocytes may indicate a chylous effusion. A mixed cell population, with increased numbers of macrophages and neutrophils may be seen with more chronic chylous effusions. Fungal disease or foreign body reaction should be considered if pyogranulomatous inflammation (equally mixed population of neutrophils and macrophages) is noted. 1278 1279

Mesothelial cells are generally present in all effusions. Reactive mesothelial cells can exhibit characteristics of malignancy and should be interpreted with extreme caution in the presence of inflammation.[56] With the exception of lymphoma, it can be difficult or impossible to definitively identify a neoplastic process on the basis of pleural fluid evaluation. Other neoplastic cells that may exfoliate into pleural fluid include carcinoma cells, mast cells, and cells from malignant melanoma. Degenerative neutrophils indicate a septic process and the presence of bacterial toxin; careful evaluation of the smear for free or intracellular bacteria should follow.

Aerobic and anaerobic bacterial culture and sensitivity should be performed on all samples in which degenerative neutrophils are present, even if bacteria are not evident. Non-degenerative neutrophils suggest a non-septic process or low-grade sepsis. Bacterial culture and sensitivity may be indicated if alternate causes are not identified. Diseases that can result in exudative pleural effusions include neoplasia, chronic diaphragmatic hernia, feline infectious peritonitis, lung lobe torsions, lymphatic obstruction or leakage, and infectious processes.

217.4.8 Biochemical Parameters and Additional Fluid Evaluation

Many biochemical parameters of pleural effusions have been studied in attempts to further classify effusions and determine underlying etiologies. Most of these assays have been validated in people but have not been fully characterized in veterinary medicine. Analyses most frequently used in veterinary medicine include triglyceride, cholesterol, pH, lactate dehydrogenase (LDH), and glucose levels. Serum and fluid triglyceride concentration comparisons are used to definitively diagnose chylothorax (see below). Glucose and pH measurements can be helpful in identifying septic effusions; studies of pleural effusions in cats indicate that a glucose less than 10 mg/dL and a pH less than 6.9 are supportive of a septic effusion.[57] In people, a glucose concentration lower than normal is suggestive of tuberculosis, malignancy, rheumatoid disease, or a parapneumonic effusion. In one study of cats with pleural and peritoneal effusions, adenosine deaminase levels in effusions from cats with FIP were higher than those in unaffected cats.[58]

In humans, much work has concentrated on testing that may help differentiate neoplastic from non-neoplastic effusions. The pH of malignant effusions is typically greater than 7.2.[57] As noted above, decreased glucose concentrations can be supportive of neoplastic disease. Telomerase enzyme activity has been evaluated and was found to be equally as sensitive but less specific than cytology in differentiating fluid of malignant versus benign origin.[59] Vascular endothelial growth factor (VEGF) is expressed by some tumors and is believed to be a causative factor in the pathogenesis of both neoplastic and non-neoplastic effusions[60–62] by increasing

capillary permeability.[63] Receptors for VEGF have been found in mesothelial cells.[64] In mice models, blockage of VEGF activity has led to a marked reduction in the volume of pleural effusion produced.[65] In people, high plasma or serum VEGF concentrations have been associated with a high tumor burden, presence of metastases and a poor prognosis.[66–68] However, elevations in VEGF are not specific for neoplasia and can also be found in inflammatory and infectious effusions. Very high VEGF levels have been noted in exudative effusions.[69] One study in dogs did not detect a difference in VEGF levels between neoplastic and non-neoplastic effusions.[70] In people, immunocytochemistry and chromosome analysis may also be useful in the diagnosis, classification, and prognostication of neoplastic effusions.

217.4.9 Eosinophilic Effusions

Pleural effusions are defined as being eosinophilic when greater than 10% of leukocytes identified are eosinophils.[71] Eosinophilic effusions have been reported in dogs in association with heartworm disease, systemic mastocytosis, interstitial pneumonia, and disseminated eosinophilic granulomatosis.[72–75] In a retrospective study of 14 cases, eosinophilic effusions were associated with diseases such as thoracic wall trauma, pneumothorax, neoplasia, congestive heart failure, and hypersensitivity states.[76] In that study, 43% of cases had neoplastic diseases. Eosinophilic pleural effusion was diagnosed 2 days after pneumothorax developed as a consequence of thoracic tube placement in one cat, and pneumothorax was diagnosed in another cat with eosinophilic peritoneal effusion. Eosinophilic pleural effusion has been associated with pneumothorax in people.[71,77] A report of a dog with pleural effusion secondary to discospondylitis cited cytology of the effusion as an exudate with *Paecilomyces* spp. fungal organisms present.[78] The pleural fluid contained a moderate number of eosinophils. It is believed that eosinophils may accumulate in the pleural space in response to pleural irritation.[79] Some authors suggest that leukotrienes or immune complexes may be chemotactic for eosinophils.[80] Corticosteroid responsive eosinophilic effusions have been reported[73,77]; therefore immune-mediated disease should be considered if alternate causes are not identified.

217.5 PYOTHORAX

Pyothorax is the presence of purulent material in the pleural space; bacterial pleuritis results in accumulation of hemopurulent fluid. The pleural fluid is classified as an exudate. Cytology usually reveals a very high nucleated cell count (often 50,000 to 100,000/uL) and is composed primarily of degenerative neutrophils. Nondegenerate neutrophils can be present if the animal was previously treated with antibiotics or in the presence of certain bacterial agents. Effusions caused by fungi and bacterial organisms such as *Actinomyces* and *Nocardia* spp. may contain nondegenerative neutrophils and macrophages if toxins produced affect only cells in close approximation to the organisms.[81] Multiple intra-and extracellular bacteria can be present; however, the possibility of contamination should be examined if only extracellular bacteria are noted. Macrophages are present in various numbers, depending on the causative organism and chronicity of the effusion. Leukophagocytosis is often seen in chronic infections. Reactive mesothelial cells are frequently present and should be interpreted with caution as they can exhibit criteria of malignancy. Multiple organisms are often cultured. In cats, obligate anaerobes or *Pasteurella* spp. are the most common isolates; in dogs obligate anaerobes or gram-positive filamentous organisms (i.e., *Actinomyces* and *Nocardia* spp.) are frequently cultured (Table 217-2).

The cause of pyothorax is often not identified. It can result from penetrating thoracic wounds, migration of foreign material (e.g., grass awns, particularly in working or hunting dogs), hematogenous spread, extension

from other sites such as discospondylitis or pneumonia, pulmonary neoplasia, pulmonary or thoracic wall trauma, or from a postoperative infection. The underlying disease process should be identified and treated if possible.

Table • 217-2 Bacteria Commonly Associated with Pyothorax in Small Animals

BACTERIA	OXYGEN REQUIREMENTS	GRAM STAIN	MORPHOLOGY	ANTIBIOTIC SENSITIVITY*
Actinomyces spp. (most common in dogs)	Facultative anaerobe to strict anaerobe	Gram-positive	Small rods; may form filaments; often beaded and difficult to discern in clinical specimens; may form sulfur granules	**Ampicillin, amoxicillin plus clavulanic acid, penicillin,** clindamycin, chloramphenicol, erythromycin, minocycline
Bacteroides spp.	Obligate anaerobe	Gram-negative	Bacilli; pleomorphic and may be beaded or cocci, often stain poorly and are difficult to see	Most Bacteroides–**ampicillin, amoxicillin plus clavulanic acid**, clindamycin, chloramphenicol, metronidazole *B. fragilis*–**amoxicillin +clavulanic acid, clindamycin,** chloramphenicol, metronidazole
Clostridium spp.	Obligate anaerobe	Gram-positive	Rods; large, frequently encapsulated, motile, spores uncommon from clinical specimens	Most Clostridium–ampicillin, **amoxicillin plus clavulanic acid,** chloramphenicol, **metronidazole** *C. perfringens*–**ampicillin, amoxicillin plus clavulanic acid,** cefoxitin, clindamycin, chloramphenicol, metronidazole, erythromycin
Escherichia coli	Aerobe, facultative anaerobe	Gram-negative	Rods but shape can vary widely; never forms spores	**Amikacin, enrofloxacin,** ceftizoxime, potentiated sulfa drugs
Fusobacterium spp.	Obligate anaerobe	Gram-negative	Bacilli; often have a cigar-shaped appearance	**Penicillin,** clindamycin, chloramphenicol, metronidazole
Klebsiella *spp.*	Facultative anaerobe	Gram-negative	Rods; mucoid and encapsulated	**Cephalosporin,** gentamicin, tobramycin, ticarcillin
Nocardia spp. (most common in dogs)	Aerobe	Gram-positive (partly acid fast)	Long, filamentous and branching cocci or bacilli; most species produce hyphae; exudates typically have appearance of tomato soup; sulfur granules may be uncommon	**Trimethoprim-sulfa, amikacin,** imipenem, ciprofloxacin, cefotaxime, ceftriaxone
Pasteurella spp. (most common in cats)	Facultative anaerobe	Gram-negative	Coccobacilli; pleomorphic, bipolar staining	**Ampicillin, amoxicillin plus clavulanic acid, cephalosporins,** aminoglycosides
Pseudomonas spp.	Aerobe	Gram-negative	Rods; slender, motile	**Ticarcillin plus clavulanic acid, amikacin, enrofloxacin, gentamicin,** tobramycin, cefotaxime

Modified from Fossum, TW: *Small animal surgery,* ed 2, St Louis, 2002, Mosby, p 813.

* Boldface type denotes typical drugs of choice.

These animals should be managed aggressively as treatment with antibiotics alone is not usually effective. A chest tube should be placed once the diagnosis is made. Bilateral thoracostomy tubes are sometimes necessary with chronic effusions as thickening of the pleura may create a complete mediastinum. Most animals can be successfully managed with intermittent tube aspiration. Thoracic lavage with warm saline or lactated Ringer's

solution should be performed two or three times daily. Twenty mL/kg should be infused slowly into the thoracic cavity and allowed to remain for 1 hour. Animals should be closely monitored for dyspnea and the lavage fluid removed earlier if necessary.

The addition of antibiotics to the lavage fluid offers no advantage over appropriately administered systemic antibiotics. Antibiotics should be chosen based on Gram stain and microbial culture and sensitivity results. Due to the high proportion of anaerobic infections, drugs with a spectrum against obligate anaerobic organisms should be used. Antibiotics should be continued for a minimum of 4 to 6 weeks. Surgery is mandatory in animals with underlying diseases such as foreign bodies, lung abscesses, or lung lobe torsions; and should be considered in animals that do not respond to medical treatment in the first 3 to 4 days. Readers are referred to a surgical text for additional information.

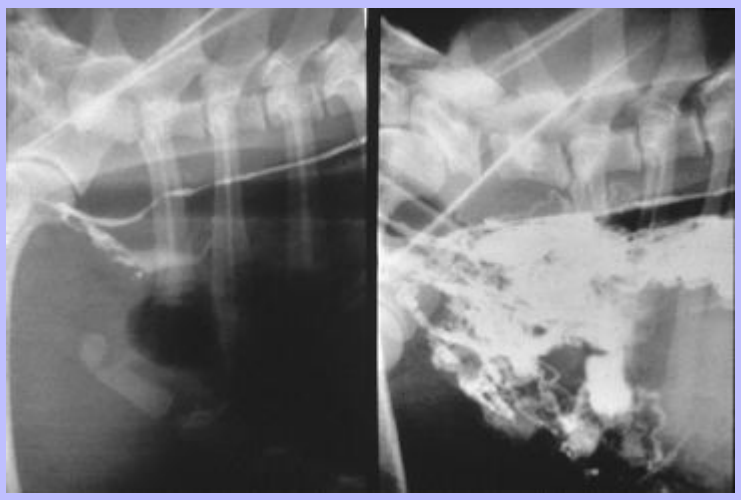
1280 1281

217.6 CHYLOTHORAX

Chyle is the milky fluid absorbed by the lacteals from food in the intestines. It is composed of lymph and triglyceride droplets (chylomicrons). *Chylothorax* refers to the accumulation of chyle in the pleural space. Chylothorax was once believed to be a result of trauma to the thoracic duct. Although this occasionally occurs in veterinary patients, the resulting effusion is usually self-limiting and resolves within 2 weeks. Trauma is, however, still considered a reasonable cause of chylothorax in human patients. Chylothorax may develop from increased lymphatic flow (due to increased hepatic lymph production), from decreased lymphatic drainage into the venous system, or from both. Disease processes that result in increased systemic venous pressures, such as right-sided heart failure, have been shown to cause chylothorax.[82] FeLV and FIV status should be evaluated in affected cats. Chyle is thought to exude from intact but dilated thoracic lymphatics (thoracic lymphangectasia) (Figure 217-6). Chylothorax may also occur in conjunction with diffuse lymphatic disease such as intestinal or generalized lymphangectasia. Chylothorax secondary to pulmonary lymphangiosarcoma has recently been reported in a dog.[83]

The thoracic duct (TD) arises from the cisterna chyli and is the major lymphatic vessel for the return of lymph to the venous system. Thoracic duct anatomy varies between and among species. It usually begins as a single duct, but multiple branches are often present. The convergence with the venous system occurs at the “venous angle” in the cranial vena cava where the external and internal jugular veins meet. In the dog the TD lies to the right of midline in the caudal thorax and crosses to the left side at approximately the fifth intercostal space, whereas in the cat it lies to the left side throughout its course through the diaphragm.

Figure 217-6 Mesenteric lymphangiogram from a normal dog (*left*) and a dog with idiopathic chylothorax (*right*). Notice the entrance of the thoracic duct into the venous system in the normal dog and the marked lymphangiectasia in the dog with chylothorax. Chylothorax is thought to occur as a result of leakage from these dilated, tortuous cranial mediastinal lymphatics.



Animals presenting with chylous pleural effusion should be thoroughly evaluated for underlying diseases that may interfere with lymphatic flow or increase the pressure against which the thoracic duct must empty. These include heart disease (cardiomyopathy, heartworm disease, pericardial effusion, tetralogy of Fallot, tricuspid dysplasia, or cor triatriatum dexter), cranial mediastinal masses (lymphoma, thymoma), fungal granulomas, venous thrombi, or congenital abnormalities of the TD. In those cases with a defined etiology, treatment is aimed at the underlying cause. Intermittent thoracocentesis palliates the clinical signs until a definitive treatment is instituted (if possible). In the majority of animals, however, a cause is not identified (idiopathic chylothorax).

Although any breed of dog or cat may be affected, breed dispositions are suspected in Afghan hounds, Shiba Inus, and Oriental cat breeds (Siamese, Himalayan). A sex predilection has not been identified and the disease has been reported in all ages. Afghans tend to develop the disease in middle age, whereas affected Shiba Inus tend to be less than 1 year of age. In one study that showed older cats more likely to be affected than younger ones, an association with neoplasia was suspected.[84]

Coughing is usually the first and may be the only clinical sign noted in both dogs and cats. Animals with a history of a chronic cough that is unresponsive to general treatment should be evaluated for the presence of thoracic fluid. As noted earlier, coughing may be caused by irritation from the effusion or from the underlying disease process. Many animals present with acute respiratory distress as an emergent situation to the veterinarian, without overt history of previous clinical signs of respiratory disease.

Physical exam findings attributable to the presence of pleural fluid include decreased or muffled heart sounds, decreased ventral lung sounds, and increased bronchovesicular sounds dorsally. Mucous membrane color varies

from normal to cyanotic, depending on the severity of respiratory compromise. Weight loss is often noted with animals with chronic disease due to the loss of fat and protein into the thoracic cavity. Other physical exam findings such as heart murmurs may be present depending on the underlying disease process.

Thoracocentesis revealing milky, opaque fluid permits a tentative diagnosis of chylothorax and should prompt the veterinarian to search for underlying causes. The fluid consistency and color will vary depending on dietary fat content and the presence of concurrent hemorrhage. Fluid samples should be placed in an EDTA tube for cytologic evaluation. Although lymph fluid is resistant to infection due to the presence of fatty acids, samples should be submitted for bacteriologic culture and sensitivity, particularly if repeated thoracocentesis has been performed. Chylous fluid may be classified as an exudate or as a modified transudate, depending on the protein levels and nucleated cell counts which can vary with chronicity and previous treatment. Lymphocytes are typical, but nondegenerate neutrophils are commonly noted with more chronic cases. Protein content is variable and may be inaccurate due to the high lipid content of the fluid. Truly chylous fluids should contain chylomicrons, should clear with the addition of ether, and be positive for the presence of lipid droplets with Sudan III stain. A definitive diagnosis of chylothorax is obtained by comparing fluid and serum triglyceride levels; in chylothorax, fluid triglyceride should be higher than that of simultaneously collected serum.

Differential diagnoses include any other causes of cough or pleural effusion. Once the diagnosis of pleural effusion is made, diseases that cause exudative effusions, such as pyothorax, are considered differentials and should be investigated. Pseudochylous effusion refers to thoracic fluid in which the fluid triglyceride level is less than that of serum and fluid cholesterol level greater. Pseudochylous effusions are rare in veterinary patients and may be associated with tuberculosis.

1281 1282

As noted earlier, treatment should be directed at the underlying disease process, if identified, and clinical signs palliated by intermittent thoracocentesis. Resolution of the effusion will depend on the underlying cause and may take several months. Surgical treatment should only be considered in animals with idiopathic chylothorax or those that do not respond to medical management.

Medical management of animals with chylothorax involves feeding a low-fat diet, performing needle thoracentesis as needed to relieve dyspnea (not on a regular basis), and supplementing the dog or cat with a benzopyrone such as Rutin (50 to 100 mg/kg, TID, PO). The effusion may spontaneously resolve over a period of weeks or months. If the animal cannot be managed medically, surgical intervention is typically recommended. Thoracic duct ligation is the most widely accepted method for treating animals with chylothorax, yet this intervention has not been reported to be highly successful in alleviating the chylous accumulation. Thoracic duct ligation resulted in complete resolution of pleural effusion in only approximately 50% of dogs operated; in cats, the success rate was even less (<40%).[84–86] A more recent study reported 100% efficacy in dogs and 80% in cats when TD ligation and/or pericardictomy were performed.[88]

Advantages of thoracic duct ligation are that if it is successful it results in complete resolution of pleural fluid (as compared to palliative procedures such as pleuroperitoneal shunting) and thus it may prevent fibrosing pleuritis from developing. Disadvantages include that operative time is long, which is problematic in debilitated animals, there is a high incidence of continued or recurrent chylous or nonchylous (from pulmonary lymphatics) effusion, and mesenteric lymphangiography is often difficult to perform, particularly in cats. Without mesenteric lymphangiography, complete ligation of the thoracic duct is difficult to ensure. Ligation of the thoracic duct using thoracoscopy has been described.[87]

Thoracic duct ligation plus pericardectomy was recently reported as a treatment for chylothorax.[88] In this study, TD ligation plus pericardectomy was performed in 18 animals, and pericardectomy alone was performed in an

additional two animals. Nineteen animals presented for evaluation of chylothorax (9 dogs, 10 cats), whereas one dog presented for serosanguineous pleural fluid after TD ligation that had been performed elsewhere. Echocardiography was normal in all animals with the exception of a subjectively thickened pericardium in six dogs and seven cats. Clinical signs of pleural fluid resolved in ten of ten dogs and eight of 10 cats after surgery. The overall success rate for surgical treatment of chylothorax in this study was 90%.

217.7 NEOPLASTIC PLEURAL EFFUSION

Differentiation of neoplastic and non-neoplastic effusions can be difficult. Neoplastic processes commonly resulting in pleural effusion include mesothelioma, lymphoma, multiple myeloma, carcinoma of the lung, and metastatic mammary neoplasia. Effusions caused by neoplastic processes are often hemorrhagic.

Mesotheliomas can arise from the mesothelial cells of the pleura, pericardium, or peritoneum and can be malignant or benign. Congenital mesotheliomas have been described in calves.[89] In people, mesotheliomas are frequently associated with exposure to asbestos.[90] Histologically, mesotheliomas can be fibrous or epithelial; in humans both are seen but pleural mesotheliomas in dogs are predominantly the epithelial type. Metastasis to other intrathoracic organs such as the myocardium, tracheobronchial lymph nodes, and lung is common. This tumor may also invade the diaphragm and enter the abdomen. A diagnosis is not usually made on fluid evaluation because of the difficulty in differentiating neoplastic versus reactive mesothelial cells (see above); a surgical or thoracoscopic biopsy is generally necessary to obtain a definitive diagnosis. Readers are referred to an oncologic textbook for additional information on diagnosis and treatment of mesotheliomas.

In human medicine, pleurodesis is often used to decrease the incidence of malignant effusions. Attempts at pleurodesis in dogs have been unrewarding[91] and are not recommended by the authors. More recent research has focused on the possible etiologies of the effusions. Vascular endothelial growth factor (VEGF) is thought to play a role in the development of malignant effusions. Studies in mice have demonstrated a reduction in the formation of pleural effusion with treatment directed at VEGF receptor inhibition.[65]

217.8 PNEUMOTHORAX

217.8.1 Traumatic Pneumothorax

Pneumothorax in small animals is most frequently closed (no communication between the pleural space and external environment) and traumatic in origin secondary to motor vehicle accidents or other blunt trauma. Pulmonary or bronchial rupture can occur when a blow to the thorax results in a sudden increase in intrathoracic pressure, theoretically against a closed glottis. Alternatively, shearing forces on the lung may result in subpleural bleb formation, similar to that seen in spontaneous pneumothorax. Pneumothorax secondary to a bronchial tear has been reported following venipuncture in a kitten.[92]

Penetrating injuries such as bite wounds and gunshot wounds can result in an open pneumothorax, where communication exists between the pleural space and external environment. Penetrating wounds may permit influx of air into the pleural space with inspiration and rapid equilibration of intrathoracic and atmospheric pressures. The normal pressure gradient is necessary for mechanical function of the lungs and proper air exchange. Loss of negative intrathoracic pressure also decreases venous return to the heart. Abdominal wounds may result in a pneumothorax if a diaphragmatic hernia is present. A tension pneumothorax develops when the fistula between the pleura and the external environment or the pleura and the lung acts as a one-way valve, which allows air to enter on inspiration but not exit on expiration. Positive pressure develops in the

pleural space causing collapse of the lungs and great veins. Fatal decreases in ventilation and cardiac output rapidly ensue. Iatrogenic tension pneumothorax has been reported secondary to lung or airway rupture in animals that receive positive pressure ventilation.[93] As with diaphragmatic hernias, young male dogs are more likely to incur vehicular or other causes of trauma and are therefore more likely to develop traumatic pneumothorax. Traumatic pneumothorax is less commonly reported in cats.

217.8.2 Spontaneous Pneumothorax

Pneumothorax is classified as spontaneous when no traumatic or iatrogenic cause is identified. Spontaneous pneumothorax is thought to result from rupture of pulmonary blebs or bullae and is considered primary when there is no evidence of underlying pulmonary disease. Subpleural blebs are most commonly located in the apices of the lungs. Primary spontaneous pneumothorax occurs most frequently in large, deep-chested dogs such as hounds. One recent retrospective study reported an over-representation of Siberian Huskies in their case population.[94] Middle-aged dogs are most commonly affected; there does not appear to be a sex predilection.

Secondary spontaneous pneumothorax is more common in dogs than the primary form and occurs when there is underlying pulmonary disease such as pulmonary abscesses, diffuse emphysema, neoplasia, dirofiliarisis, pneumonia or pulmonary parasites such as *Paragonimus* spp. Spontaneous pneumothorax has also been reported in cats with *Dirofilaria immitis* infection.[15] It may also be seen secondary to chronic granulomatous infections or chronic airway obstruction and subsequent overpressurization of abnormal lungs.[95,96] The majority of affected people are cigarette smokers, which suggests that the underlying pulmonary disease could be a result of interference of the normal function of $alpha_1$-antitrypsin in inhibiting elastase. It is believed that $alpha_1$-antitrypsin is inactivated in people who smoke, which allows increased elastase-induced destruction of pulmonary parenchyma.

1282 1283

217.8.2.1 History and Physical Examination

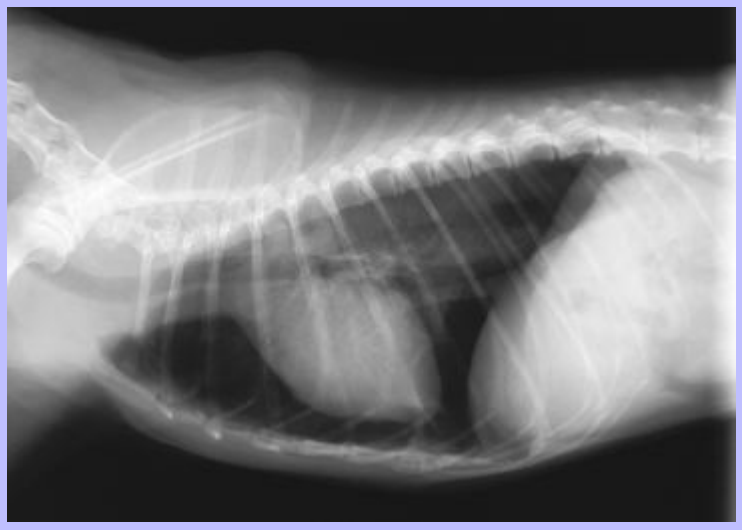
Animals with pneumothorax generally present with acute dyspnea and shallow, rapid respiration. A history of trauma is often vague, which makes it sometimes difficult initially to distinguish between traumatic and spontaneous pneumothorax. In animals with secondary spontaneous pneumothorax, a history attributable to underlying respiratory disease (e.g., chronic cough, fever) may be ascertained. Dogs with pneumothorax are initially able to compensate by increasing their chest wall expansion with inspiration. Animals with hypoxemia will appear cyanotic. Hypoxemia is thought to be a result of impairment of gas exchange, increased pulmonary shunting, and V/Q (ventilation-perfusion) mismatch[97] (increased alveolar-arterial PO_2 difference). In traumatic pneumothorax, concurrent injuries such as rib fractures and pulmonary contusions may exacerbate the clinical signs of respiratory compromise. Auscultation of the thoracic cavity may reveal decreased or muffled heart and lung sounds dorsally. Tension pneumothorax is a rapidly fatal condition. A barrel-shaped chest may be evident as pressure within the thoracic cavity increases. Cyanosis and signs attributable to markedly decreased cardiac output are evident.

217.8.2.2 Diagnosis

Thoracocentesis should be performed to stabilize the dyspneic animal prior to thoracic radiographs being taken. Pneumothorax is most commonly bilateral. Radiographic signs consistent with a pneumothorax include elevation of the heart off the sternum, collapse of the lung lobes and retraction from the chest wall,

and a radiolucent area of free air in which no pulmonary vascular structures are visible, most evident in the caudal thorax (Figure 217-7). In severe cases, the diaphragm may appear flattened or caudally displaced. Apparent elevation of the heart from the sternum is a result of atelectasis of the dependent lung lobes allowing the heart to shift its position with the chest. To identify small volumes of free air, the most sensitive radiographic view is a horizontal beam taken with the animal in lateral recumbency. Although it may be difficult to identify in the presence of collapsed lung lobes, radiographs should be carefully evaluated for underlying pulmonary parenchymal or other thoracic diseases such as trauma or neoplasia. Pulmonary blebs are difficult to identify radiographically. Bullae may be an incidental finding in some cases. Removal of air with thoracocentesis is diagnostic of pneumothorax if radiographs are unclear or unavailable. Pneumomediastinum is characterized by the ability to distinguish thoracic structures (i.e., aorta and great vessels, trachea, vena cava, esophagus) within the mediastinum that are not usually apparent on thoracic radiographs.

Figure 217-7 Lateral radiograph of a dog with pneumothorax. Note the apparent elevation of the heart from the sternum.



217.8.2.3 Treatment

A thoracostomy tube may be required in animals in which air rapidly accumulates. Intermittent or continuous aspiration can be used depending on the volume of air recovered from the thoracic cavity and rate at which it accumulates. Once the animal has been stabilized, the cause of the pneumothorax should be identified. Traumatic pneumothorax is most commonly managed conservatively; surgical intervention is rarely necessary. Thoracocentesis or chest tubes (see Chapter 103) can be used to manage air accumulation and dyspnea while the pulmonary lesions heal, usually within 3 to 5 days. Supplemental oxygen therapy may be beneficial in animals with pulmonary contusions or hemorrhage. Pain management is essential in animals that have experienced trauma; analgesics may help improve ventilation by decreasing the pain associated with thoracic wall movement. Recurrence of traumatic pneumothorax is uncommon. Open chest wounds should be covered immediately. Once the animal has been hospitalized, the wound can be addressed and covered with a sterile, occlusive dressing. Readers are referred to a surgical text for more detailed information on thoracic wound management.

Animals with spontaneous pneumothorax generally require thoracostomy tube placement. As opposed to animals with traumatic pneumothorax, those with spontaneous disease often require surgical intervention. A median sternotomy allows access to both sides of the lungs and permits thorough exploration of the thoracic cavity. If not immediately evident, pulmonary and airway leaks may be identified by filling the pleural space with warm physiologic saline and looking for air bubbles. Animals that undergo surgical treatment of spontaneous pneumothorax are less likely to have recurrence and have lower mortality than those that are managed conservatively.[94] Surgical exploration may permit identification of the underlying etiology that may have not been readily apparent previously. Thoracoscopic evaluation of the thorax has been reported for people and dogs with spontaneous pneumothorax and may obviate the need for surgery if a cause can be identified and treated.[98–100]

218 CHAPTER • 218 Pulmonary Hypertension and Pulmonary Thromboembolism

Kristin A. MacDonald

Lynelle R. Johnson

218.1 Pulmonary Hypertension

Pulmonary hypertension (PH) is defined by a systolic pulmonary artery pressure greater than 25 mm Hg. The incidence of PH is difficult to define due to lack of clinical awareness, nonspecific clinical signs, and difficulty in confirming the diagnosis. Unfortunately, many patients with PH are diagnosed late in the course of disease when irreversible vascular pathology has developed. PH results from many diseases and pathophysiologic mechanisms and most commonly occurs secondary to chronic cardiopulmonary disease.

218.1.1 Relevant Pulmonary Physiology

Normal pulmonary vasculature is a low-resistance, low-pressure, high-capacitance circuit. Normal, awake dogs at sea-level have a systolic pulmonary artery (PA) pressure between 15 to 25 mm Hg, end-diastolic PA pressure of 5 to 10 mm Hg, and a mean PA pressure of 10 to 15 mm Hg.[1] When cardiac output increases, such as during exercise, there is recruitment of additional pulmonary arterioles to maintain normal PA pressure. Regional pulmonary perfusion is regulated by pulmonary arteriolar vasoconstriction. Hypoxic vasoconstriction matches pulmonary perfusion to alveolar ventilation and limits the impact of low ventilation on arterial oxygenation. However, with global alveolar hypoxia, the protective effects of hypoxic vasoconstriction are offset by widespread vasoconstriction and development of PH.

The vascular endothelium mediates vascular tone and remodeling through release of several neurohormonal factors, and endothelial injury plays a key role in development of PH. In the normal lung, there is a balance between locally acting vasodilators including prostacyclin (PGI_2) and nitric oxide (NO) versus potent vasoconstricting substances including thromboxane, endothelin-I (ET-1), and angiotensin II (AT-II). Endothelial dysfunction in PH contributes to smooth muscle cell proliferation, increased production of vasoconstrictor mediators including ET-1 and AT-II, and decreased synthesis of vasodilating substances including PGI_2 and NO.[2] Pulmonary artery thrombi are seen histologically in both primary PH (PPH) and secondary PH in people. Pro-coagulant affects may be mediated by increased TXA_2 and tissue factor, as well as reduced anti-coagulant mediators including NO, PGI_2, and thrombomodulin.[3]

218.1.2 Classification of Pulmonary Hypertension

Classification of PH through hemodynamic and pathophysiologic mechanisms helps to guide interventional treatment. Mean pulmonary artery pressure (MPAP) is related to pulmonary blood flow (PBF) and pulmonary vascular resistance (PVR) by the equation

$$\text{MPAP} = (\text{PVR} \times \text{PBF}) + \text{Pulmonary capillary wedge pressure (PCWP)}$$

Abnormalities of any component of this equation can cause PH.

Pre-capillary PH occurs due to abnormalities of the pulmonary arterial vascular bed and is characterized by increased systolic, mean, and diastolic PAP, increased PVR, and normal PCWP. PVR is closely related to total cross-sectional area of the small muscular arteries and arterioles. Given the high capacitance of the pulmonary vasculature, 50% of the pulmonary vasculature must be destroyed before PH develops.[4] Diseases that cause pre-capillary PH include primary pulmonary hypertension (PPH), Eisenmenger's complex, chronic pulmonary disorders, pulmonary thromboembolism (PTE), and peripheral pulmonary artery branch stenosis. PPH has not yet been identified in veterinary medicine. Eisenmenger's syndrome is an irreversible, obliterative vascular disease that results from severe left to right shunting congenital heart disease that reverses to shunt right to left. Chronic respiratory disorders may result in PH in some individuals through hypoxic pulmonary vasoconstriction, extramural compression of the pulmonary arterioles, and destruction of pulmonary microvasculature. In the absence of pulmonary arterial pathologic changes (plexiform lesions, necrotizing arteritis, hyalinizing fibrosis), PH due to hypoxic vasoconstriction may be dynamic and respond to therapeutic intervention.

In post-capillary PH, PAP passively increases due to elevated PCWP. PA diastolic pressure is within 5 mm Hg of the PCWP, and PVR is normal. Left-sided congestive heart failure (CHF) is the most common cause of increased PCWP and may result from severe mitral valve disease, dilated cardiomyopathy, or diastolic heart disease. A mixed hemodynamic response may be seen with chronic elevations in PCWP and consists of a disproportionate elevation in PA pressures in comparison to elevated PCWP. The mechanism for increased PVR in response to elevated PCWP is not entirely clear but likely involves endothelin-1 release, endothelial dysfunction, and abnormal pulmonary vasodilatory reserve.[4] Approximately 30% of human patients with chronic pulmonary venous hypertension develop increased PVR.[4] Based on clinical experience, a low percentage of dogs with severe mitral regurgitation have a mixed hemodynamic response of PH.

Pulmonary blood flow (PBF) can be increased selectively by left to right shunting congenital heart diseases (ASD, VSD, PDA) and some patients are at risk for development of Eisenmenger's physiology. PBF is also increased by high output cardiac disease (arteriovenous fistula, chronic anemia, and hyperthyroidism); however, most patients do not develop recognizable PH. Pneumonectomy leads to selective increases in pulmonary blood flow, but PH is not recognized as a complication in dogs.

Cor pulmonale is defined as heart disease due to PH resulting from chronic pulmonary disease. The most common cause of cor pulmonale in veterinary medicine is heartworm disease in dogs. PH leads to acquired pressure overload of the right ventricle characterized by chamber dilation primarily and also concentric hypertrophy. RV myocardial failure may occur due to inadequate reduction of wall stress and may be worsened by myocardial ischemia from reduced right coronary artery perfusion pressure.[2] The extent of concentric hypertrophy and dilation of the RV ventricle depends on the age of the animal, the severity and duration of pressure overload, and the time course of progression.

1284 1285

218.1.3 Clinical Features

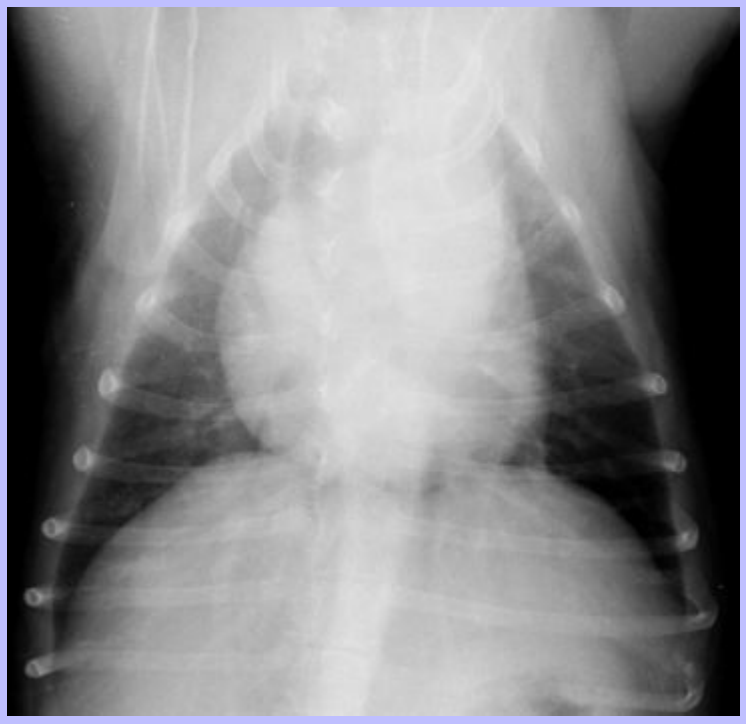
Clinical manifestations of PH are difficult to distinguish from those of underlying cardiopulmonary disease. Ascites may be the most obvious abnormality and is often accompanied by other signs of right heart failure including jugular vein distension or pulsation, subcutaneous edema, and cachexia. The most common clinical signs are nonspecific respiratory abnormalities such as coughing, tachypnea, and respiratory distress. Syncope is relatively common in dogs with PH. Adventitious lung sounds may be ausculted with primary respiratory disease or CHF. Cyanosis can be seen in patients with right-to-left cardiac shunts or severe respiratory disease.

Cardiac auscultation may reveal a split or loud pulmonic component to the second heart sound. Right and left apical systolic murmurs are commonly heard due to tricuspid and mitral regurgitation, respectively.

A minimum database (CBC, chemistry, urinalysis) and heartworm test should be performed to identify underlying diseases that may be associated with PH. Hypoxemia and acidosis should be identified since hypoxemia can cause PH and both may worsen PH.

Thoracic radiographs are necessary to detect respiratory or cardiac diseases that may be associated with PH. Thoracic radiography is almost always abnormal, and cardiomegaly is most commonly seen. Identification of RV enlargement and dilated central pulmonary arteries with rapid tapering towards the periphery should greatly increase clinical suspicion of severe PH (Figure 218-1). Eisenmenger's complex is characterized by pulmonary undercirculation and right heart enlargement. Substantial left atrial enlargement and perihilar to caudo-dorsal pulmonary infiltrates indicate left sided CHF and possible post-capillary PH.

Figure 218-1 Dorsoventral thoracic radiograph of a dog with PH. There is severe right heart enlargement and dilated central portions of the pulmonary arteries.



Electrocardiographic assessment of right heart enlargement is insensitive, and abnormalities are present only with severe PH. Deep S waves and right axis deviation may be seen with severe RV hypertrophy, and tall peaked P waves may indicate right atrial enlargement. Sinus tachycardia is a common rhythm abnormality.

Echocardiography is a useful, noninvasive tool to detect PH and cor pulmonale in veterinary and human medicine.[5,6] Echocardiographic characteristics include RV concentric hypertrophy and dilation, dilation of the

main pulmonary artery and main branches, systolic flattening of the interventricular septum, and paradoxical septal motion (Figure 218-2). In severe PH, the left ventricular dimensions may be reduced due to ventricular underfilling and ventricular interdependence. Pulmonic stenosis (PS) must be ruled out by a normal PA systolic blood flow velocity of less than 1.5 m/s before PH can be documented. In the absence of PS, the RV systolic pressure equals the PA systolic pressure. Using the modified Bernoulli equation (Pressure gradient = 4 × velocity^2), spectral Doppler allows reasonably accurate estimations of RV systolic pressure via measurement of triscuspid regurgitation velocity, and PA diastolic pressure via measurement of pulmonic insufficiency velocity (Figure 218-2). The RV: RA pressure gradient is added to the estimated RA pressure (5 mm Hg is normal, 10 to 15 mm Hg in right heart failure) for the estimated RV systolic pressure, which approximates PA systolic pressure.

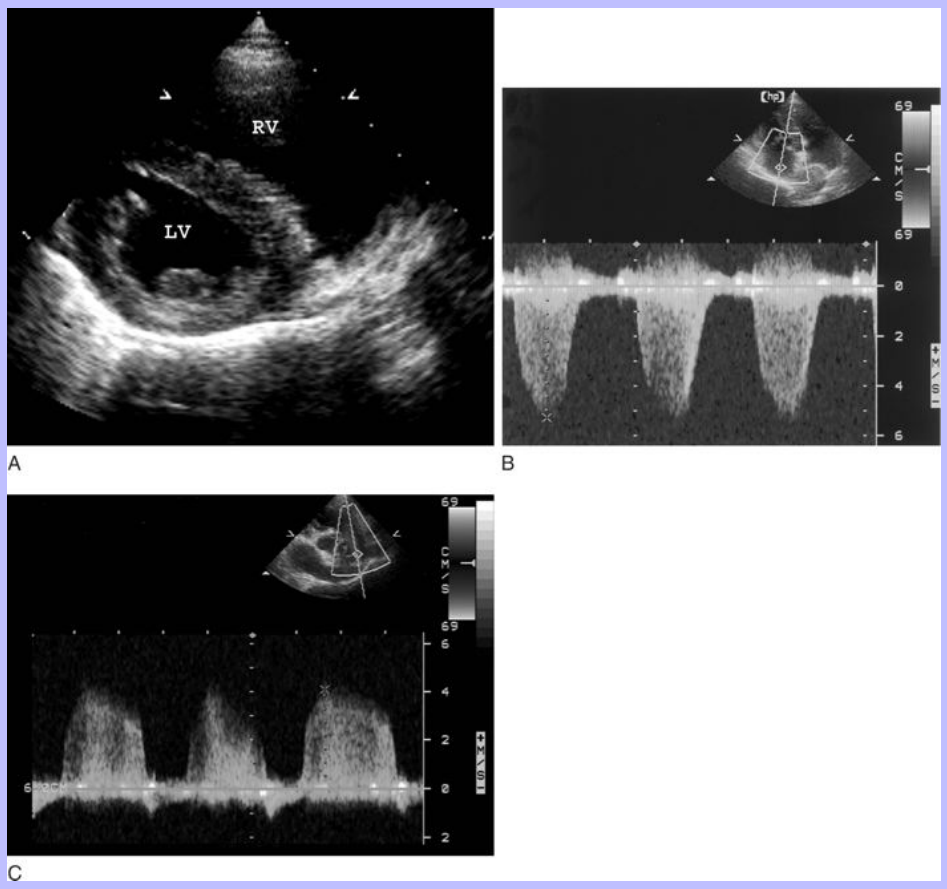
Right heart catheterization is the gold standard for diagnosis of PH and determination of the hemodynamic classification. Unfortunately, catherization requires sedation anesthesia, and these patients are already at increased risk for anesthetic complications. Cardiac output and pressures can be measured, which allows calculation of PVR. Cardiac catheterization allows for pharmacologic tests of vasodilators to identify reversible lesions and evaluate potential pharmacologic treatments.

218.1.4 Treatment

Treatment of PH is aimed at correcting the specific hemodynamic abnormality. Left CHF is treated with diuretics, angiotensin-converting enzyme (ACE) inhibitors, and possibly careful use of afterload reducing agents (amlodipine or hydralazine). Resolution of symptomatic CHF often reduces post-capillary PH and clinical signs of syncope. Surgical or interventional techniques may be used to correct left to right shunting congenital heart diseases but should never be attempted in patients with right to left shunts since it will hasten death. Cautious use of diuretics and ACE-inhibitors are indicated for right heart failure, since patients may develop symptomatic hypotension if they become significantly volume underloaded in the face of fixed PVR. ACE-inhibitors have been shown to delay pulmonary vascular remodeling in experimental animals and have produced beneficial hemodynamic effects in people with cor pulmonale.[7] Digoxin improved cardiac output and reduced circulating norepinephrine concentration in people with primary PH and symptomatic right heart failure[2] and could be considered for treatment of severe PH and right heart failure in veterinary patients.

Treatment of precapillary PH is aimed at reducing PVR and RV pressure overload. Pulmonary vasodilator trials may be performed during cardiac catheterizations to identify responsive patients; however, most veterinary patients likely have fixed PVR at the time of diagnosis. Short-acting vasodilators (adenosine, inhaled nitric oxide, or PGI_2) may be used to identify patients that have reversible vasoconstriction, as evidenced by more than 10 mm Hg decrease in MPAP with no change or an increase in cardiac output, and/or a decrease in PVR by 25%.[4] Only about 20% of humans have a positive pressor response, and these individuals benefit from treatment with high doses of the calcium-channel blocker (diltiazem).[4] No studies have evaluated short-acting pulmonary vasodilator trials and subsequent therapy with calcium channel blockers in veterinary patients with PH.

Figure 218-2 **A,** Two-dimensional echocardiogram of a dog with PH. The right basilar short axis view shows severe right ventricular dilation and concentric hypertrophy that is characteristic of severe acquired pressure overload. The interventricular septum is flattened, which indicates that the right ventricular pressure is greater than the left ventricular pressure. **B,** Continuous wave Doppler measurement of tricuspid regurgitation (TR) velocity in a dog with PH. The TR velocity is 5.2 m/s. Using the modified Bernoulli equation, there is a 110 mm Hg pressure gradient between the RV and RA during systole. Adding 5 mm Hg estimated RA pressure, the estimated RV and PA systolic pressure is 115 mm Hg. **C,** Continuous wave Doppler measurement of pulmonic insufficiency (PI) in a dog with PH. The PI velocity is 4 m/s, and the diastolic pressure gradient between the PA and RV is 64 mm Hg, which closely estimates the PA diastolic pressure.



Intravenous PGI_2 has been shown to improve exercise capacity, hemodynamics, vascular remodeling, and short-and long-term survival in humans.[7] However, lifelong intravenous PGI_2 therapy is not an acceptable treatment modality in veterinary medicine. New oral (beraprost) and subcutaneous (treprostinil) synthetic prostacyclin analogs are under intense investigation in human medicine[7] and may be useful in veterinary medicine. Other promising pulmonary vasodilators being researched for primary and secondary PH include endothelin receptor antagonists (bosentan) and phosphodiesterase inhibitors (sildenafil).[7]

Prognosis for PH is variable and depends on the type and severity of underlying etiology, degree of PH, and reversibility of vascular pathology. In humans with primary PH, mean PA pressure, RA pressure, and PVR are inversely proportional to survival.[2] Earlier identification and treatment of patients with PH may slow the progression, but prognosis remains poor to grave.

1286

1287

218.2 PULMONARY THROMBOEMBOLISM

218.2.1 Etiology and Pathophysiology

Pulmonary thromboembolism (PTE) is a life-threatening condition that occurs in more than 600,000 human patients a year.[8] Despite increased awareness and sophisticated imaging modalities in human medicine, only 30% of fatal PTE is diagnosed antemortem.[8] Similarly, PTE was suspected antemortem in only 38% of dogs and 14% of cats with postmortem evidence of major PTE.[9,10] PTE comprised 0.9% of all postmortem diagnoses in dogs, which likely underestimates the true incidence in the population.[9]

Pulmonary vascular obstruction can result from thrombus formation, or embolization of thrombi, parasites, fat, or neoplastic cells. Heartworm disease is the most common cause of PTE in dogs. It results in mechanical obstruction of pulmonary blood flow as well as enhanced reactive pulmonary vasoconstriction and reduced endothelium-dependent vasorelaxation.[11] Venous stasis, endothelial injury, and hypercoagulability contribute to thrombus formation within pulmonary arteries/arterioles (in-situ thrombosis) and to thromboembolic disease of the pulmonary capillary bed. PTE is a secondary condition, and immune-mediated hemolytic anemia (IMHA), neoplasia, cardiac disease, protein-losing nephropathy or enteropathy, hyperadrenocorticism, disseminated intravascular coagulation, sepsis, trauma, and recent surgery are associated with PTE in dogs and cats.[9,10,12] A large number of dogs and cats with PTE (47% to 64%, respectively) have multiple underlying disease processes.[9,12] Identification of risk factors and underlying diseases associated with PTE should be used to initiate early prophylactic treatment for PTE and aggressive treatment for the primary disease.

In PTE, PVR is increased due to mechanical obstruction of blood flow and reflex vasoconstriction from release of vasoactive mediators (serotonin, thromboxane) from the thrombus. Low-output cardiac failure and shock may occur with acute, major PTE. Functional status of the cardiopulmonary system plays a role in determination of the hemodynamic consequences of PTE.

Pathophysiologic consequences of PTE include abnormal gas exchange, altered ventilatory control, dysregulated pulmonary mechanics, and potentially pulmonary infarction.[2] Hypoxia results from ventilation/perfusion (V/Q) mismatch, increased alveolar dead space, and intrapulmonary or intracardiac right-to-left shunting. Hypoxia can be worsened by pulmonary edema caused by enhanced blood flow to non-thrombosed regions of the lung. Reduced surfactant function in the region of thrombosis leads to

atelectasis and reduced lung compliance. Release of humoral factors causes bronchoconstriction, increased airway resistance, and tachypnea. All of these factors contribute to hypoxia, increased work of respiration, and respiratory distress.

218.2.2 Clinical Signs and Diagnostic Tests

PTE is seen most often in middle-aged to older animals, with no sex or breed predisposition. PTE, like PH, can mimic and often accompany other cardiopulmonary diseases. Sudden onset respiratory distress and tachypnea are common historical or physical examination abnormalities seen in 58% to 96% of dogs and 55% of cats with PTE.[11,12] The list of differential diagnoses is extensive and includes airway obstruction, pneumonia, acute CHF, ARDS or other noncardiogenic pulmonary edema, pleural space disease, or asthma in cats.

When PTE is suspected, identification of an underlying disease and definition of the degree of cardiopulmonary dysfunction are essential. Definitive documentation of PTE remains difficult in both human and veterinary medicine. CBC, chemistry, and urinalysis should be performed, and a coagulation panel can be used to support the presence of concurrent DIC. Plasma D-dimer is used in the diagnosis of PTE in humans, with 96% sensitivity and 52% specificity.[2] Plasma D-dimer is a breakdown product of cross-linked fibrin, which is produced when fibrin is degraded by plasmin. D-dimer is produced in a number of disease conditions in both human and veterinary medicine. The utility of D-dimer in the diagnosis of PTE in veterinary medicine in unknown, but a negative test might be useful in ruling out PTE. Plasma anti-thrombin III activity should be measured if protein losing nephropathy or enteropathy is diagnosed.

Thoracic radiographic abnormalities are common but are rarely specific for PTE. In fact, 10% to 30% of dogs and 14% of cats had normal thoracic radiographs despite necropsy proven PTE[9,10], which indicates that PTE should be a top differential diagnosis in an animal with marked respiratory distress and normal thoracic radiographs. Pulmonary infiltrates may be interstitial, alveolar, or lobar in dogs and cats. Alveolar infiltrates may represent hemorrhage, edema, or infarction. Pulmonary vascular abnormalities including enlarged central pulmonary arteries, disproportionate vascular tapering, and oligemia were common in retrospective review of thoracic radiographs in cats with PTE.[10] Cardiomegaly and mild to moderate pleural effusion were common in dogs and cats.

Arterial blood gas analysis is often abnormal in dogs with PTE, and common abnormalities include hypoxemia, hypocapnea, and increased alveolar-to-arterial gradient.[9] However, normal arterial oxygenation does not exclude the diagnosis of PTE.[2] Response to supplemental oxygen administration can be variable due to the presence of additional cardiac or pulmonary pathology and pathophysiologic sequelae of embolization.

Echocardiographic abnormalities were present in 94% of people with angiographically confirmed PTE, compared with only 13% of patients with similar clinical signs.[6] Unfortunately in veterinary medicine, echocardiography is rarely utilized in the work-up of animals suspected of PTE, and in one study less than 20% of dogs with PTE were evaluated.[9] Thrombus visualization with trans-thoracic echocardiography is limited to thrombi within the heart, main pulmonary artery, or proximal left or right branches. The majority of dogs (88%) with necropsy proven PTE had thrombi located in the main PA and lobar branches.[9] Since some of these proximal thrombi might be visualized with echocardiography, cardiac ultrasound should be considered in dogs with suspected PTE.

Perfusion scanning with an intravenous injection of technetium magroaggregated albumin, is a safe, noninvasive technique for evaluation of PTE. Perfusion deficits may occur in regions of thrombosis or in nonventilated regions with reflex vasoconstriction. When combined with a ventilation scan using technetium radioaerosol, the ventilation: perfusion (V:Q) scan has enhanced sensitivity for detection of PTE. Definitive positive V:Q scans are defined as multiple segmental or lobar perfusion defects in areas of normal ventilation and no radiographic evidence of pulmonary infiltrates. Although V:Q scans are commonly used in human medicine to increase the likelihood of documenting PTE, fewer than half of patients with PTE have a high probability scan.[2] Since ventilation scans are less practical in veterinary medicine and require specialized facilities to handle radioactive materials, this imaging modality is not commonly used. However, an abnormal perfusion scan can be considered suggestive of PTE.

Pulmonary angiography is the gold standard for diagnosis of PTE in humans but is rarely used in veterinary medicine since anesthesia is usually required, and patients with severe PTE and PH are high-risk anesthetic candidates. Percutaneous right heart catheterization via a jugular sheath under deep sedation may be a safer alternative for veterinary patients. Ionic contrast agents can induce severe hypotension due to reduction in systemic vascular resistance in the face of fixed PVR, and this may worsen RV ischemia and function.[13] 1287

Selective PA angiograms and use of nonionic contrast media reduces risk of serious complications.[13] 1288

Definitive angiographic diagnosis of PTE depends on visualization of an intraluminal filling defect in the pulmonary artery, or abrupt vessel occlusion and visualization of the trailing edge of the thromboembolus.[2]

Spiral computed tomography (CT) and magnetic resonance (MR) angiography are noninvasive imaging modalities that show promise for the future diagnosis and management of PTE. However, requirement for general anesthesia in veterinary patients undergoing CT or MRI makes these modalities less attractive in unstable, high-risk patients.

218.2.3 Treatment

Treatment of PTE must be directed against the primary underlying condition, and efforts must be made to improve gas exchange and cardiopulmonary function. Oxygen administration is indicated to reverse hypoxemia due to V/Q mismatch or diffusion abnormalities; however, pulmonary infarction and dysregulated hypoxic vasoconstriction may result in refractory hypoxemia. Immediate stabilization is necessary for animals in low output cardiac failure. Judicious fluids and inotropic support with dobutamine can be used to improve cardiac output and restore tissue perfusion.

Early and aggressive thrombolytic treatment of PTE is reserved for hemodynamically unstable patients and is uncommonly used in veterinary medicine. The goal of thrombolysis is to reduce PA pressure rapidly, improve RV function, and improve pulmonary perfusion. Although there are reports of successful thrombolytic therapy in experimental canine PTE (in dogs with normal thrombolytic and anticoagulant systems)[14] and in animals with systemic thrombi, there are no published studies evaluating thrombolytic therapy in naturally occurring PTE in veterinary medicine. In experimental canine PTE, tissue plasminogen activator (TPA) caused a rapid, dose-limiting thrombolysis with use of 1 mg/kg intravenously over 45 minutes, and TPA appeared to cause faster and more complete thrombolysis than streptokinase and urokinase.[14] Streptokinase has been effectively used in arterial thromboembolism in dogs and cats (90,000 U IV over 30 minutes, then 45,000 U/hour IV continuous infusion for various time intervals).

Anticoagulant therapy with heparin or warfarin is used to prevent further thrombus formation. Heparin is highly protein bound and has a low bioavailability. Doses ranging from 100 to 300 IU/kg SQ q6-8h can be used to prolong partial thromboplastin time (PTT) to 1.5 to 2 times baseline for adequate anticoagulation. Fresh frozen plasma may be needed to replenish antithrombin III. Low–molecular-weight heparin (LMWH) offers an attractive alternative for anticoagulant therapy, since it is less protein bound than unfractionated heparin, has greater bioavailability, provides a more predictable dose response, and has a longer half-life than heparin. LMWH therapy does not require laboratory monitoring since it does not prolong the APTT, and it is associated with fewer bleeding episodes.[2] In normal dogs, a high dose of 150 U/kg of dalteparin produced adequate anti-Xa activity with no bleeding complications and clinically insignificant changes in APTT and thrombin time.[15] Enoxaparin has been used with anecdotal clinical success for treatment of systemic thromboembolism in veterinary medicine. Long-term anticoagulation may also be achieved with oral warfarin (0.1 to 0.2 mg/kg PO q24h). Before warfarin is given, adequate anticoagulation with heparin is needed to balance the initial hypercoagulable phase of warfarin from reduced proteins C and S.

Although rarely done, large central thrombi may be removed by surgical thrombectomy, and percutaneous removal with a specialized thrombolytic catheter has been used in an experimental canine model of PTE.

Aggressive treatment of underlying diseases that have been associated with PTE is paramount, and prophylactic anticoagulation therapy may prevent PTE in these patients. Heparin can be administered at low doses (10 to 75 units/kg SQ TID) without affecting coagulation parameters. Given its biokinetic properties and ease of monitoring, LMWH is an attractive option for preventative anticoagulant therapy.

219 CHAPTER • 219 Oral and Salivary Gland Disorders

Mark M. Smith

219.1 ORAL NEOPLASIA

Neoplasia of the oral and pharyngeal cavities is relatively common in the dog and cat, ranking fifth and seventh most common, respectively.[1] Benign and malignant neoplastic disease may be of dental or nondental origin.[2] The annual incidence of oral and pharyngeal neoplasia in dogs is 20 per 100,000, with malignant melanoma and squamous cell carcinoma (SCC) diagnosed most commonly.[1] The annual incidence rate is lower in cats (11 per 100,000), with the predominant neoplastic types being SCC and fibrosarcoma.[1,3]

Predisposing factors in the development of oral neoplasia include the patient's age, gender, breed, and size and the pigmentation of the oral mucosa. Geriatric patients are predisposed in general, although fibrosarcoma has been reported to occur more frequently in young, large breed dogs.[2] Papillary SCC, virus-induced papillomatosis, and undifferentiated malignancies may also be included in the differential diagnosis for young dogs with oral masses.[4,5] Male dogs have been reported to be at risk for malignant melanoma and fibrosarcoma. Breeds with an increased risk for oral neoplasia irrespective of type include the German shepherd and short-haired pointer, weimaraner, golden retriever, boxer, and cocker spaniel.[6] Large breed dogs have a higher incidence of fibrosarcoma and nontonsillar SCC, whereas small breeds have a higher incidence of malignant melanoma and tonsillar SCC.[6] Dogs with heavily pigmented oral mucosa are predisposed to malignant melanoma.

219.1.1 Benign Neoplasms

Papilloma, fibroma, lipoma, chondroma, osteoma, hemangioma, hemangiopericytoma, histiocytoma, and epulides are reported in the oropharyngeal region in the dog.[6] Papilloma and epulis are common benign oral neoplastic conditions in the dog.

Canine oral papillomatosis (COP) are multiple lesions of viral etiology. Grossly, COPs appear on the mucosa as pale, smooth elevations that develop a rough surface early in the disease process (Figure 219-1).[7] Older lesions of 3 to 4 weeks' duration usually have deep, closely packed fronds. Lesions observed during regression appear shriveled and dark gray. Complete regression requires 1 to 2 weeks and leaves no apparent scarring.

Epulides originate from the periodontal stroma and are often located in the gingiva near incisor teeth (Figure 219-2). The epulides are separated into three types based on histologic origin: fibromatous or fibrous epulis, ossifying epulis, and squamous or acanthomatous epulis.[6] The fibromatous and ossifying epulides are pedunculated, nonulcerating, and noninvasive masses. Acanthomatous epulis, although benign, has characteristics of malignancy, including local invasiveness and bone destruction[6]; however, acanthomatous epulis does not metastasize.

Periodontal epulides may be considered odontogenic neoplasms, because they are closely associated with or may contain dental structures. Fibromatous and ossifying epulides have also been described as peripheral odontogenic fibromas, containing varying amounts of bone, osteoid, dentinoid, or cementum-like substances.[7,8] Additionally, acanthomatous epulis, sometimes referred to in the literature as an *adamantinoma,*

may be more properly classified as acanthomatous ameloblastoma or peripheral ameloblastoma.[9] The more common, specific odontogenic neoplasms are ameloblastoma and odontoma. Ameloblastomas arise from vestigial layers of the dental laminae of the mandible, generally in the incisor region. The neoplasm emanates from enamel organ tissue but does not produce dental hard products. These lesions are expansile, slow-growing neoplasms.[6] Odontomas are of odontogenic origin and resemble the embryologic pattern of tooth development. The mass may comprise enamel, dentin, cementum, and sometimes small teeth. Odontomas may form on or near the crown or root of a normal tooth and may resemble displaced or extra teeth. Lesions with characteristics resembling normal teeth are considered compound, whereas complex odontomas have a more disorganized arrangement.[6]

219.1.2 Malignant Neoplasms

Malignant melanomas grow rapidly and are characterized by early invasion of the gingivae and bone. Metastasis to regional lymph nodes occurs early in the disease process, with lung the most common site of visceral metastasis.[6,11] Malignant melanomas are dome shaped or sessile, and they either have varying amounts of pigmentation, ranging from black and brown to mottled, or are nonpigmented (Figure 219-3). A minority of oral melanocytic neoplasms (25%) may be benign, but all suspected melanomas should be considered malignant pending histologic evaluation. Melanomas of the mucocutaneous junction are invariably malignant.

1291

Figure 219-1 Papillomatosis (*arrow*) of the labial mucosa in a young dog.

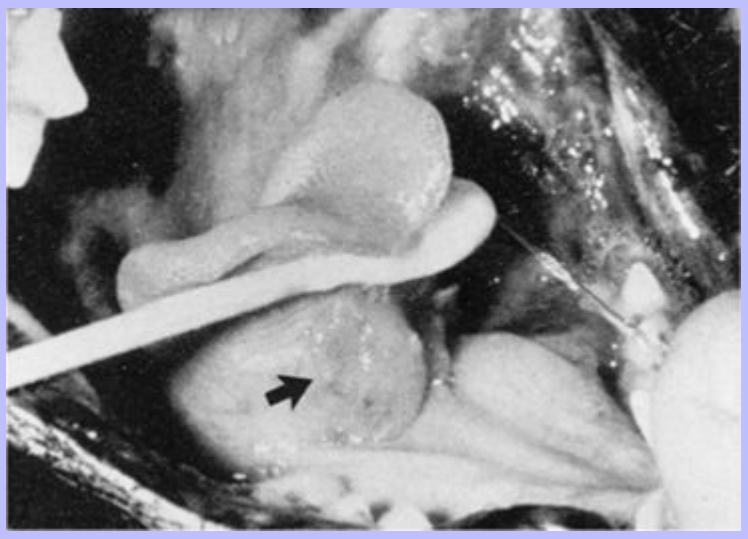
Figure 219-2 Intraoperative view of acanthomatous ameloblastoma of the mandibular incisor area in a dog.

Squamous cell carcinoma may project from the gingival mucosa but more commonly is an ulcerated, erosive lesion. It frequently involves the gingiva mesial to the canine teeth in dogs and ventral to the tongue in cats (Figure 219-4). Other common oral sites include the buccal and labial mucosa, hard palate, and tongue.[3,6,12–15] SCC destroys the mucosa and submucosa and is locally invasive in muscle and bone. Bone involvement is particularly common in dogs, showing a 77% occurrence rate. Metastasis to local and regional lymph nodes is common, whereas visceral metastasis to the lung is rare and occurs late in the disease process.

Fibrosarcoma occurs in oral locations similar to those of SCC but has a greater frequency along the lateral maxillary arcade between the canine and fourth premolar teeth.[6] The neoplasm is firm and smooth and has nodules that may become ulcerated (Figure 219-5). Fibrosarcomas are invasive, and recurrence after local excision is common. Regional lymphatic and visceral metastasis is unusual. Conversely, low-grade fibrosarcomas appear benign clinically and rarely present with ulceration. However, these tumors are biologically malignant and require a high index of suspicion on the part of both the clinician and the pathologist.[16]

Figure 219-3 Malignant melanoma of the mandibular buccal mucosa in a dog.

Figure 219-4 Sublingual squamous cell carcinoma (*arrow*) in a cat. (From Norris AM et al: Oropharyngeal neoplasms. In Harvey CE [ed]: Veterinary Dentistry. Philadelphia, WB Saunders, 1985.)



219.1.3 Clinical Signs, Diagnosis, and Staging

Clinical signs associated with oral neoplasms depend on the lesion's size and location. Food prehension may be abnormal and cause ulceration secondary to trauma in patients with larger neoplasms. Inability to swallow or associated pain may result in the appearance of saliva drooling from the lip commissures at inappropriate times. The saliva is blood tinged when concomitant with ulcerated lesions. Clinical signs associated with dental disease may be related to abnormal mastication. Painful dental structures or partial obstruction of functional dental areas lead to disuse. Subsequent periodontal disease is related to excessive plaque and calculus accumulation in these areas. Severe destructive periodontal disease, halitosis, and tooth loss are potential sequelae. Although severe destructive periodontitis is not associated with a mass lesion, it is often associated with bone lysis and may resemble SCC.

1291 1293

Figure 219-5 Fibrosarcoma (*arrow*) of the maxillary premolar area in a dog.

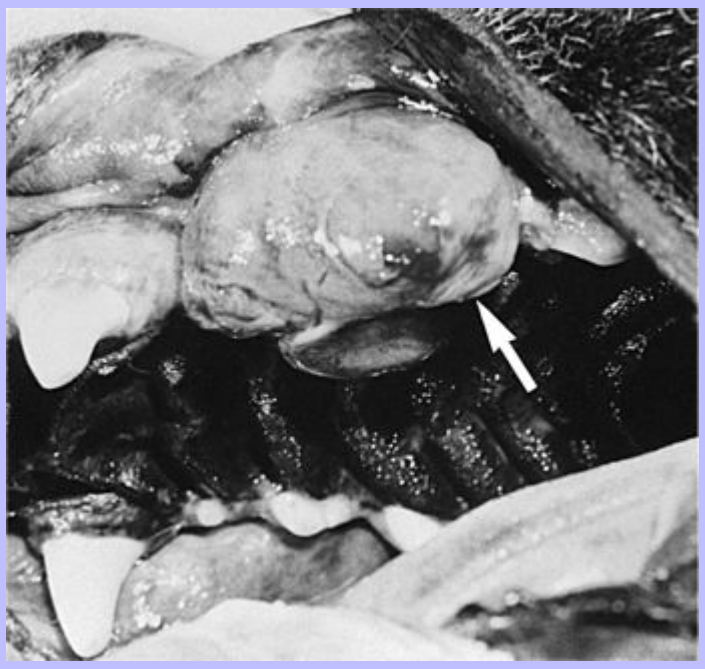


Figure 219-6 Algorithm for the diagnosis and treatment of oral neoplasms.

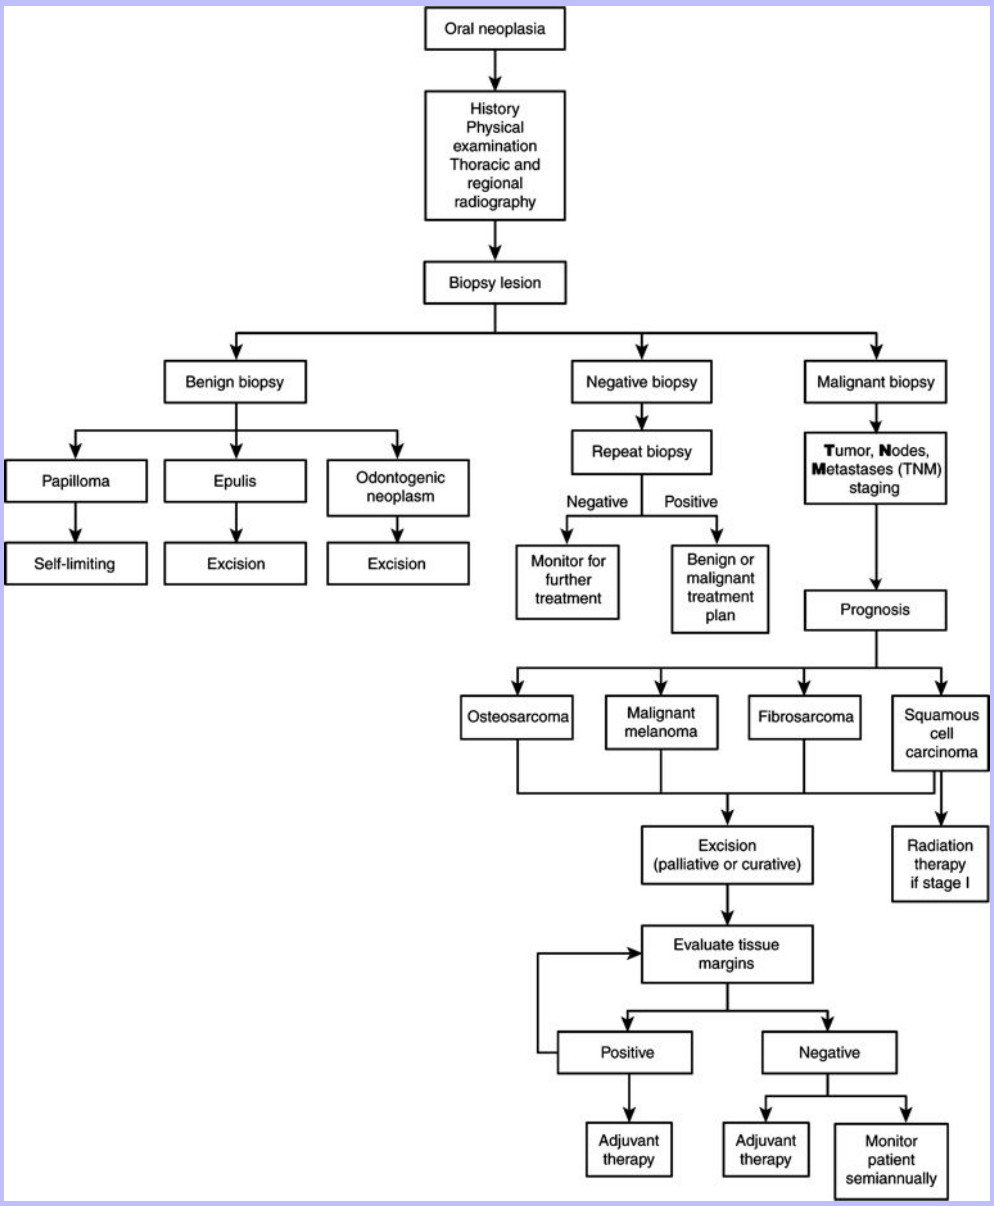


Diagnosis of oral neoplastic conditions is based on histopathologic examination (Figure 219-6). The differential diagnoses include malignant and benign neoplasms. Recent advances in the development and application of immunohistochemistry techniques in veterinary medicine may provide methods for early detection of malignant neoplasms.[17–20]

Staging of the neoplastic disease should be considered as an active investigative process to be performed in concert with the diagnostic evaluation (Table 219-1).[21] The final result of this process is potentially valuable prognostic information. A complete blood count (CBC), chemistry profile, and urinalysis results should be reviewed to detect organ abnormalities related to metastatic disease or to concurrent disease that would alter the type or preclude the use of general anesthesia.

Thoracic radiographs (right and left lateral, ventrodorsal views) are taken to determine whether visceral metastasis to the lung has occurred. The size of the neoplasm is estimated in the awake patient and may be more accurately assessed after administration of general anesthesia. Skull radiographs or computed tomography (CT) performed during anesthesia can provide information on the presence of bone invasion.

Table • 219-1 Clinical Staging System for Tumors of the Oral Cavity

T: Primary tumor

- T_0 No evidence of tumor
- T_1 Tumor <2 cm maximum diameter
  - T_{1a} Without bone invasion
  - T_{1b} With bone invasion
- T_2 Tumor 2 to 4 cm maximum diameter
  - T_{2a} Without bone invasion
  - T_{2b} With bone invasion
- T_3 Tumor >4 cm maximum diameter
  - T_{3a} Without bone invasion
  - T_{3b} With bone invasion

N: Regional lymph nodes (RLN)

- N_0 No evidence of RLN involvement
- N_1 Movable ipsilateral nodes
  - N_{1a} Nodes histologically negative
  - N_{1b} Nodes histologically positive
- N_2 Movable contralateral or bilateral nodes
  - N_{2a} Nodes histologically negative

N_{2b} Nodes histologically positive

N_3 Fixed nodes

M: Distant metastasis

M_0 No evidence of distant metastasis

M_1 Distant metastasis present

STAGE GROUPINGS

STAGE	T	N	M
I	T_1	N_0, N_{1a}, or N_{2a}	M_0
II	T_2	N_0, N_{1a}, or N_{2a}	M_0
III*	T_3	N_0, N_{1a}, or N_{2a}	M_0
IV	Any T		
	Any T	Any N_{2b} or N_3	M_0
	Any T	Any N	M_1

From World Health Organization: *Report of the Second Consultation on the Biological Behaviour and Therapy of Tumors of Domestic Animals.* WHO, Geneva, 1978.

* Any bone involvement.

The regional lymph nodes should also be evaluated. Enlargement indicates either metastasis or reactivity related to oral inflammation. Regardless of size, the regional lymph nodes should be evaluated by fine needle aspiration (false-negative results are possible) or by incisional or excisional biopsy. Minor surgery to remove a regional lymph node provides worthwhile prognostic information which may influence the owner's decision to pursue definitive treatment.[22,23] The most accessible regional lymph nodes are the submandibular and parotid nodes; the medial retropharyngeal node receives afferent lymphatics from these lymph nodes. Lymph node should be differentiated from salivary tissue, the latter having a tan color with distinct lobulations. A negative lymph node biopsy result does not preclude the possibility of regional metastasis, which may occur along perineural or vascular routes, or metastasis to other, less accessible lymph nodes, such as the medial retropharyngeal node.[23] Unfortunately, oral malignant neoplasms are often detected late in the disease process because their location may not be readily observed by the owner or veterinarian. Consequently, oral neoplasms have usually progressed to at least stage II disease at the time of diagnosis. Higher primary tumor (T)-stage tumors with bone involvement are associated with a poor prognosis.[11]

219.1.4 Treatment

Animals with no radiographic signs of visceral metastasis to the lung should be considered candidates for aggressive therapy. The concept of complete local excision of all visible tumor followed by, or concurrent with, chemotherapy or radiation therapy for treatment of presumed micrometastasis has achieved marked acceptance in human oncologic therapy and is being applied in veterinary medicine.[21,24–26] Surgery is integral

to this multimodality treatment plan, especially for large, aggressive neoplasms.[27–30] Resective surgery plus radiation and/or chemotherapy are usually well tolerated by dogs and cats, leaving conservative management for only the more debilitated or geriatric patients.[31]

The goal of surgery for oral neoplasms in small animals is generally curative resection or palliation.[32] The ideal surgical procedure is one that offers the greatest possibility of cure, restores or maintains function, and has an acceptable cosmetic result. Benign neoplasms that do not involve bone are surgically excised. Malignant neoplasms are also excised; however, an attempt to acquire tumor-free margins is critically important.[33–35] A 2 cm margin of tumor-free tissue is recommended, often necessitating ostectomy as a component of the operative procedure.[36] Neoplasms with radiographic evidence of local bone metastasis require resective procedures, including maxillectomy and mandibulectomy. Hemimaxillectomy and hemimandibulectomy maximize the removal of the entire bony component of the neoplastic process. Segmental bone resective procedures that result in partial maxillectomy or mandibulectomy, without the opportunity for frozen section analysis of tissue margins, risk incomplete resection due to intrabony perineural and microvascular metastatic routes.[37,38] This is particularly important for mandibular lesions, for which hemimandibulectomy may be preferred to partial or segmental mandibulectomy because cosmesis and function are acceptable despite a greater degree of resection.[31,39] Extended dissection from the primary site may improve the incidence of free margins related to surgical resection of direct metastatic pathways, especially for neoplasms of the floor of the mouth. The cranial cervical area may be approached in conjunction with reconstructive surgery. Direct observation of regional lymph nodes allows assessment of gross transcapsular spread of the tumor, which may warrant wider margins for adhered lymph nodes.[40,41]

1293 1294

Peripheral odontogenic fibromas are treated by aggressive, local surgical resection. Based on the common locations of this neoplasm compared with malignant neoplasms, the operative procedures would be either rostral mandibulectomy or rostral maxillectomy.[42,43]

Odontogenic tumors are treated by local excisional surgery requiring partial or segmental ostectomy.[44–46]

Radiation therapy may be particularly indicated for stage I SCC or after resective surgery for SCC with nonfree margins. This form of treatment is most effective if used in combination with surgical excision of stage II to stage IV SCC or possibly for affected regional lymph nodes.[12] Recent studies report encouraging results from radiation therapy for the treatment of canine SCC, fibrosarcoma, and malignant melanoma.[11,47] This modality should be considered for treatment of oral malignancies with or without surgery. However, as with surgery, larger, more caudally located tumors have a poorer prognosis. Severe, acute radiation reactions may occur approximately 16% of the time; the most common chronic reaction is bone necrosis and fistula formation.[11] Although the latter reaction may be difficult to treat successfully, a relatively low percentage of chronic reactions to radiation therapy may be considered an expected sequela of effective treatment.[11]

Acanthomatous ameloblastomas are sensitive to radiation therapy; however, because malignant neoplastic disease develops at the irradiated site in approximately 18% of dogs, surgical excision may be a more appropriate therapeutic option imorbidity is minimized.[48,49] The type of radiation administered (orthovoltage versus megavoltage) may influence the potential carcinogenic affect of radiation.[50] Smaller acanthomatous ameloblastomas located in the rostral portion of the oral cavity have a more favorable prognosis after radiation therapy than do larger, more caudal lesions.[50] Acute and chronic radiation reactions may occur, as in treatment for oral malignant neoplasms.

Chemotherapy or chemoradiation therapy may provide short-term palliation for oral neoplasia not amenable to surgery, for resections with non-free margins, and for recurrence after surgical excision. Cisplatin has been used in dogs for oral SCC, and doxorubicin and cyclophosphamide have been used for oral fibrosarcoma and SCC in cats.[2] The results of clinical research with radiosensitizing agents (e.g., etanidazole) may show improvement in median survival times for small animals with oral neoplasms.[51–53] Intratumoral administration of carboplatin has proved efficacious in the treatment of SCC of the nasal plane in cats[54] and may have application in the treatment of oral SCC. Systemic carboplatin may be considered as adjunctive treatment for microscopic local or metastatic malignant melanoma.[55] Chemoradiation, including hypofractionated megavoltage irradiation and cisplatin or carboplatin therapy, prolonged survival times in dogs with incompletely resected oral malignant melanoma.[56]

219.1.5 Prognosis

Malignant oral neoplasms have a guarded to poor prognosis regardless of their size or location in the oral cavity. The prognosis may be affected by the size of the lesion and the patient's age and species. Dogs younger than 6 years of age with SCC mesial to the second premolar have a better prognosis than older dogs with neoplasms in other locations. Cats with oral SCC have a shorter tumor-free interval than dogs regardless of the type of treatment.[57,58] The most positive prognosis for oral SCC in dogs is attained with both surgery and radiation therapy. Treatment of oral SCC in cats is strictly palliative, with no improved survival interval.[2,57] Oral malignant melanoma may be resected locally with tumor-free margins, but regional or distant metastasis usually occurs. Tumor-free margins for oral fibrosarcoma are more difficult to achieve, which makes local recurrence likely. A 1-year survival rate of 71% has been reported for dogs with mandibular osteosarcoma treated with surgery only; another study indicated less favorable results with surgery only, reporting a median survival time of 5.5 months.[59,60]

Benign oral neoplasms and odontogenic neoplasms, including epulides, have an excellent prognosis after complete surgical excision.[43–46]

219.2 SELECTED ACQUIRED DISEASES OF THE LIPS, CHEEKS, AND PALATE

Feline eosinophilic granuloma complex (FEGC) comprises an eosinophilic ulcer, plaque, and a linear granuloma. Oral lesions are usually a linear granuloma or an eosinophilic ulcer; the latter has a predisposition for the maxillary lips (80%).[61] Intraoral lesions appear as one or more discrete, firm, raised nodules (Figure 219-7). Clinical signs include dysphagia and/or ptyalism. Although the etiology of this disease is unknown, bacterial and viral infections and immune-mediated and hypersensitivity diseases have been associated with FEGC.[61,62] Biopsy of the lesion, with the aforementioned diseases in mind, should be performed to confirm the diagnosis and to differentiate it from neoplastic disease. Ancillary tests should include a CBC, which usually shows an absolute eosinophilia. Concurrent or potentially causative hypersensitivity diseases should be considered during the diagnostic phase of treatment. The mainstay of FEGC treatment is corticosteroid therapy. Intralesional triamcinolone (3 mg weekly), oral prednisolone (1.0 to 2.0 mg/kg given twice daily), and subcutaneous methylprednisolone acetate (20 mg every 2 weeks), administered until FEGC resolves, are efficacious treatments.[61] Progestational compounds (progesterone or medroxyprogesterone) are often used to treat FEGC. These compounds are not approved for use in cats and have potential side effects that make them undesirable, including adrenocortical suppression, polydipsia, polyuria, polyphagia, obesity, personality change, reproduction

1294

1295

abnormalities, mammary hypertrophy, neoplasia, and diabetes mellitus. Cats with untreated chronic lesions, responsive previous lesions, and lesions refractory to corticosteroid therapy have a 50% recurrence rate within 5 months.[61] Failure of treatment is usually related to inadequate dosage or premature cessation of therapy. Animals that do not respond to either corticosteroids or progestational compounds have a poor prognosis and are candidates for more aggressive therapy, such as irradiation, cryosurgery, laser therapy, or immunotherapy.[62–64]

Figure 219-7 Oral lesions (*arrows*) of feline eosinophilic granuloma complex. (Courtesy Dr. M. Leib, Blacksburg, VA.)

The term *stomatitis* refers to an inflammation of the oral mucosa. Oral inflammatory lesions in dogs and cats have multiple causes, necessitating a consistent and logical diagnostic approach. A complete history and thorough physical examination are essential. Dogs and cats with no evidence of debilitating systemic disease should receive a short-acting intravenous anesthetic to allow an unimpeded visual and tactile oral examination. Oral ulcerations occur in at least four different immune-mediated diseases, including systemic lupus erythematosus, bullous (pemphigus) disease, idiopathic vasculitis, and toxic epidermal necrosis. The many infectious diseases that are manifested by lesions in the oral cavity include feline leukemia virus, feline immunodeficiency virus, feline syncytium-forming virus, feline calicivirus, feline herpes virus, and feline infectious peritonitis (see Chapters 170-173).[65] Canine distemper and feline panleukopenia virus may cause stomatitis, although other organs are more severely affected. Candidiasis (infection with *Candida albicans*) may cause severe stomatitis in dogs and cats.[61,66] Many cats with stomatitis have immunosuppressive disease or

systemic debilitation or have received chronic immunosuppressive therapy. Although the oral manifestation may appear as a white, pseudomembranous covering of the tongue, the lesions are usually irregular, ulcerated areas in zones of inflamed mucosa.

Feline oral inflammatory disease ranges from simple gingivitis to varying degrees of stomatitis in which inflammation extends beyond the mucogingival junction into the oral mucosa.[67] Cats with chronic gingivitis/stomatitis may have ulceration and extension of granulation tissue involving the palatoglossal folds and fauces. Clinical signs include halitosis, ptyalism, dysphagia, inappetence, and weight loss. Extensive disease is marked by root resorption and possibly bony sequestrae in edentulous areas. Unfortunately, because the causation is usually unknown, treatment is symptomatic, including professional cleaning of the teeth, therapy with antimicrobials or with systemic or local corticosteroid agents similar to those used for FEGC, and laser therapy to stimulate re-epithelialization over inflamed, ulcerated areas. It is not unusual for refractory cases to require extraction of all molars and premolars or all teeth to alleviate the symptoms of this disorder.

Stomatitis may be described as idiopathic despite a thorough diagnostic evaluation. Immunemediated ulcerative gingivitis/stomatitis afflicts Maltese terriers, although the etiology is verified in only 20% of animals.[61] If diagnostic test results are negative in idiopathic stomatitis, it is appropriate to assume a possible immune-mediated component. A prudent treatment plan includes regular cleaning of the teeth, oral preventive medicine at home, and intermittent or chronic provocative corticosteroid therapy. Antimicrobial therapy emphasizing anaerobic pathogens (e.g., metronidazole, amoxicillin, clavulanic acid/amoxicillin) may be administered on an intermittent, chronic basis.

219.3 SELECTED ACQUIRED DISEASES OF THE SALIVARY GLANDS

Neoplasia involving the salivary glands is uncommon. There is evidence that spaniel breeds and poodles, as well as Siamese cats, are predisposed to neoplasia of the salivary glands.[68] In a report of 24 primary salivary tumors in dogs, the parotid gland was involved nearly twice as often as the other major salivary glands; the mean age of the 24 dogs studied was 10 years.[68] Another recent study indicates that the mandibular gland is most commonly affected.[69] Multiple tumor types that affect the salivary glands have been described, including mucoepidermoid tumors, SCC, malignant mixed tumors, adenoid cystic carcinoma, acinic cell carcinoma, adenocarcinoma, undifferentiated carcinoma, and sarcoma. Although primary SCC of the sublingual salivary gland occurs, it should be considered only after an invasive carcinoma involving the oral mucosa or accessory oral salivary glands has been ruled out. The prevalence of salivary gland neoplasms in cats is almost twice that in dogs, with the mandibular salivary gland most commonly affected.[68] Adenocarcinoma is the most common neoplasm affecting the salivary glands in dogs and cats.[68] Adenocarcinoma, regardless of the gland affected, is locally infiltrative, with frequent metastasis to the lung and regional lymph nodes. Cats have more advanced-stage disease at the time of diagnosis than do dogs.[68] Salivary neoplasms should be staged according to the primary tumor–regional lymph node–distant metastasis (TNM) system to allow appropriate prognostication and development of a treatment plan. Thoracic radiographs and incisional biopsy of the neoplasm and nearest regional lymph nodes provide necessary information.

Total surgical excision of salivary malignant neoplasms is difficult because of their invasive characteristics and the intricate neurologic and vascular anatomy of the salivary gland region. Therefore local treatment should include radiotherapy, with or without surgical intervention to debulk the neoplasm.

Mucocele is the most common recognized clinical disease of the salivary glands in dogs. A mucocele comprises an accumulation of saliva in the subcutaneous tissue and the consequent tissue reaction to saliva. The mucocele

has a nonepithelial, nonsecretory lining consisting primarily of fibroblasts and capillaries. The incidence of salivary mucocele reportedly is fewer than 20 in 4000 dogs. Although the condition has been reported in dogs as young as 6 months of age, salivary mucocele occurs most often in dogs 2 to 4 years of age. It occurs more frequently in German shepherds and miniature poodles.

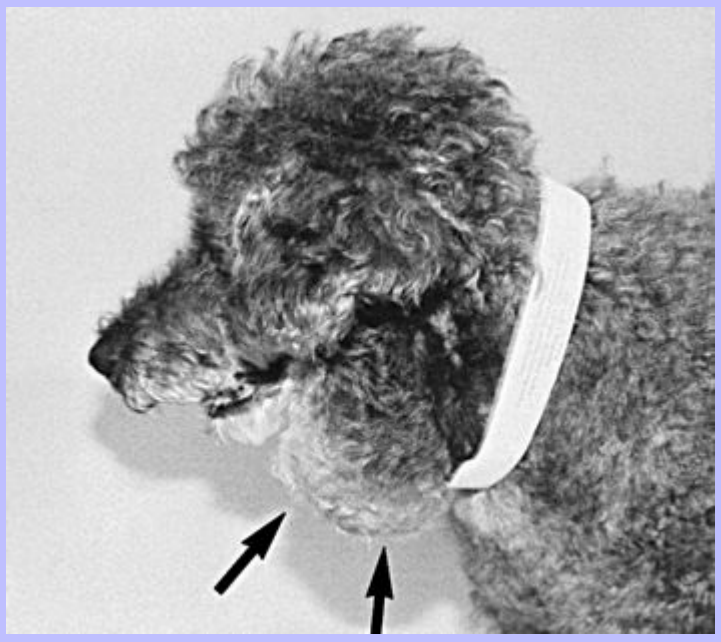
Trauma has been proposed as the cause of salivary mucocele because of the activity of young dogs and the documented damage to the salivary gland-duct complex and the formation of the mucocele. The inability to induce salivary mucocele traumatically in healthy dogs suggests the possibility of a developmental predisposition in affected dogs.

The sublingual gland is the most common salivary gland associated with salivary mucocele. Sialography has shown that the mucocele most often originates in the rostral portion (that portion of the sublingual gland superimposed on the mandible) of the sublingual gland-duct complex. Regardless of the location of origin, the mucocele usually forms near the intermandibular area (cervical mucocele). Other locations associated with the formation of a mucocele caused by a sublingual gland-duct defect are sites under the tongue, which involves the floor of the mouth (sublingual mucocele) and the pharynx (pharyngeal mucocele).

The clinical signs associated with salivary mucocele depend on the location of the mucocele. A cervical mucocele initially is an acute, painful mass resulting from an inflammatory response. Cessation of the inflammatory response results in a marked decrease in size. A decreased inflammatory response allows for the more common presenting history of a slowly enlarging or intermittently large, fluid-filled, painless mass (Figure 219-8). Blood-tinged saliva secondary to trauma caused by eating, abnormal prehension of food, or reluctance to eat are clinical signs that can be associated with sublingual mucocele. The most common clinical signs associated with a mucocele of the pharyngeal wall are respiratory distress and difficulty swallowing secondary to partial obstruction of the pharynx.

1295
1296

Figure 219-8 Cervical mucocele in a poodle.



Zygomatic salivary mucoceles are infrequently reported in dogs. A visible periorbital mass is usually the presenting clinical sign of zygomatic mucocele. Ophthalmic signs secondary to the mucocele depend on the location and size of the mucocele (e.g., exophthalmos or enophthalmos).

Diagnosis of salivary mucocele is based on the clinical signs, history, and results of paracentesis (Figure 219-9). Mucocele paracentesis reveals a stringy, sometimes blood-tinged fluid with low cell numbers. Mucin and amylase analyses of the fluid are not reliable diagnostic procedures. A chronic cervical mucocele may contain palpable firm nodules that are remnants of sloughed inflammatory tissue previously lining the mucocele. Sialoliths, which are concretions of calcium phosphate or calcium carbonate, may occur with chronic mucocele.

The physical examination and history usually denote the origin of the mucocele. Cervical mucoceles that appear on the midline usually shift to the originating side when the patient is placed in exact dorsal recumbency. Sialography can be used to determine the affected side if careful observation and palpation of the mucocele are unsuccessful. Sialography is also a diagnostic aid when considerations include traumatic injury to one of the salivary glands, salivary neoplasia, a mass or fistulous tract of unknown origin in the head and neck region, or a foreign body in the head or neck. The disadvantages of sialography include the need for general anesthesia and the difficulty associated with locating the duct opening or openings.

Various techniques have been used to treat cervical mucoceles. Mucocele drainage, removal of the mucocele only, and chemical cauterization of the mucocele have been reported. The basis for these therapies was the belief that a mucocele was a true cyst with a secretory lining. The fact that a mucocele is not a cyst but a reactive, encapsulating structure has prompted surgical removal of the affected gland-duct complex. The intimate anatomic association of the sublingual and mandibular glands and their ducts requires resection of both structures. Surgical removal of both the sublingual and mandibular salivary glands, combined with drainage of the mucocele, has been advocated for treatment of cervical mucoceles.

Pharyngeal and sublingual mucocele are treated by removal the mandibular and sublingual salivary glands, based on the common etiology of a sublingual gland-duct defect. Another treatment technique for these mucoceles involves marsupialization. However, resective surgery is preferred for pharyngeal mucoceles, because life-threatening upper airway compromise and morbidity from swallowing dysfunction (e.g., aspiration pneumonia) are potential complications of conservative management or recurrence.

The zygomatic salivary gland can be affected by neoplasia, inflammation, or mucocele. The clinical signs of zygomatic mucocele and neoplasia are similar. Additional signs, such as osteolytic changes of the zygomatic arch and enlargement of the submandibular lymph node, may accompany neoplasia that originate in the zygomatic gland. Surgical removal of the zygomatic gland is indicated either for neoplasia or for mucocele of zygomatic origin.

220 CHAPTER • 220 Diseases of the Esophagus

Albert E. Jergens

220.1 NORMAL ANATOMY AND FUNCTION

The esophagus functions to transport ingesta and liquids from the oral cavity to the stomach.[1,2] Its anatomy consists of the striated muscle (cricopharyngeus muscles) of the upper esophageal sphincter (UES), striated and smooth muscle of the body of the esophagus, and the smooth muscle of the lower esophageal sphincter (LES). The entire length of the canine esophagus is composed of striated muscle, whereas the distal one third of the feline esophagus is composed of smooth muscle. The vagus nerve and associated branches (glossopharyngeal, pharyngeal, and recurrent laryngeal nerves) innervate the esophagus. This neural network contains somatic motor nerves from the brain stem nucleus ambiguus to the esophageal striated muscle, autonomic nerves to the esophageal smooth muscle, and general visceral afferent nerves from esophageal sensory receptors.

The high pressure maintained by the UES and LES during fasting ensures unidirectional flow between the oral cavity and the stomach. The LES is also responsive to gut hormones via receptors for gastrin and secretin families. The esophageal phase of swallowing begins with relaxation of the UES, which permits movement of a bolus of food into the proximal esophagus. The peristaltic wave generated in the pharynx is further propagated through the esophagus and carries a bolus aborally to the LES (primary peristalsis). If primary peristalsis fails to propel the bolus to the stomach, then a secondary peristaltic wave is quickly generated by intraluminal distension and completes transport of the bolus to the stomach. Relaxation of the LES in advance of these propagated pressures permits food to empty into the stomach. After the bolus passes, the LES contracts to prevent reflux of gastric contents into the esophagus.

220.2 DIAGNOSIS OF ESOPHAGEAL DISEASES

220.2.1 History

In general, animals with overt esophageal dysfunction are not diagnostic challenges. Clients often report hallmark signs of esophageal disease including regurgitation (liquids or solids), dysphagia (difficult swallowing), odynophagia (painful swallowing), repeated swallowing attempts, and excessive salivation in affected animals. Regurgitation is the most consistent sign of esophageal disease and should be clearly differentiated from oropharyngeal dysphagia and vomiting (Table 220-1). Some animals may also have a mix of signs, such as vomiting and regurgitation, which may occur when chronic vomiting leads to esophagitis.

Other historical clues of esophageal disease may be made based on age and the character of signs. Congenital idiopathic megaesophagus shows distinct canine breed predispositions (see later), and vascular ring anomaly and cricopharyngeal dysphagia may also manifest in very young patients. Acute severe signs in either a young or older animal are suggestive of esophageal foreign body. Conversely, slowly worsening regurgitation is more commonly seen with hiatal defects (causing gastroesophageal reflux), developing stricture, or esophageal tumors. Adult animals showing esophageal dysphagia may have histories of recent anesthesia, ingestion of corrosive chemicals, or pill administration. Concurrent muscle weakness or neurologic signs may implicate extra-esophageal disorders, such as myasthenia gravis (MG) or polyneuropathy, as causes for secondary esophageal disease. Evidence of pain during swallowing is most often due to foreign body ingestion or esophagitis but is uncommonly observed with motility disturbances.

220.2.2 Physical Examination

The physical examination findings in animals with primary esophageal disease are variable. Most animals with acute causes for regurgitation (foreign body or mild esophagitis) show minimal abnormalities with the exception of hyper-salivation and variable dysphagia. Mucopurulent nasal discharge, pulmonary crackles, and fever suggest aspiration pneumonia. Weight loss, malnutrition, and emaciation can be seen with long-standing esophageal disease, such as stricture and idiopathic megaesophagus. Observations in animals with dysautonomia may include dilated pupils and dry mucus membranes. A carefully performed physical examination serves to exclude other gastrointestinal (GI) and systemic diseases.

220.2.3 Diagnostic Tests

Although history provides important clues as to the likelihood of primary esophageal disease, select laboratory tests, radiography, and endoscopy are necessary for definitive diagnosis in most instances (Figure 220-1). Significant alterations in baseline laboratory tests (complete blood count [CBC], serum biochemistry, urinalysis) are uncommonly observed. Exceptions include elevations in CK (associated with myositis), non-regenerative anemia (associated with malnutrition), and proteinuria (suggestive of immune-mediated disease). Specialized serologic assays useful for the diagnosis of regurgitation include an adrenocorticotropic hormone (ACTH) stimulation test (hypoadrenocorticism) and acetylcholine receptor antibody titer (acquired MG).

Survey thoracic and soft-tissue cervical films should be performed in all animals suspected as having esophageal disease. Obvious abnormalities may include radiopaque foreign bodies, hiatal defect, esophageal dilatation (megaesophagus), alveolar opacities (aspiration pneumonia), or evidence of esophageal perforation (pneumomediastinum).

Contrast radiography is a helpful adjunct to survey imaging, being most useful in confirming luminal obstruction (stricture, mass, extraluminal compression), mucosal irregularity (mass, severe esophagitis), and significant alterations in esophageal motility. An esophagram is most often performed using liquid barium suspension followed by a barium meal. Contrast material is rapidly cleared from the normal pharynx and esophagus by a series of brisk, aborally directed peristaltic waves.[2] Persistent pooling of contrast material at any level of the esophagus should be considered abnormal and confirmed on repeat films. If esophageal perforation is suspected, a water-soluble iodinated contrast agent (iohexol, gastrografin) should be used. Dynamic contrast studies (videofluoroscopy) provide more detailed quantitative information regarding esophageal motility.

Table • 220-1 Differentiation of Oropharyngeal Dysphagia, Esophageal Dysphagia, and Vomiting

PARAMETER	OROPHARYNGEAL DYSPHAGIA	ESOPHAGEAL DYSPHAGIA	VOMITING
Abdominal effort	None	None	Marked
Prodromal nausea	None	None	Present
Character of ejected food	Undigested	Undigested	Usually digested
Timing of food ejected	Immediate	Often delayed	Often delayed
Swallow attempts of a single bolus	Multiple	Usually single	Single
Ability to drink	Poor	Variable	Normal
Pain on swallowing	Possible	Possible	Absent
Associated signs	Dyspnea, cough	Dyspnea, cough	+/−Systemic signs

Modified from Guilford WG: Approach to clinical problems in gastroenterology. *In* Guilford WG, Center SA, Strombeck DR (eds): *Strombeck's Small Animal Gastroenterology,* 3rd ed. Philadelphia, WB Saunders Co, 1996, p 55.

Flexible endoscopy (esophagoscopy) provides the clinician the most direct means to quickly and noninvasively assess the esophagus for luminal or mucosal abnormalities. Normal esophageal mucosa is smooth, glistening, and pale pink. Abnormal findings include mass lesions (neoplastic most common), esophagitis (evidenced by mucosal erythema, hemorrhage, erosions), stricture, segmental or generalized dilatation, and perforation. Mucosal biopsy of the esophagus is uncommonly required except for intraluminal mass lesions. Exfoliative brush cytology may be superior to mucosal biopsy (due to technical constraints) for diagnosis of esophageal neoplasia. Interventional procedures allow for esophageal foreign body removal, dilatation of esophageal strictures, and feeding catheter placement via percutaneous gastrostomy or gastro-jejunostomy techniques.

More specialized diagnostic procedures, such as esophageal manometry (for assessment of motility or LES competency) and distal esophageal pH monitoring (for gastroesophageal reflux), are infrequently performed in clinical practice.

220.3 CRICOPHARYNGEAL DYSPHAGIA

Cricopharyngeal dysphagia is a congenital neuromuscular disorder characterized by failure of the UES to relax (achalasia) or a lack of coordination between UES relaxation and pharyngeal contraction (asynchrony). This results in interrupted transport of a bolus through the UES into the cervical esophagus. The cause for this disorder is unknown; however, a dysfunction of the inhibitory neuron mediating UES relaxation has been incriminated.[3]

220.3.1 Clinical Signs

Affected animals demonstrate progressive dysphagia characterized by repeated attempts to swallow, gagging, retching, and regurgitation (often immediately after eating). Clinical signs most often appear at the time of, or shortly after, weaning. A moist, productive cough may develop as a consequence of aspiration pneumonia. Physical examination is generally unremarkable with the exception of moist crackles in animals with pneumonia.

220.3.2 Diagnosis

Videofluoroscopy of the pharynx and UES using liquid barium or paste is the diagnostic test of choice. Intermittent or persistent failure of UES to relax and dilate subsequent to bolus formation and pharyngeal contractions is observed. Static contrast films may demonstrate barium retention in the pharynx or aspiration into the trachea (Figure 220-2). Ancillary tests (serum CK, electromyography [EMG], muscle biopsy) should be performed in animals having more generalized signs of neuromuscular disease (muscle weakness, atrophy, neurologic deficits).

220.3.3 Treatment

Cricopharyngeal dysphagia is best managed by performance of cricopharyngeal myotomy. The failure rate for surgery alone may be high, especially if aspiration pneumonia or malnutrition is present.[4] In these instances, more aggressive medical management (enteral tube feeding) is warranted rather than surgery. Mature animals and those with cricopharyngeal asynchrony respond less favorably to surgical intervention. Medical therapy includes treatment of aspiration pneumonia and enteral nutritional support in emaciated patients.

220.4 ESOPHAGITIS

Esophagitis denotes acute or chronic inflammation of the esophageal mucosa which may extend to the underlying muscularis. It may be caused by chemical injury from ingested substances (corrosives, pill or capsule retention), gastroesophageal reflux (secondary to general anesthesia, hiatal defects, persistent vomiting, malpositioned nasoesophageal or pharyngostomy tubes), or esophageal foreign bodies.[5] Mucosal damage caused by reflux is attributed to prolonged contact with gastric acid, pepsin, bile salts, and trypsin. Reduced esophageal clearance by peristalsis and failure to neutralize acid by bicarbonate-rich saliva contribute to anesthesia-associated reflux esophagitis. Drug-or chemical-induced esophagitis is caused by changes in mucosal pH, hyperosmolarity, and other mechanisms. Disturbances in esophageal motility may accompany esophagitis regardless of the cause. The reported prevalence of acute esophagitis is low; however, this is likely an underestimation due the subtlety of clinical signs and radiographic findings associated with this disorder.[6]

220.4.1 Clinical Signs

The clinical signs vary as to the type of chemical injury, severity of inflammation, and extent of esophageal involvement. Animals with mild esophagitis may be asymptomatic. Moderate-to-severe esophagitis causes anorexia, dysphagia, odynophagia (seen as extension of the head and neck during swallowing), and hypersalivation. Regurgitation is often intermittent, but it may be persistent. Thick, ropey saliva that is blood-tinged is often expelled. The physical examination may be unremarkable in animals with mild esophagitis. Cachexia and weight loss may be seen with prolonged disease.

Figure 220-1 Diagnostic approach to an animal with regurgitation and suspected esophageal disease. (Adapted from Washabau RJ: Diseases of the esophagus. *In* Ettinger SJ, Feldman ED [eds]: *Textbook of Veterinary Internal Medicine*. 5th ed. Philadelphia, WB Saunders Co, 2000, p 1144.)

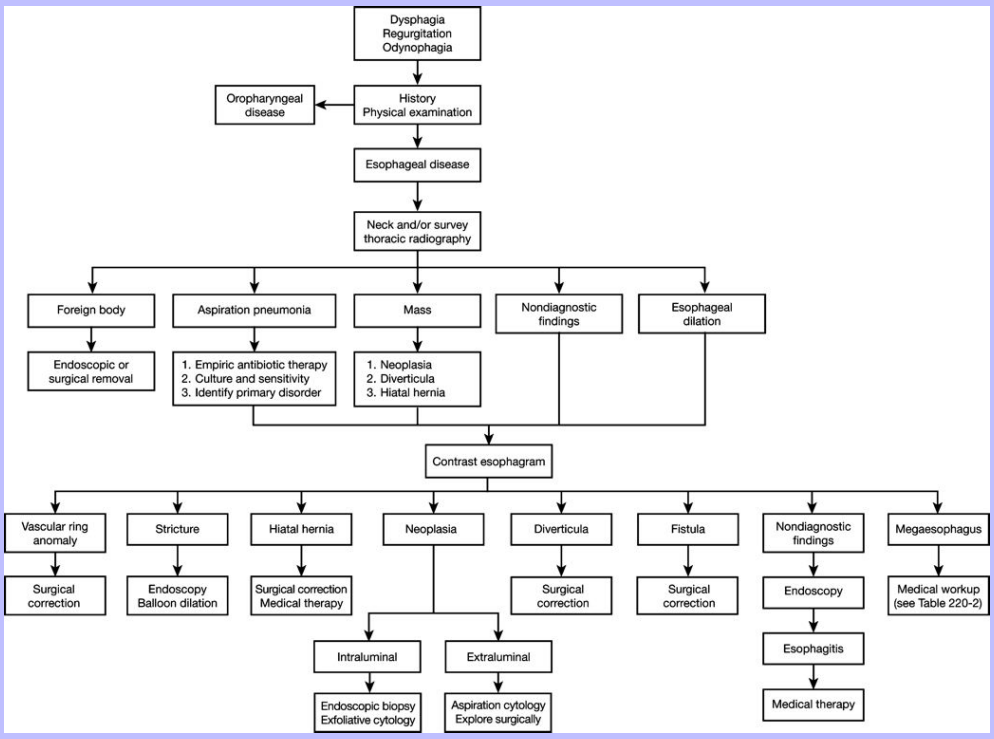

Figure 220-2 Contrast esophagram (static image) performed in a 5-month-old puppy with cricopharyngeal dysphagia. Reader should note the abnormal reflux of liquid barium into the nasopharynx.

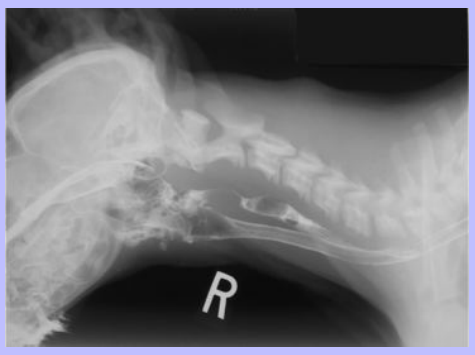

220.4.2 Diagnosis

Results of routine hematology, serum biochemistry, urinalysis, and survey thoracic radiographs are usually normal. Segmental or diffuse esophageal dilatation may be seen with severe mucosal inflammation (Figure 220-3). Barium contrast radiography is infrequently performed but may confirm esophageal dilatation, disturbances in motility, and stricture. Esophagitis is an endoscopic diagnosis that does not require mucosal biopsy. A spectrum of mucosal abnormalities may be observed during esophagoscopy including increased erythema, erosions, and alterations in mucosal texture (Figures 220-4 and 220-5). Lesions are usually most evident in the distal esophagus, adjacent to and including the LES. The presence of gastroesophageal reflux with a dilated LES is suggestive of a hiatal disorder.

220.4.3 Treatment

Mild esophagitis frequently resolves with minimal treatment other than dietary management. The clinician should provide frequent, smaller-sized meals of a low-fat, high-protein content to enhance LES tone and to minimize reflux. Animals having more severe esophagitis, especially those with anorexia, weight loss, or the inability to retain food, will require drug therapy and gastrostomy tube feeding. Sulcralfate suspension (0.5 to 1.0 g orally, three times a day) is the most beneficial and specific therapy for reflux esophagitis.[7] It selectively binds to eroded mucosa and provides effective barrier protection against refluxed gastric contents. Metoclopramide should be administered (0.1 to 0.2 mg/lb per os, subcutaneously, three times a day) or cisapride (0.05 to 0.25 mg/lb per os, twice a day) to decrease esophageal reflux (by increasing LES pressure) and to promote gastric emptying. Gastric acid secretory inhibitors (ranitidine 0.5 to 1.0 mg/lb orally or intravenously, twice a day; famotidine 0.25 to 0.5 mg/lb orally, once a day; omeprazole 0.35 mg/lb orally, once a day) should be given to decrease acidity of gastric juice. Broad-spectrum antibiotics are indicated in the occasional animal having concurrent aspiration pneumonia. A water bolus should be routinely administered to cats receiving tablets or capsules per os to prevent medication-associated esophagitis.[5]

Figure 220-3 Contrast esophagram (lateral view) performed with food in a 5-year-old dog. Generalized esophageal dilatation is observed secondary to severe reflux esophagitis. Esophageal function completely normalized after medical therapy for esophagitis.

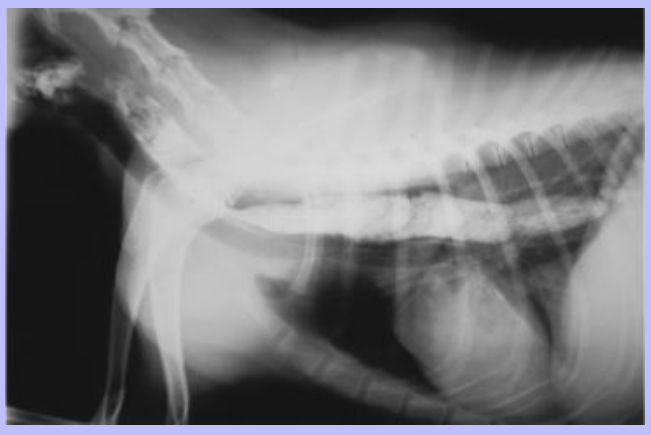

Figure 220-4 Endoscopic appearance of severe esophagitis in the distal canine esophagus. Marked mucosal erythema and dilation of the lower esophageal sphincter (LES) is evident.

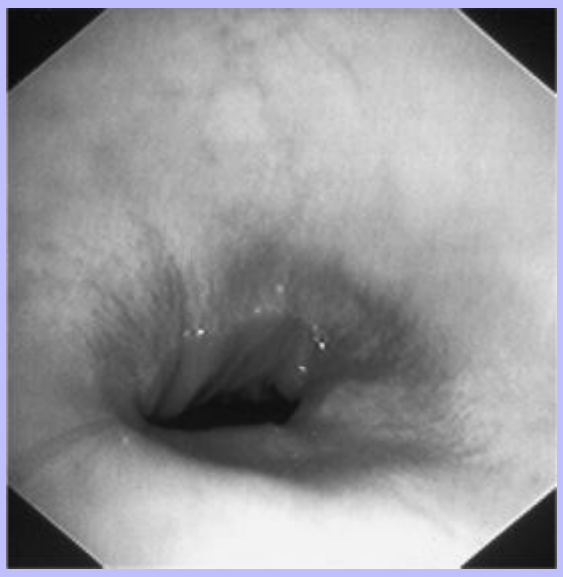
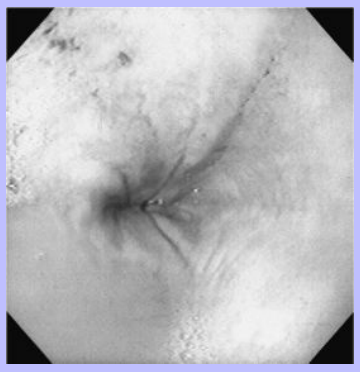


The duration of drug therapy is empiric and varies with severity of signs and endoscopic lesions. Mild lesions are treated for 5 to 7 days; moderate-to-severe esophagitis is treated for 2 to 3 weeks. The prognosis in most cases of esophagitis is good with appropriate medical therapy. Animals having severe disease warrant a guarded prognosis because permanent changes in esophageal structure (stricture formation) or function (segmental or generalized hypomotility) may occur.

1301

1302

Figure 220-5 Endoscopic appearance of reflux esophagitis in the distal canine esophagus. Pooled liquid reflux and multifocal erosions are seen along the mucosa adjacent to the lower esophageal sphincter (LES).



220.5 ESOPHAGEAL FOREIGN BODIES

The ingestion of foreign bodies is a common cause of esophageal dysphagia in the dog but is less common in cats. Foreign bodies usually lodge at points of minimal esophageal distension including the thoracic inlet, at the base of the heart, or at the diaphragmatic hiatus. The most common objects ingested are bones, fish hooks, needles, sticks, and play toys. Retained foreign bodies cause partial or complete mechanical obstruction. Muscle spasm and tissue edema occur around the foreign body, making passage of the object down the esophagus more difficult. Mucosal abrasion, laceration, and perforation may occur with sharp or angular objects that are lodged intraluminally.

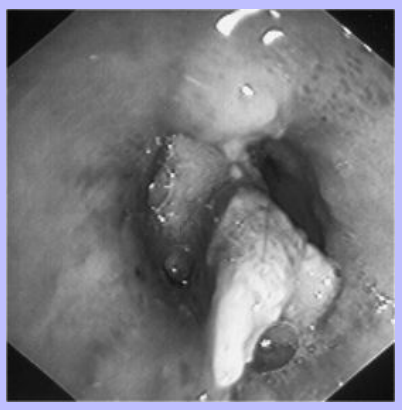
220.5.1 Clinical Signs

The severity of clinical signs is related to the size of the foreign body and duration of esophageal obstruction.[8] Most dogs and cats with large esophageal foreign bodies are presented for evaluation of acute onset of regurgitation, dysphagia, odynophagia, gagging, and excessive salivation. Smaller foreign bodies which are undiagnosed initially may cause identical signs of several days duration.

220.5.2 Diagnosis

Foreign body ingestion may be reported by the owner. Physical examination is variable, ranging from unremarkable to the presence of halitosis seen with tissue necrosis. Cervical esophageal foreign bodies may be palpable. The findings of depression, anorexia, fever, and cough support aspiration pneumonia or esophageal perforation. A hemogram may reveal a leukocytosis with infection. Clinicians should evaluate thoracic radiographs for aspiration pneumonia (alveolar pulmonary opacities) or esophageal perforation (pneumomediastinum, mediastinitis). Contrast radiography is necessary to identify radiolucent objects. A water-soluble positive-contrast agent (iohexol, gastrografin) should be used rather than barium sulfate if esophageal perforation is suspected. Esophagoscopy should be performed to confirm the diagnosis and to assess secondary mucosal damage.

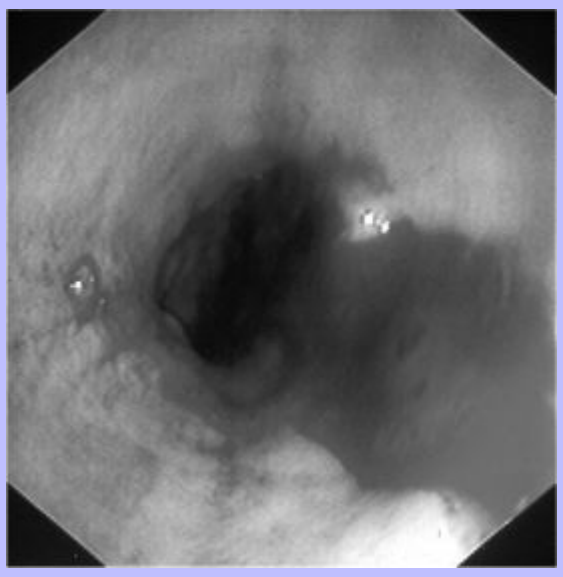
Figure 220-6 Endoscopic appearance of a large angular bone lodged in the thoracic esophagus of a 2-year-old dog. Minor erosive lesions are also present.



220.5.3 Treatment

Esophageal foreign bodies are medical emergencies and should be promptly removed. Endoscopic removal of foreign bodies using a flexible instrument that accommodates a variety of retrieval (grasping) instruments is usually successful. Larger grasping forceps, normally used with rigid endoscopes, may be passed along the side of the flexible endoscope to grasp objects. Distal esophageal foreign bodies may be pushed into the stomach if they cannot be extracted orally. Gastrostomy is not required for most bone foreign bodies, but nondigestible materials retained in the stomach will require surgical removal. The clinician should thoroughly evaluate the esophageal mucosa after foreign body extraction for hemorrhage, lacerations, and perforations (Figures 220-6 and 220-7). Postprocedural thoracic radiographs should be obtained to assess for pneumomediastinum and pneumothorax.

Figure 220-7 Endoscopic appearance of the thoracic esophagus after successful extraction of a bone foreign body (see Figure 220-6). Reader should note the severe trauma and hemorrhage to the esophageal mucosa as a consequence of foreign body retrieval.



1302

1303

Food or water should be restricted for 24 to 48 hours, depending on the extent of esophageal trauma. Animals with severe mucosal damage will require complete esophageal rest and gastrostomy tube feedings. The clinician should institute medical therapy for esophagitis (see Esophagitis earlier in this chapter). Small esophageal perforations are successfully treated with broad-spectrum antibiotics such as ampicillin (11 mg/lb subcutaneously, intramuscularly, or intravenously, three times a day).[9] Surgery (esophagotomy) is indicated if the foreign body cannot be removed endoscopically.

The prognosis after endoscopic foreign body removal is generally excellent. Significant esophageal trauma or large perforation carries a guarded prognosis. Permanent sequellae may include fistula, diverticulum, or stricture formation, as well as segmental defects in motility.

220.6 ESOPHAGEAL STRICTURE

Esophageal stricture is an abnormal circumferential narrowing of the esophageal lumen that occurs secondary to severe eso-phagitis. After mucosal injury, inflammation extends beyond the mucosa into the muscular layer and heals by fibrosis. Fibrotic changes (maturation with contraction) in the esophageal wall cause luminal narrowing. Strictures may occur at any point along the length of the esophagus. The time period from severe esophagitis to lumenal stenosis is approximately 1 to 3 weeks.[10] The most important causes for stricture are gastro-esophageal reflux (secondary to general anesthesia) and trauma from esophageal foreign bodies.

220.6.1 Clinical Signs

Classical signs for esophageal dysfunction (regurgitation, dysphagia, ptyalism) are observed and tend to be progressive. Animals often are more tolerant of liquid meals rather than solid meals. A ravenous appetite with weight loss is common because of the inability to transport food past the strictured site.

220.6.2 Diagnosis

A diagnosis of stricture is often suggested by clinical history. The physical examination generally reveals no significant abnor-malities other than weight loss. Survey thoracic radiographs are usually normal. Contrast radiography using liquid barium or barium mixed with food demonstrates esophageal lumenal stenosis (Figure 220-8). Contrast studies are useful in assessing the number, location, and length of strictures. Most animals have a single esophageal stricture. Esophagoscopy confirms stricture and permits differentiation of benign from malignant stricture via results obtained from mucosal biopsy and endoscopic exfoliative cytology.

Figure 220-8 Contrast esophagram (lateral view) using liquid barium in a 4-year-old domestic shorthaired (DSH). A 1.5 cm long esophageal stricture is visualized over the base of the heart. Reader should note that the esophagus is dilated cranial to the stricture.

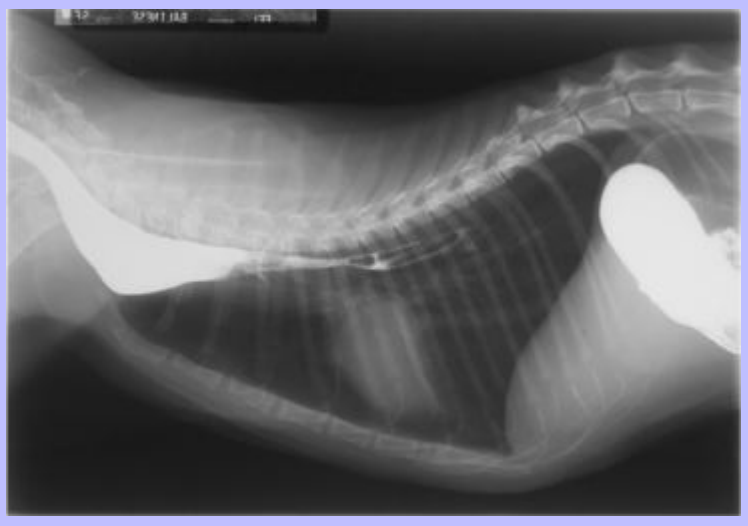


Figure 220-9 Balloon dilatation of an esophageal stricture in a cat using endoscopic guidance (see Figure 220-8). Esophagoscopy demonstrates a 4 mm diameter stricture in the thoracic esophagus.

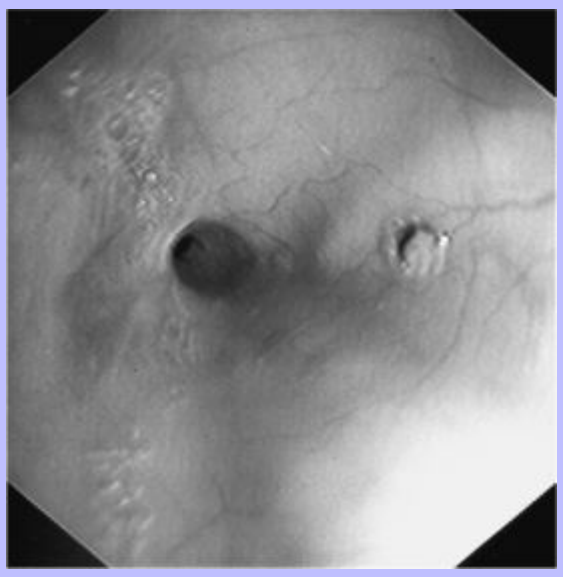


220.6.3 Treatment

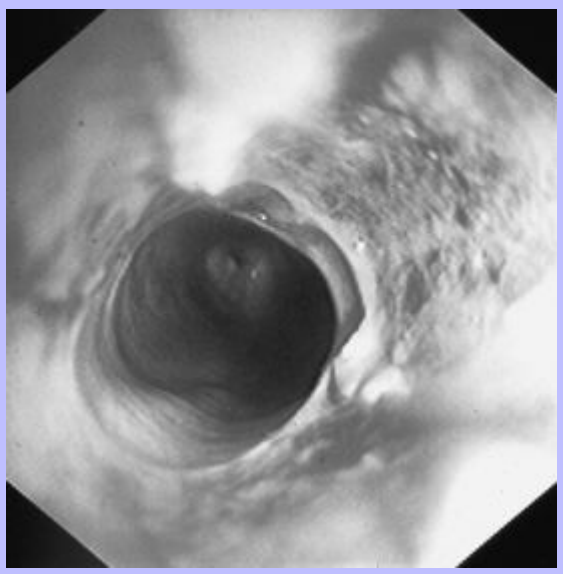
Benign strictures are best treated by mechanical dilatation using a balloon catheter under endoscopic guidance. Balloon catheter dilatation is superior to rigid bougienage because less likelihood of perforation exists, fewer repeated dilatations are required, and a longer clinical response occurs between dilatations.[11] A technique for balloon catheter dilatation in both dogs and cats has been previously described.[11–13] A special polyethylene catheter (Ridgiflex Dilator, Microvasive Inc., Watertown, MA) is carefully advanced adjacent to the endoscope and centered in the lumen of the stricture. The balloon is distended to a desired pressure (not to exceed the maximum pressure recommended by the manufacturer) and held for 2 to 3 minutes. The catheter is then deflated to evaluate lumenal diameter and the extent of iatrogenic trauma. The procedure is immediately repeated using a greater catheter pressure to dilate the stricture further (Figures 220-9 to 220-11). Balloon dilatations are usually performed two to four times (each requiring a separate anesthetic procedures) at intervals of 2 to 3 days because restricture occurs rapidly.[14] Those strictures associated with active esophagitis will require a greater number of dilatation procedures. Complications of balloon dilatation include excessive hemorrhage (common) and esophageal perforation (rare).

1303

1304

Figure 220-10 Balloon dilatation procedure using maximum balloon inflation pressure.

Figure 220-11 Iatrogenic esophagitis that occurs secondary to aggressive balloon dilatation. Reader should note the significant hemorrhage and fibrous tissue tears at the dilated stricture site.



Medical therapy of esophagitis is required after mechanical dilatation. The clinician should withhold feedings for 24 hours or place a gastrostomy tube for enteral feedings in animals with severe mucosal trauma. To prevent further injury to the esophageal mucosa from gastroesophageal reflux, H_2-blockers, drugs to enhance LES tone, or both should be administered. Animals with severe esophagitis are also treated with an oral sucralfate slurry (0.5 to 1.0 g dissolved into 5 ml water, orally, three times a day). The use of corticosteroids (prednisone 0.5 to 1.0 mg/lb orally, divided twice a day for 10 to 14 days) may prevent healing by fibrosis and stricture recurrence. Dietary management and medical therapy of gastroesophageal reflux should be continued for 10 to 14 days after balloon dilatation.

The prognosis for benign strictures is good with successful dilatation. Surgical resection of benign strictures is less desirable because success rates are less than with balloon dilatation procedures. Furthermore, restricture at the surgical site is a common sequellae. Malignant esophageal strictures carry a poor prognosis and are treated with a combination of surgical resection (if possible), balloon dilatation (if needed), and appropriate postsurgical irradiation, chemotherapy, or both.

220.7 MEGAESOPHAGUS AND ESOPHAGEAL HYPOMOTILITY

Megaesophagus is a disorder characterized by diffuse esophageal dilation and aperistalsis. This syndrome may occur as a congenital idiopathic disorder (uncommon), or it may manifest in adult animals as an idiopathic (common) or acquired lesion. A familial predisposition for congenital megaesophagus has been suggested for the Irish setter, Great Dane, German shepherd, Labrador retriever, Chinese Shar Pei, Newfoundland, miniature schnauzer, and fox terrier breeds.[1,3,6] Congenital megaesophagus in cats is rare, but Siamese cats may be predisposed. The pathogenesis of congenital idiopathic megaesophagus is poorly understood but may involve a defect in vagal afferent innervation of the esophagus.[15,16]

The underlying pathophysiologic mechanism for acquired idiopathic megaesophagus is unknown. Functional responses of the upper and LESs remain intact, and a defect in the afferent neural pathway responsive to esophageal distension is suspected.[17,18] Acquired secondary megaesophagus may result from many disorders, especially diseases causing diffuse neuromuscular dysfunction (Table 220-2). MG accounts for at least 25% of the acquired causes in dogs.[19,20] Dysautonomia is a generalized autonomic neuropathy in which megaesophagus and esophageal hypomotility are consistent findings.[21] This idiopathic disorder is more frequently recognized in cats and is attributed to degenerative lesions involving autonomic ganglia that affect esophageal function. Other causes of segmental or diffuse esophageal hypomotility include foreign bodies, stricture, vascular ring anomalies, and esophagitis. Esophageal dysfunction in Chinese Shar Peis may also result from segmental hypomotility and esophageal redundancy.[22]

220.7.1 Clinical Signs

Regurgitation is the salient clinical sign seen with megaesophagus. Considerable variability exists in the frequency and timing of regurgitation episodes after meal ingestion. Puppies with congenital megaesophagus often begin regurgitating when weaned to solid foods. Weight loss and emaciation occur secondary to malnutrition in animals having long-standing disease. Respiratory distress (moist cough, dyspnea) and fever indicate aspiration pneumonia, which is the most common complication of megaesophagus. Additional clinical signs including muscle pain and stiff gait with polymyositis, generalized weakness with neuromuscular disease, and GI signs with lead toxicity or Addison's disease may be detected in animals having mega-esophagus associated with an acquired disorder.

220.7.2 Diagnosis

The clinician should suspect megaesophagus in any adult animal, particularly dogs, with a history of regurgitation. Survey radiographs of the cervical neck and thorax usually reveal the presence of a dilated air-, fluid-, or ingesta-filled esophagus (Figure 220-12). The presence of pulmonary alveolar opacities are indicative of aspiration pneumonia. Barium contrast radiography (esophagram) confirms dilatation and provides evidence of other structural abnormalities (mechanical obstruction). Esophageal motility is best evaluated with fluoroscopy, which assesses the presence and intensity of esophageal peristalsis. Routine hematology, serum biochemistry, and urinalysis should be performed to screen for acquired causes of mega-esophagus. An acetylcholine receptor antibody titer should be performed to evaluate for acquired MG, even in the absence of generalized muscle weakness, because MG may mimic idiopathic megaesophagus. Additional laboratory tests are performed on the basis of clinical suspicion (see Table 220-2). Esophagoscopy is rarely required for diagnosis of megaesophagus, except when obstructive disease (neoplasia) or reflux esophagitis are suspected. A clinical diagnosis of dysautonomia is made in most cases based on the unique historical (depression, anorexia, constipation, regurgitation) and physical examination (dry mucous membranes, pupillary dilation, prolapsed nictitating membranes, diminished pupillary light response, bradycardia, and areflexic anus) findings.[21]

220.7.3 Treatment

Animals with acquired secondary megaesophagus are treated specifically for the disorder causing abnormal esophageal motor function (see Table 220-2). Treatment of idiopathic megaesophagus and those acquired forms that fail to respond to specific medical therapy is primarily supportive and symptomatic. The clinician should offer small, frequent meals from an elevated or upright position to assist passage of ingesta into the stomach. Food consistency should be varied (gruel versus bulk boluses) to determine which types of food are best tolerated. Animals that are severely malnourished or that have aspiration pneumonia should have a gastrostomy tube placed for enteral nutritional support. Broad-spectrum antibiotics should be given for treatment of aspiration pneumonia. Clients should be counseled that recurrent pneumonia is a common problem necessitating prompt detection and treatment for long-term success.

1304

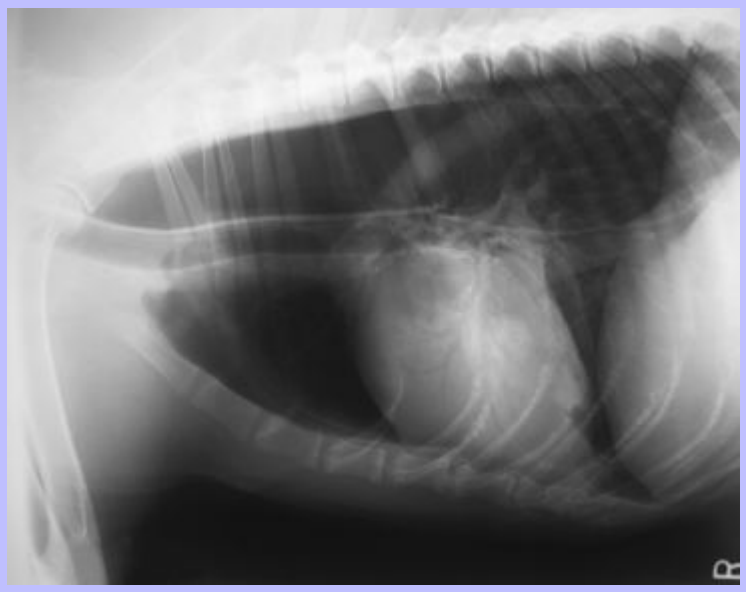
1305

Table • 220-2 Diagnosis and Treatment of Megaesophagus

CAUSE	DIAGNOSTIC TEST	TREATMENT
Neuromuscular Disease		
Idiopathic	Diagnosis of exclusion	Small, frequent elevated feedings
Myasthenia gravis (MG)	Acetylcholine receptor antibody titer, tensilon test, +/−EMG	Pyridostigmine (0.5–1.5 mg/lb PO bid, +/−prednisone (0.5–1.0 mg/lb PO, SC bid)
Systemic lupus erythematosis (SLE)	ANA, skin biopsy	Prednisone (0.5–1.0 mg/lb PO, SC bid)
Polymyositis/polymyopathy	CK, muscle biopsy, EMG	Prednisone (0.5–1.0 mg/lb PO, SC bid)
Glycogen storage disease (type II)	Muscle/liver biopsy, urine metabolic screening	Supportive/symptomatic care
Dermatomyositis	Skin/muscle biopsy	Prednisone (0.5–1.0 mg/lb PO bid)
Dysautonomia	Clinical diagnosis	Supportive/symptomatic care
Distemper	CSF tap, distemper titer	Supportive care
Tetanus	EMG, serum toxin assay	Supportive care
Esophageal Obstruction		
Neoplasia	Contrast radiography, esophagoscopy and biopsy	Surgical resection, chemotherapy
Vascular ring anomaly	Survey/contrast radiography	Surgical correction
Stricture	Contrast radiography, esophagoscopy	Balloon dilatation
Foreign body	Survey/contrast radiography, esophagoscopy	Endoscopic retrieval
Toxicity		
Lead	Hematology, blood lead	Chelation therapy (calcium EDTA)
Organophosphate	Blood cholinesterase activity	Gastric lavage, atropine (0.1 mg/lb SC once) Pralidoxime chloride (5–7.5 mg/lb slow IV)
Miscellaneous		
Hypoad renocorticism	ACTH stimulation test	Prednisone (0.05 mg/lb PO bid), fludrocortisone (0.005 mg/lb PO bid)
Hiatal hernia	Contrast radiography, esophagoscopy	Surgical correction
Gastric dilatation-volvulus	Survey radiography	Surgical correction, supportive care
Esophagitis	Esophagoscopy	Sucralfate (0.5–1.0 g slurry PO tid), ranitidine (0.5–1.0 mg/lb PO ranitidine (0.5–1.0 mg/lb PO bid), metoclopramide (0.2 mg/lb PO tid)
Thymoma	Survey radiography, thymic aspirate	Surgical resection

Adapted from Washabau RJ: Diseases of the esophagus. *In* Ettinger SJ, Feldman ED (eds): *Textbook of Veterinary Internal Medicine,* 5th ed. Philadelphia, WB Saunders Co, 2000, p 1150.

Figure 220-12 Survey thoracic radiograph (lateral view) performed in a 10-year-old dog with idiopathic megaesophagus. A diffusely dilated, air-filled esophagus is readily visualized.



Promotility drugs are currently of unproven benefit in the management of idiopathic megaesophagus in dogs. Both metoclopramide and cisapride are smooth muscle prokinetic agents that have no effect on the striated muscle of the esophageal body.[23] Indeed, preliminary data indicate that cisapride actually decreases the esophageal transit rate of a food bolus in healthy dogs.[24] Cisapride may be a useful prokinetic agent in cats with distal esophageal motility disturbances because of the smooth muscle component in this segment of the feline esophagus.

Affected animals should be re-evaluated at 1-to 2-month intervals to monitor disease progression. Thoracic radiographs should be repeated to assess esophageal dilatation and aspiration pneumonia. Some animals with congenital idiopathic mega-esophagus may improve over time (months) with diligent supportive care. The prognosis with acquired idiopathic mega-esophagus is generally poor. These animals usually succumb to repeated episodes of aspiration pneumonia or are euthanized because of their irreversible disease. Animals with acquired secondary megaesophagus may respond to specific drug therapy. The prognosis in dogs with megaesophagus caused by acquired MG is favorable, with approximately 50% of dogs responding to supportive therapy.[19]

1305 1306

220.8 VASCULAR RING ANOMALY

Vascular ring anomalies are congenital malformations of the major arteries of the heart that entrap the intrathoracic esophagus and cause esophageal obstruction. Persistent right aortic arch (PRAA) is the best-documented anomaly in both dogs and cats; it occurs when the embryonic right aortic arch (rather than the left fourth aortic arch) becomes the functional adult aorta. Circular entrapment of the esophagus occurs by the

aorta on the right, the ligamentum arteriosum dorsolaterally on the left, the pulmonary trunk on the left, and the heart base ventrally. This anomaly is considered to have a familial tendency because German shepherds and Irish setters appear to be predisposed.[6] Other less common vascular anomalies include persistent right or left subclavian arteries, double aortic arch, persistent right dorsal aorta, left aortic arch and right ligamentum arteriosum, and aberrant intercostal arteries.

220.8.1 Clinical Signs

Affected puppies and kittens usually present for regurgitation of solid foods at the time of weaning. Weight loss with failure to thrive despite a good appetite is commonly observed. The presence of a moist cough, dyspnea, and fever suggest aspiration pneumonia. Physical examination often reveals a thin, stunted animal that is otherwise normal.

220.8.2 Diagnosis

Vascular ring anomalies should be differentiated from other causes of regurgitation in young animals such as congenital idiopathic megaesophagus, esophageal foreign body, and cricopharyngeal dysphagia. The signalment and a compatible history of regurgitation since weaning are very suggestive of a vascular ring anomaly. Survey thoracic radiographs usually demonstrate esophageal body dilation cranial to the base of the heart. Radiographic abnormalities to the caudal esophagus are seldom seen. A barium esophagram should be performed to confirm the location of esophageal obstruction and severity of esophageal distension (Figure 220-13). Fluoroscopy is useful to evaluate for segmental or generalized esophageal motility disturbances. Angiography is occasionally performed for definitive confirmation of the type and location of the vascular anomaly prior to surgery. Esophagoscopy will differentiate intraluminal stricture from extraluminal compression. Strictures appear as distinct intraluminal fibrous rings that remain static when viewed endoscopically; whereas with vascular ring anomaly, rhythmic pulsations of the great arteries compressing the esophagus externally are observed (Figure 220-14).

Figure 220-13 Contrast esophagram (lateral view) performed in a 7-month-old dog with a persistent right aortic arch. Abrupt attenuation of the liquid barium contrast column is observed at the base of the heart along with segmental (cranial) esophageal dilatation.

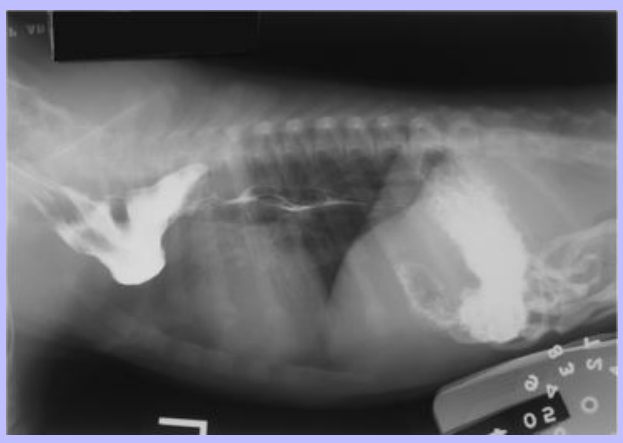


Figure 220-14 Dynamic endoscopic appearance of persistent right aortic arch in a 3-year-old dog (see Figure 220-13). Extraluminal pulsations of blood through the anomalous artery cause the stenosis to intermittently "close" **(A)** and "open" **(B)**.

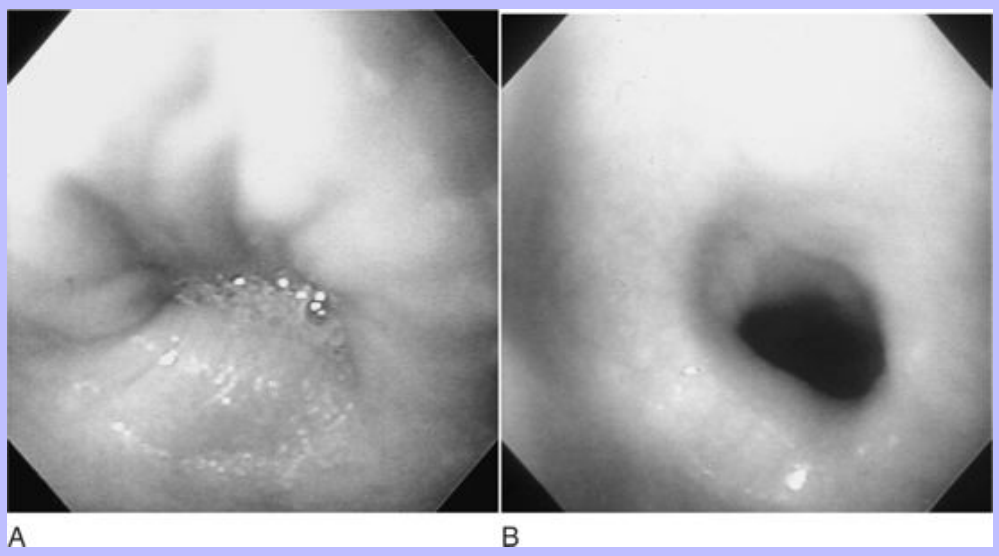


220.8.3 Treatment

Definitive therapy for PRAA is surgical ligation and transection of the ligamentum arteriosum. Animals with severe debilitation from malnutrition will require enteral nutritional support via gastrostomy tube feedings. Aspiration pneumonia should be effectively treated with broad-spectrum antibiotics before surgery. Significant clinical improvement usually follows corrective surgery, although esophageal hypomotility and regurgitation may persist. In these instances, affected animals are managed with elevated feedings as described for idiopathic megaesophagus.

1306
1307

The best prognosis for return of normal esophageal function is obtained with early diagnosis and prompt surgical intervention. Progressive esophageal dilatation that causes irreversible myenteric nerve degeneration and esophageal hypomotility may occur if a diagnosis is not made at an early age.

220.9 ESOPHAGEAL DIVERTICULA

Esophageal diverticula are rare pouchlike sacculations of the esophageal wall that may be congenital or acquired. Congenital diverticula are due to developmental abnormalities of the esophagus that permit herniation of the mucosa through the muscularis. Acquired diverticula are classified as either *pulsion* or *traction* forms. Pulsion diverticula result from conditions of increased intraluminal pressure secondary to obstruction (stricture or foreign body) or altered motility.[25,26] Traction diverticula result from periesophageal inflammation and fibrosis. With the traction form, contraction of fibrotic adhesions leads to eversion and out-pouching of the esophageal wall. The

accumulation of ingesta (impaction) within diverticula leads to esophagitis, mechanical obstruction (seen with large diverticula), and disturbed esophageal motility.

220.9.1 Clinical Signs

Large multilobulated diverticula are most likely to cause signs of regurgitation, odynophagia, and retching. Postprandial regurgitation results from mechanical obstruction and motility disturbances. Severe cases with mucosal ulceration may eventually perforate and cause signs of mediastinitis and respiratory distress. Clinical signs may not occur with small diverticula.

220.9.2 Diagnosis

Survey thoracic radiographs may reveal an air or soft-tissue opacity adjacent to the esophagus. Diverticula should not be confused with the normal esophageal redundancy seen in young brachycephalic breeds and Chinese Shar Peis. Performance of contrast radiography shows a focally dilated segment of the esophagus that fills partially or completely with contrast material. Esophagoscopy confirms a saclike out-pouching of the esophageal lumen containing impacted ingesta and having localized esophagitis.

220.9.3 Treatment

Diverticulectomy is the preferred therapy. Large diverticula will require greater excision and reconstruction of the esophageal wall. Small diverticula may be managed medically with smaller-sized, upright feedings of a liquid or semiliquid diet to minimize impaction of ingesta in the diverticulum. Traction diverticuli are often managed with broad-spectrum antibiotics, whereas pulsion diverticula are treated for their specific cause (see Esophagitis, Stricture, earlier in this chapter). Most cases warrant a guarded prognosis because complications, such as stricture formation and segmental hypomotility, may persist after surgery.

220.10 ESOPHAGEAL FISTULA

An esophageal fistula is an abnormal communicating tract between the esophagus and usually the respiratory system (esophagopulmonary, esophagotracheal, and esophago-bronchial fistula). Both congenital and acquired fistulas have been described. Acquired fistulas are usually associated with retained esophageal foreign bodies, especially bones. Other causes include trauma, neoplasia, or periesophageal inflammation. In most cases, the lodged foreign body causes mural necrosis, esophageal perforation, and leakage of esophageal contents into adjacent tissues. Healing leads to development of a communicating tract with resultant airway contamination from esophageal contents. Esophageal fistula is relatively uncommon in the dog and cat.

220.10.1 Clinical Signs

Clinical signs are primarily associated with respiratory tract and include coughing and dyspnea. Coughing after drinking is a common presenting sign. Dysphagia and regurgitation are less commonly observed in association with an esophageal foreign body. Anorexia, lethargy, weight loss, and fever are seen with mediastinitis or aspiration pneumonia. The physical examination findings of cough, fever, pulmonary crackles, and weight loss reflect chronic respiratory disease.

220.10.2 Diagnosis

Survey thoracic radiographs usually reveal a localized alveolar, bronchial, or interstitial lung pattern (or a combination of these patterns). The right caudal lung lobe in dogs and the left caudal and accessory lobes in cats are most commonly affected.[27] Radiopaque foreign bodies may be observed in the esophagus. A barium esophagram is required for definitive diagnosis of esophageal-airway communication. Clinicians should avoid using iodinated contrast agents in these procedures because they are hyperosmolar and potentially irritating to exposed tissues. Endoscopic examination (esophagoscopy, bronchoscopy) is of limited value in confirming small fistulas. A CBC may reflect associated inflammation (periesophagitis, pneumonia) and nonregenerative anemia.

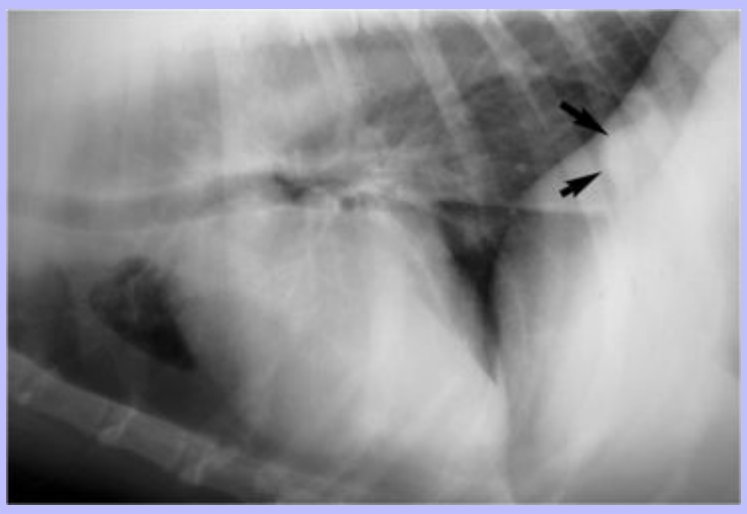
220.10.3 Treatment

Surgical correction of the fistulous tract is required. Esophagotomy for a retained esophageal foreign body should be performed. Lobectomy may be necessary as a result of pulmonary consolidation or foreign material contained within the airways. Postsurgical therapy includes esophageal rest and administration of appropriate antibiotics for infection (based on culture and susceptibility testing of involved tissues). A good prognosis is given to animals after successful surgery. The prognosis is guarded if severe complications, such as dehiscence, stricture, or pulmonary abscessation, are present.

220.11 ESOPHAGEAL NEOPLASIA

Tumors of the esophagus are rare, accounting for less than 0.5% of all cancers in the dog and cat.[28] Neoplasms may be of primary esophageal, periesophageal, or metastatic origin. Esophageal fibrosarcoma and osteosarcoma are the most common malignant tumors in dogs, developing from malignant transformation of esophageal granulomas associated with *Spiracerca lupi* infection.[29] Squamous cell carcinoma is the most commonly diagnosed primary esophageal tumor in cats. Other less commonly reported primary esophageal tumors in the dog and cat include leiomyo(sarco)ma and undifferentiated carcinoma. Periesophageal tumors arising from a variety of adjacent structures (lymph nodes, thyroid, thymus, and heart base) cause local esophageal invasion, direct mechanical obstruction, or both. Metastatic lesions (thyroid, pulmonary, and gastric carcinomas) commonly involve the esophagus but less frequently cause clinical signs of esophageal disease.

Figure 220-15 Survey thoracic radiograph (lateral view) showing generalized esophageal dilatation (megaesophagus) in a 9-year-old rottweiler. A distinct soft-tissue opacity (*arrows*) is visualized in the distal esophagus at the level of the lower esophageal sphincter (LES).

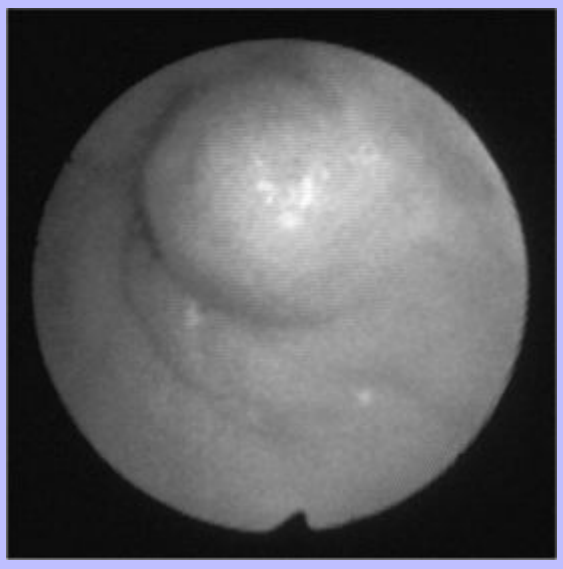


220.11.1 Clinical Signs

Animals with esophageal neoplasia have signs consistent with progressive esophageal obstruction, including chronic regurgitation, dysphagia, odynophagia, and ptyalism. Anorexia, weight loss, and depression are more typical of advanced disease (metastasis, systemic effects of cancer) and malnutrition resulting from the inability to retain food. The physical examination findings may reveal weight loss and emaciation, and large periesophageal masses involving the cervical esophagus might be palpable.

Figure 220-16 Contrast esophagram (ventrodorsal view) in a 10-year-old cat. Cervical esophageal dilation with narrowing of the barium contrast column caused by partial esophageal obstruction is observed. Reader should note the lateral displacement of the air-filled trachea suggestive of a periesophageal mass.

Figure 220-17 Endoscopic appearance of an esophageal mass located adjacent to the lower esophageal sphincter (LES) in a dog (see Figure 220-15). Histopathology proved the mass to be a leiomyosarcoma.



220.11.2 Diagnosis

Clinicians should consider a diagnosis of esophageal neoplasia in middle-aged and older animals having chronic progressive signs of obstructive esophageal disease. Survey thoracic radiographs may be normal or reveal variable esophageal dilatation, an intraluminal mass, or evidence of a periesophageal lesion displacing the esophagus (Figures 220-15 and 220-16). The lungs should be evaluated for aspiration pneumonia (alveolar opacities) and metastasis (nodular opacities). A barium esophagram typically confirms the presence of an intraluminal mass or obstructive lesion. Esophagoscopy with mucosal biopsy and exfoliative cytology is required for definitive diagnosis of esophageal neoplasia (Figures 220-17 and 220-18). Endoscopic biopsy of the esophagus is difficult because the mucosa is tough and it is technically demanding to position the biopsy instrument (forceps) perpendicular to the mucosa. Biopsies with small pinch forceps often provide nonrepresentative superficial epithelial specimens. Both mucosal biopsy and exfoliative cytology are most beneficial in the diagnosis of epithelial-based neoplasms, such as squamous cell carcinoma and lymphosarcoma.

Figure 220-18 Endoscopic appearance of an invasive periesophageal mass in a cat causing near complete esophageal obstruction (see Figure 220-16). Endoscopic exfoliative cytology confirmed a diagnosis of lymphoblastic lymphosarcoma (see Figure 220-20).

220.11.3 Treatment

Successful treatment of malignant esophageal neoplasia is uncommon because the disease is often well advanced at the time of diagnosis. This is especially true for animals having secondary complications such as severe malnutrition, esophageal hypomotility, and aspiration pneumonia. Chemotherapy, radiation therapy, and surgery are palliative techniques for treatment of malignant tumors. In contrast, benign esophageal neoplasms (leiomyoma) carry a good prognosis with complete surgical resection.[30] Lymphosarcoma (typically diagnosed as a periesophageal mass) is generally responsive to multiple drug chemotherapy regimens.

220.12 HIATAL HERNIA

Hiatal hernia may present at two distinct entities in the dog and cat: (1) sliding hiatal hernia, which is a cranial displacement of the distal esophagus and stomach into the mediastinum through the esophageal hiatus, and (2) periesophageal hiatal hernia, which involves cranial displacement of a portion of the stomach into the mediastinum through a defect adjacent to the esophageal hiatus.[31,32] Sliding hiatal hernia is the most common form and may occur as a congenital or acquired lesion in the dog and cat.

Most hiatal hernias are probably congenital and occur as developmental defects (enlargement) of the esophageal hiatus or phrenicoesophageal ligament. Males and Chinese Shar Pei dogs appear to have an increased incidence and develop clinical signs shortly after weaning.[6] Acquired hiatal hernias occasionally occur secondary to trauma (via damage to diaphragmatic nerves and muscles resulting in hiatal laxity) and respiratory distress (caused by

increased negative intrathoracic pressure seen with intermittent airway obstruction [laryngeal paralysis]). Regardless of the cause, hiatal herniation reduces LES pressure and leads to gastroesophageal reflux, esophagitis, and segmental or diffuse esophageal hypomotility.

220.12.1 Clinical Signs

Intermittent signs of reflux esophagitis (persistent regurgitation, vomiting, occasional hematemesis and hypersalivation) predominate. Weight loss may be observed in animals having chronic disease. Dyspnea is common due to aspiration pneumonia and compression of the lungs seen with large hernias. Affected animals may be thin on physical examination.

220.12.2 Diagnosis

Survey thoracic radiographs often reveal the presence of a caudodorsal, gas-filled, soft-tissue opacity. Varying degrees of esophageal dilatation and alveolar opacities (consistent with aspiration pneumonia) may also be observed. Performance of a positive contrast esophagram confirms hiatal herniation and the presence of esophageal dilatation. Fluoroscopy is useful in evaluation of the magnitude of esophageal hypomotility present. Esophagoscopy, generally not a first-choice diagnostic test, may confirm reflux esophagitis and cranial displacement of both the LES and rugal folds of the stomach into the esophageal lumen.

220.12.3 Treatment

Reconstructive surgery is indicated for treatment of large congenital hiatal hernias. Normal hiatal anatomy is restored by performance of diaphragmatic crural apposition, esophagopexy, and left fundic tube gastropexy techniques.[31,33] Animals having smaller, intermittent hiatal hernias should be medically managed for reflux esophagitis, using H_2 receptor antagonists (to reduce gastric acidity), sucralfate suspensions (as a mucosal cytoprotectant), and drugs (cisapride or metoclopramide) to enhance LES tone, which inhibits gastroesophageal reflux. Animals failing medical management will require surgical intervention.

A good prognosis is warranted in animals after successful surgery. A guarded prognosis is given to animals with concurrent esophageal motility disturbances.

220.13 MISCELLANEOUS ESOPHAGEAL DISORDERS

Major causes for *esophageal perforation* include esophageal foreign bodies (large or angular-shaped bones and those objects retained for a prolonged period causing pressure necrosis) and penetrating trauma to the cervical esophagus caused by bite wounds (Figure 220-19). Predominant signs of anorexia, depression, odynophagia, moist cough, fever, and a rigid stance are observed. A diagnosis is often suspected based on history and survey radiographic findings that show a pneumomediastinum, pneumothorax, and mediastinal or pleural effusion. A contrast esophagram using a water-soluble contrast agent (Omnipaque) should be performed to determine the location and extent of the esophageal tear. Esophagoscopy may detect large tears but is an insensitive tool for localizing small tears. Treatment is generally conservative, using broad-spectrum antibiotics, fluid therapy, and nutritional support by tube gastrostomy feedings. Clinicians should monitor therapeutic responses by repeating thoracic radiographs. Large perforations will require surgical correction.

Periesophageal obstruction is uncommonly associated with intrathoracic mass lesions (neoplasia, lymphadenopathy, large abscess) that cause partial extraluminal compression. Clinical signs usually indicate

slowly progressive esophageal dysphagia, often accompanied by extra-esophageal signs of dyspnea, cough, and exercise intolerance. Survey thoracic radiographs usually identify an intrathoracic mass with esophageal encroachment. A contrast esophagram may or may not determine whether intraluminal versus extraluminal compression is present. Esophagoscopy is more useful in characterizing whether or not the stenosis is extraluminal, and whether potential mucosal invasion has occurred. Definitive diagnosis depends on identification of the mass lesion with fine needle aspiration, endoscopic exfoliative cytology (Figure 220-20), or biopsy via thoracotomy.

1309
1310

Figure 220-19 Endoscopic appearance of cervical esophageal perforation in a dog caused by penetrating bite wounds to the neck. The dog responded completely to conservative medical management.

GI intussusception is a rare disorder of young dogs caused by invagination of the stomach, and occasionally other structures such as the spleen, proximal duodenum, and pancreas, into the esophagus.[34] Prolapse of a large portion of the stomach causes abrupt clinical deterioration with mortality rates in excess of 95% reported.[35] The cause for GI intussusception is unknown; however, congenital megaesophagus possibly predisposes to this disorder due to decreased esophageal motility and reduced LES tone. Animals with GI intussusception usually have histories of acute vomiting, regurgitation, dyspnea, hematemesis, and abdominal discomfort. Survey abdominal radiographs confirm the presence of a soft tissue and gas opacity in the dorsocaudal mediastinum. A contrast esophagram usually shows gastric rugae within the esophageal lumen and the presence of esophageal obstruction. Esophagoscopy may also confirm a bulging mass (gastric rugal folds) contained within the lumen of the esophagus. Treatment of large intussusceptions necessitates manual reduction and gastropexy to prevent recurrence. Small lesions may be carefully reduced endoscopically and subsequently managed medically for reflux esophagitis.

Figure 220-20 Endoscopic exfoliative cytology obtained from a cat with an invasive periesophageal mass (see Figure 220-18). A uniform population of lymphoblasts, consistent with lymphosarcoma, is present. Multidrug chemotherapy resulted in complete clinical remission for 9 months.

221 CHAPTER • 221 Diseases of the Stomach

Kenneth W. Simpson*

221.1 FUNCTIONAL ANATOMY

The stomach's main function is to act as a reservoir that controls the size and rate of passage of ingesta into the small intestine. The stomach also initiates the digestion of protein and fat and facilitates the absorption of vitamins and minerals.

Anatomically the stomach is composed of four regions, the cardia, fundus, body, and antrum (Figure 221-1). The fundus and body expand to accommodate ingesta. The antrum is thick and muscular and grinds food into small particles that are triturated into the duodenum. The lower esophageal sphincter prevents reflux of ingesta into the esophagus and the pyloric sphincter controls efflux into the duodenum.

The gastric wall has three layers: the mucosa, muscularis, and serosa. The mucosa has a superficial epithelium, gastric glands, and an innermost layer of smooth muscle, with fine structure and function varying depending on the gastric region (Figure 221-2). The mucosa in the cardia and pylorus is thinner and less glandular than in the fundus and body. The mucosa of the body contains mucous neck cells (pepsinogen A, gastric lipase), parietal cells (acid, pepsinogen A, intrinsic factor), and chief cells (pepsinogen A).[1–3] A variety of neuro-endocrine cells involved with the secretion of gastric acid are interspersed between the glands. The predominant cells are enterochromaffin-like and somatostatin-producing cells in the fundus, and gastrin and somatostatin-producing cells in the antrum. Localized small aggregates of lymphoid tissues are observed at the base of the gastric glands. Intertwined between gastric glands is a rich network of blood vessels and lymphatics and nerves. Beneath the submucosa are two layers of smooth muscle that run perpendicuar to each other. The serosa is the outermost layer.

221.1.1 Regulation of Acid Secretion

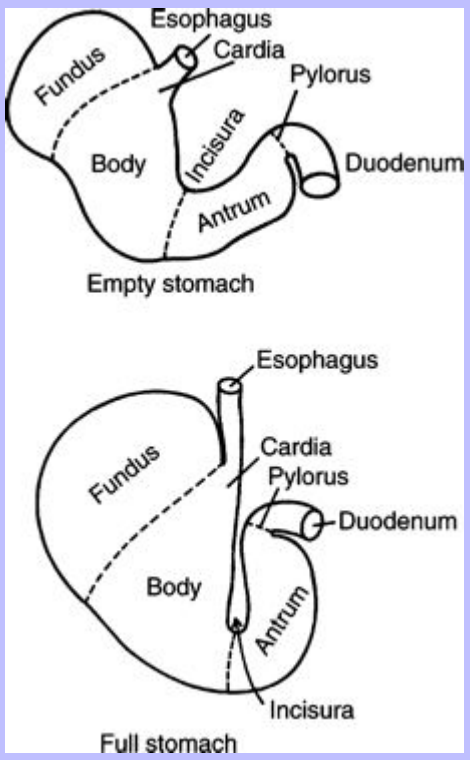
Acid secretion is regulated by a variety of neurochemical and neurohumeral stimuli.[4,5] Luminal peptides, digested protein, acetylcholine, and gastrin-releasing peptide (GRP) stimulate gastrin secretion from G cells and effect histamine release from enterochromaffin-like cells (ECL cells) (Figure 221-3).

Histamine release from mast cells and binding of acetylcholine and gastrin to parietal cells also contribute to secretion. Somatostatin released in response to gastric pH levels below 3 decreases gastrin, histamine, and acid secretion.

Unstimulated acid secretion in dogs and cats is minimal (dogs <0.04 mmol/kg.75/hr)[6] and H^+/K^+-ATPase, "the acid pump," is present in tubulovesicles within the cytoplasm of parietal cells.[7] In the stimulated state H^+/K^+-ATPase and KCl transporters are incorporated into the parietal cell canalicular membrane and hydrogen ions, derived from the ionization of water within the perietal cells, are transported into the gastric lumen in exchange for K^+ by H^+/K^+-ATPase. Potassium and chloride transporters in the canalicular membrane enable luminal transfer of potassium and chloride. OH^- combines with CO_2, catalyzed by carbonic anhydrase, to form HCO_3^-, which diffuses into the blood (the "alkaline tide"). Stimulation results in a rapid

increase in fluid and hydrogen ion secretion, with pH rapidly declining to around pH 1. The concentrations of K^+ (10 to 20 mmol/L) and Cl^- (approximately 120 to 160 mmol/L) in gastric juice are higher than in plasma.

Figure 221-1 Gastric anatomy of the empty and full stomach. (From Guilford, Strombeck, 1996, p 239, Saunders.)



The stomach is protected from gastric acid by a functional unit known as the *gastric mucosal barrier* (GMB).[8–10] The GMB comprises tightly opposed epithelial cells coated with a layer of bicarbonate rich mucus and an abundant mucosal blood supply that delivers bicarbonate, oxygen, and nutrients. Local production of prostaglandins (PGE_2) is important in modulating blood flow, bicarbonate secretion, and epithelial cell renewal. When damage occurs, epithelial cells rapidly migrate over superficial mucosal defects aided by the local production of growth factors such as EGF (epidermal growth factor).

221.1.2 Gastric Motility

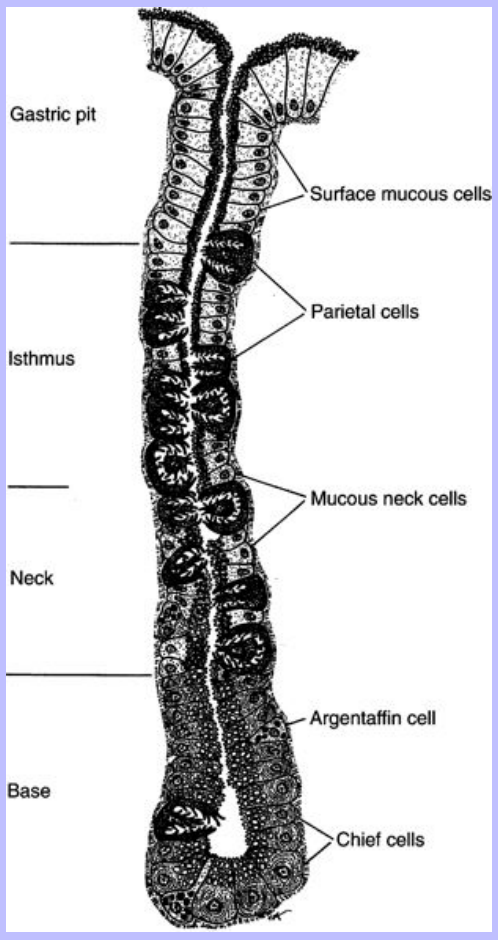
Normal gastric motility is the result of the organized interaction of smooth muscle with neural and hormonal stimuli. The rate of gastric emptying is determined by the difference in pressure between the stomach and the duodenum and the resistance to flow across the pylorus. Liquids are expelled more rapidly than solids and the rate of expulsion of liquids increases with volume. The rate of expulsion of solids depends on caloric density. In dogs, digestible solids smaller than 2 mm are emptied into the duodenum and gastric emptying is modulated via intestinal osmo-and chemoreceptors. Carbohydrates, amino acids, and especially fats retard gastric

emptying. The release of cholecystokinin (CCK) in response to fatty and amino acids, such as tryptophan, is one factor that slows gastric emptying. Large, undigestible solids are expelled from the stomach in the fasted state by phase III of the migrating motility complex (MMC) in response to the release of motilin.

221.1.3 Digestion and Assimilation of Nutrients

The stomach has a limited role in the digestion of proteins, fats, and micronutrients. Pepsin, which digests proteins, is secreted as pepsinogen in response to acetylcholine and histamine in tandem with gastric acid. Dog gastric lipase, which digests fat, is secreted in response to pentagastrin, histamine, prostaglandin E_2, and secretin and parallels the secretion of gastric mucus. Although pepsin is active only at acid pH, dog gastric lipase remains active in the small intestine and constitutes up to 30% of total lipase secreted over a 3-hour period.[11] Although gastric lipase and pepsin are not essential for the assimilation of dietary fat and protein, the entry of peptides and fatty acids into the small intestine likely helps to coordinate gastric emptying and pancreatic secretion.

Figure 221-2 Histologic appearance of the cardiac, fundic, pyloric gastric mucosa.



Intrinsic factor, which is necessary for cobalamin (vitamin B_{12}) absorption, is produced by parietal cells and cells at the base of antral glands in the dog but not the cat.[1,12] The importance of gastric intrinsic factor secretion in dogs is questionable as the pancreas is the major site of secretion in both dogs and cats. Gastric acidity may also have an effect on the availability of minerals such as iron and calcium.

221.1.4 Gastric Flora

The concept of the stomach as a sterile place was completely dispelled by the isolation of the gastric bacterium *Helicobacter pylori* from people in 1983.[13] The stomach of dogs and cats also harbors a diverse spectrum of large, spiral, acid-tolerant *Helicobacter* species and a variety of aerobes and anaerobes that may play a role in the development of gastritis or possibly cancer (see chronic gastritis). A mixed flora of aerobes and anaerobes (approximately 10^6 to 10^7cfu/mL is rapidly established soon after birth in dogs,[14] and colonization with *Helicobacter* spp., which are likely acquired from the dam, has been documented as early as 6 weeks of age. *Helicobacter* spp. are adapted to life in an acid environment and produce urease that catalyzes the formation of ammonia from urea to buffer gastric acidity. Other bacterial species, such as *Proteus*, *Streptococcus,* and *Lactobacillus,* cultured from the canine stomach, may transiently increase after a meal or coprophagia. Acid secretion and gastric emptying likely regulate much of this transient flora and bacteria may proliferate in the event of gastric acid hyposecretion due to glandular atrophy or pharmacologic inhibition. From a diagnostic standpoint it is important to realize that bacteria such as *E. coli* and *Proteus* spp. produce urease that can lead to a false-positive test result for *Helicobacter* spp.

221.2 DISEASES OF THE STOMACH

Gastric disease is usually the result of inflammation, ulceration, neoplasia, or obstruction and manifests clinically as vomiting, hematemesis, melena, retching, burping, hypersalivation, abdominal distension, abdominal pain, or weight loss. The clinical approach is simplified by considering gastric diseases as a group of clinical syndromes based on the combination of etiology, pathology, and clinical presentation (Table 221-1).

Because a large and varied group of non-gastric disorders can cause similar clinical signs, a systematic approach is essential to determine if gastric disease is the cause. The diagnostic approach initially focuses on historical and physical findings, with clinicopathologic testing and diagnostic imaging employed in patients with systemic involvement or chronic signs.

221.2.1 Signalment, History, and Physical Examination

The age and breed of the patient are helpful in diagnosis of certain gastric disorders. Young dogs are more likely to ingest foreign bodies or to suffer from outflow obstruction caused by *Pythium insidiosum*, whereas gastric cancer is typically encountered in much older dogs and cats. Gastric dilatation and volvulus are typically encountered in giant breed or dogs with deep chests such as Great Danes and Irish Setters. There are also breed predispositions to hypertrophic gastropathy (Drentse patrijshond, basenji, and small breed brachycephalic dogs, such as shih tzu), atrophic gastritis (Lundehund) and gastric cancer (Belgian shepherd, rough Collie, Staffordshire bull terrier, beagle, Lundehund).

1312

1313

Table • 221-1 Diseases of the Stomach

CLINICAL SYNDROME	PREDOMINANT FEATURES
Acute gastritis	Vomiting of sudden onset
Ulceration or erosion	Vomiting, hematemesis, melena, ± anemia
Gastric dilatation/volvulus	Non-productive retching, abdominal distention, tachycardia
Chronic gastritis	Chronic vomiting of food or bile
Delayed gastric emptying	Acute to chronic vomiting more than 8 to 10 hr after feeding
Neoplasia	Chronic vomiting, weight loss, ± anemia

Vomiting is the principal clinical sign of gastric disease (see Table 221-1), and a major objective of the history is to distinguish vomiting from regurgitation (active abdominal effort, presence of bile), and to obtain a clear picture of the vomiting episodes (duration, frequency, contents, color, progression, relation to eating). Where vomiting cannot be adequately distinguished from regurgitation it is important to observe “vomiting episodes” and the animal eating. Where regurgitation is still a possibility, thoracic radiographs help to detect esophageal dilatation or obstruction.

A thorough review of the environment (indoor, outdoor, single or multi-animal household), access to foreign bodies, toxins or medications, vaccination status, body systems (attitude, mentation, presence of polyuria, polydipsia, weight loss, diarrhea, coughing, sneezing, exercise tolerance), past medical history, and physical examination helps to discriminate many non-gastric from gastric causes of vomiting.

Physical examination is frequently normal in patients with primary gastric disease. Abdominal distension may be detected in those with GD/GDV or delayed gastric emptying. Abnormal perfusion, hydration status,

temperature, respiratory rate, mucosal pallor, and abdominal pain often accompany diseases such as GD/GDV, gastric outflow obstruction, ulceration, and perforation.

Historical and physical findings are integrated to determine if the patient is systemically well or unwell, and clinical signs are acute (lasting less than 10 days), chronic, mild, or severe (Figure 221-4). Non-productive vomiting, retching, and abdominal distension in deep-chested large breed dogs are frequently associated with gastric dilatation/gastric dilatation and volvulus (GDV), which requires rapid diagnosis and treatment.

The presence of fresh or digested blood ("coffee grounds"), in vomitus, with or without melena raises the possibility of gastric ulcers or erosions.

Vomiting of food greater than 8 to 10 hours after ingestion suggests delayed gastric emptying and requires investigation to distinguish gastric outflow obstruction from defective gastric propulsion.

Weight loss is infrequently associated with gastric disease but can accompany cancer, fungal infections, outflow obstruction, and gastropathies that are part of a more generalized disease process, such as basenji and Lundehund gastroenteropathy.

If vomiting is acute and the animal is systemically well, with no historical or physical "red flags," further diagnostic testing is often postponed in favor of symptomatic therapy. If the animal is systemically unwell or has significant historical or physical abnormalities the emphasis is on efficiently identifying conditions that require surgical intervention, such as gastric dilatation and septic peritonitis, and ruling out non-gastrointestinal causes of vomiting, before proceeding to more specialized or invasive diagnostic procedures aimed at detecting primary gastric and intestinal disorders (see Figure 221-4).

221.2.2 Clinicopathologic Testing

Clinicopathologic testing helps to differentiate primary gastro-intestinal disease form non-GI disease, and to ascertain the metabolic consequences of GI disease. Blood and urine samples should be obtained prior to treatment.

In sick patients, the rapid evaluation of microhematocrit (PCV), total solids (TS), blood glucose, blood urea nitrogen, urine specific gravity, glucose, ketones and protein, and plasma concentrations of sodium and potassium help to detect life threatening diseases such as renal failure (azotemia and unconcentrated urine) and hypoadrenocorticism (Na:K <27:1), and guide initial management pending more definitive testing.

Abnormalities in *complete blood count* are infrequent with primary gastric disease. Hemoconcentration as a consequence of dehydration or shock frequently accompanies GDV, gastric perforation, or gastric obstruction. The combination of a hematocrit level greater than 55% and normal or decreased protein concentrations is encountered in dogs with hemorrhagic gastroenteritis (see Chapter 222). Anemia, erythrocyte microcytosis, and thrombocytosis may be present in dogs with chronic gastric bleeding. Stomatocytosis has been described in Drentse patrijshond dogs with familial stomatocytosis-hypertrophic gastritis. Basophilic stippling of red cells suggests lead toxicity.

Biochemical abnormalities in primary gastric disease are usually restricted to alterations in electrolytes and acid-base, pre-renal increases in creatinine and BUN, and occasionally hypoproteinemia.

Vomiting of gastric and intestinal contents usually involves the loss of chloride, potassium, sodium and bicarbonate containing fluid and dehydration is variably accompanied by hypochloremia, hypokalemia, and

hyponatremia.[15,16] Determination of *acid-base status* by measurement of total CO_2 or venous blood gas analysis enables the presence of metabolic acidosis or alkalosis to be detected.

Metabolic acidosis is generally more common than metabolic alkalosis in dogs with GI disease.[15] Where the gastric outflow tract or proximal duodenum is obstructed, the loss of chloride may exceed that of bicarbonate, and hypochloremia, hypokalemia, and metabolic alkalosis occur.[15–17] The metabolic alkalosis is enhanced by elevated HCO_3^- conservation due to volume, and potassium and chloride depletion.[18] The net effect is a preferential conservation of volume at the expense of the extracellular pH. The renal reabsorption of almost all filtered bicarbonate and the exchange of sodium for hydrogen in the distal tubule promote an acid urine pH despite an extracellular alkalemia ("paradoxical aciduria").[18,19]

Metabolic alkalosis in patients with gastrointestinal signs is not invariably associated with outflow obstruction and has been encountered in dogs with parvovirus enteritis and acute pancreatitis.[20] Diseases characterized by acid hypersecretion, such as gastrinoma, may also be associated with metabolic alkalosis and aciduria. Basal gastric acid secretion in two dogs with gastrin-producing tumors (1.7 and 2.7 mmol/hr/kg.[75] HCl) was maximal in the unstimulated state.[21] In this situation hypochloremia, hypokalemia, metabolic alkalosis, and dehydration is likely due to the hypersecretion of gastric acid and its loss in vomitus.[21] Venous blood gases and *plasma osmolality* are often determined in animals suspected of ethylene glycol ingestion, with the findings of metabolic acidosis and a high osmolal gap (calculated by subtracting calculated from measured osmolality) supportive of ingestion.

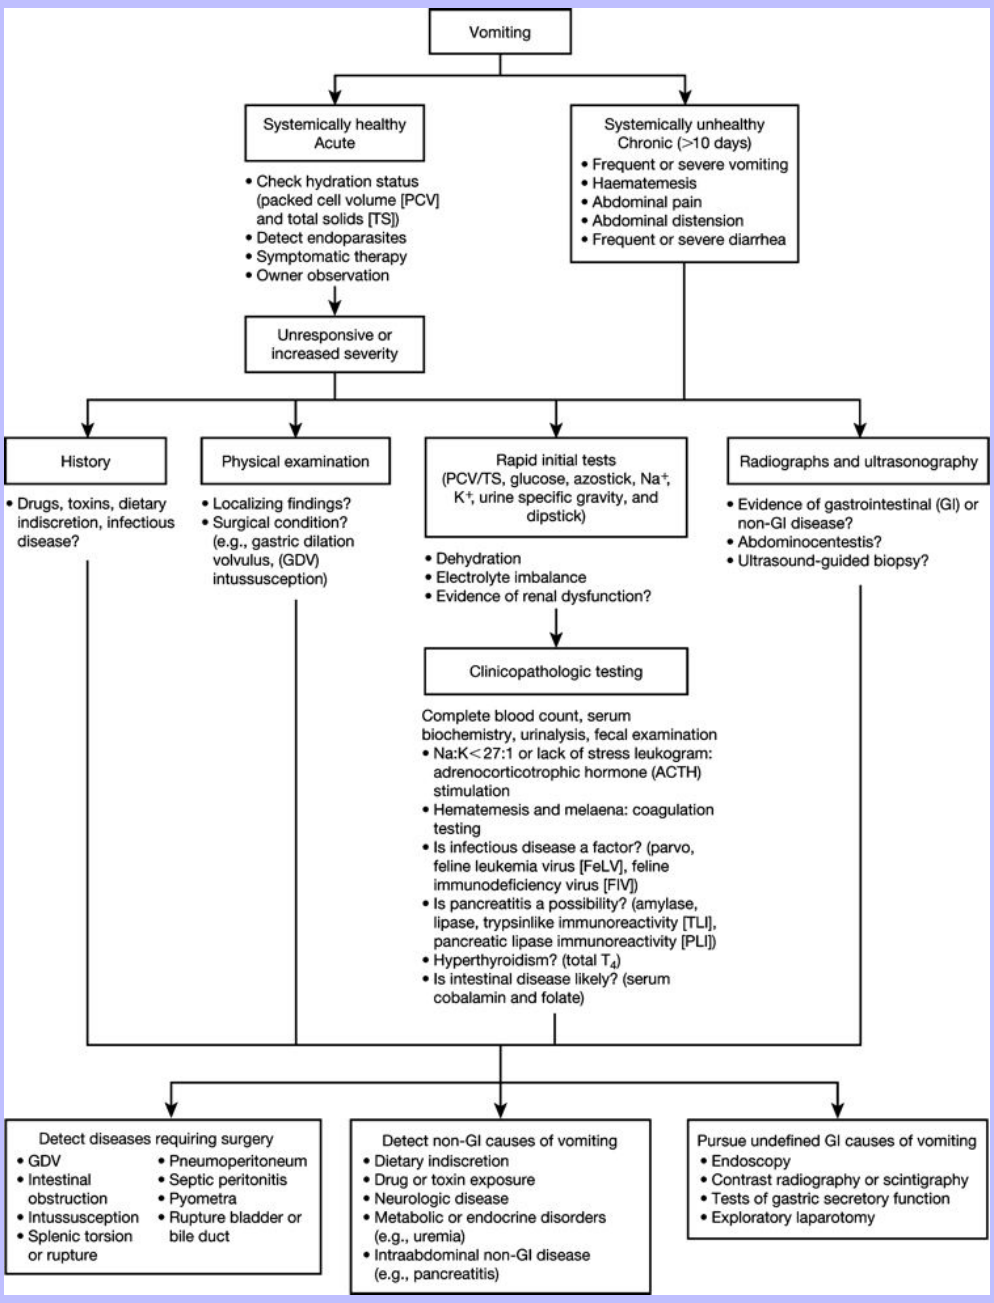
Elevated BUN in the absence of elevated creatinine may indicate gastric bleeding. Low albumin may be detected in basenji or Lundehund dogs with protein-losing gastroenteropathy, dogs with *Pythiosis,* and dogs or cats with gastric neoplasia. Elevated globulin concentrations have been observed in basenji gastro-enteropathy, *Pythium* infection, and gastric plasmacytoma. Elevations in creatinine, urea, calcium, potassium, glucose, liver enzymes, bilirubin, cholesterol, triglycerides, and globulin and decreases in sodium, calcium, urea, or albumin frequently herald non-GI causes of vomiting.

Urine should be evaluated for specific gravity, pH, glucose, casts, crystals, and bacteria. Thorough urinalysis is important; for example, white cell casts in the urine may be the only evidence that pyelonephritis is the cause of vomiting and should not be overlooked.

Coagulation testing is indicated in patients with melena or hematemesis to detect underlying coagulopathies and in those with acute abdomen to detect DIC. Infectious diseases associated with vomiting and diarrhea require *fecal examination* (giardia, endoparasites, *Salmonella* spp., *Campylobacter* spp., and parvovirus [ELISA] or *serologic testing* [FelV, FIV]) for diagnosis.

1313
1315

Figure 221-4 Diagnostic approach to the vomiting patient.



Additional clinicopathologic tests are required to detect hypoadrenocorticism (ACTH stimulation), liver dysfunction (pre-and post-prandial bile acids), hyperthyroidism in cats (T_4), pancreatitis (amylase, lipase

[pancreas-specific where possible], and trypsin-like immunoreactivity), and intestinal disease (serum cobalamin and folate).

221.3 IMAGING

Abdominal radiography is the test of choice for the initial evaluation of gastric disease, vomiting, and abdominal pain. Survey radiographs provide information on gastric position and contents that help to diagnose gastric distension/GDV, foreign bodies, and gastric outflow obstruction. They also enable the evaluation of the size and shape of the liver, kidneys, and spleen and detection of intussusception, peritonitis, pneumoperitoneum, and changes suggestive of pancreatitis.

Contrast radiographs may provide further information when survey radiographs are inconclusive. However, the combination of ultrasonography and endoscopy is generally more effective for detecting obstructive, inflammatory, and neoplastic GI disorders than contrast radiographic procedures, and contrast radiography is often restricted to the investigation of delayed gastric emptying associated with defective propulsion or "functional" intestinal disorders.[22] Ultrasonography can be employed to evaluate gastric wall thickness and gastric emptying, but its major value is usually the detection of non-gastric lesions in those with signs of GI disease.

When ultrasound and endoscopy are not available, distension of the stomach with air (negative contrast) may reveal gastric thickening, masses, or foreign bodies. Positive contrast with barium sulfate can provide further information and is also used to evaluate patency of the gastric outflow tract. The combination of fluoroscopy and positive contrast is helpful for evaluating pyloric patency and gastric emptying. In the absence of endoscopy and ultrasonography contrast radiographic procedures can be followed up with surgical biopsy to achieve a definitive diagnosis.

221.3.1 Endoscopy

Endoscopy enables direct visualization and biopsy of the stomach and duodenum and is the best way of diagnosing primary gastric inflammation, ulceration, or neoplasia; removing small foreign bodies; and evaluating patients prior to quantification of gastric emptying. It does not provide good information on submucosal lesions or functional diseases. With mural thickening or gastric masses, endoscopic biopsies are frequently too superficial and surgical biopsy is required for accurate diagnosis. Further information on equipment and techniques and photographs of a wide range of gastrointestinal lesions and can be found in endoscopic atlases.[23,24]

221.3.2 Evaluation of Gastric Emptying

Procedures used to evaluate delayed gastric emptying include barium contrast (liquid or mixed with food), barium-impregnated polyspheres (BIPs), nuclear scintigraphy, and the ^{13}C-octanoate breath test.[25,26] Tests of gastric emptying are often used to confirm a suspicion of delayed gastric emptying in patients with normal or equivocal survey radiographs. They are also used where gastric outflow obstruction and obvious causes of defective propulsion have been ruled out prior to and after prokinetic drugs. The limitations and benefits of these approaches are discussed under Delayed Gastric Emptying and Motility Disorders.

221.3.3 Gastric Secretory Testing

Gastric secretory testing is primarily performed in patients with esophagitis, gastrointestinal ulceration, mucosal hypertrophy, or copious amounts of gastric fluid that are suspected of having acid hypersecretion.

In its simplest form, fasting gastric pH and serum gastrin are measured to determine if acid hypersecretion is likely. Antisecretory therapy should be discontinued for 48 hours prior to testing, and renal and hepatic dysfunction detected, as these increase circulating gastrin. The broad range of fasting, unstimulated gastric pH in dogs and cats (pH 1 to 8) makes definitive statements regarding acid production difficult. However, the presence of a gastric pH of less than 3 in the face of a high serum gastrin rules out the possibility of achlorhydria, or mast cell tumor, and raises the possibility of gastrinoma.[21] Dogs with mast cell tumors and hyperhistaminemia induced acid hypersecretion have low serum gastrin concentrations[27], whereas dogs with achlorhydria likely have a high gastrin, but a gastric pH greater than 3.

Measurement of serum gastrin following the intravenous infusion of secretin or calcium is used to further investi-gate the possibility of exogenous gastrin production by pancreatic tumors, gastrinomas (Zollinger-Ellison syndrome) (see Chapter 244). Basenji dogs with gastroenteropathy and diarrhea have been reported to have elevated gastrin release in response to secretin stimulation, without evidence of gastrinoma.[28] Provocative testing of gastric acid secretion with penta-gastrin or bombesin stimulation may be performed to detect achlorhydria in patients with atrophic gastritis, or elevated serum gastrin and gastric pH levels higher than 3, and in those with idiopathic small intestinal bacterial overgrowth to determine if achlorhydia is a contributing factor. Pentagastrin stimulated acid secretion in dogs reaches a peak of 28 mL/kg$^{.75}$/hr, 4.1 mmol HCl/kg.^{75}/hr, 0.34 mmol K^+/kg$^{0.75}$/hr and 0.09 Na^+ mmol/kg$^{0.75}$/hr.[6] Sedation with oxymorphone and acepromazine is an alternative to anaesthesia for secretion studies in dogs.[28] In cats, acid output (mean±SD) in response to pentagastrin (8 μg/kg/hr) ranges from pH 0.9 to 1.1, with secretion rates (median values) of 1.2 mmol/15 min to 1.4 ± .5 mmol/15 min in conscious cats and 1.2 (0.6 to 2.7) mmol/kg$^{.75}$/hr in anesthetized cats.[29]

221.4 ACUTE GASTRITIS

Acute gastritis is the term applied to the syndrome of vomiting of sudden onset presumed to be due to a gastric mucosal insult or inflammation (Box 221-1). In most patients the cause is inferred from the history, such as dietary indiscretion, the diagnosis is rarely confirmed by biopsy, and treatment is symptomatic and supportive. 1315
Animals with acute gastritis associated with drug toxicity, foreign body ingestion, or meta-bolic disorders 1316
frequently present with hematemesis, melena, concurrent diarrhea, or other signs of systemic illness and require a more thorough diagnostic approach to determine the cause (as discussed above) and to provide optimal care. This author has found little evidence in the literature to support the role of viral infections such as parvovirus, distemper, or infectious canine hepatitis in acute gastritis.

221.4.1 Box • 221-1 Causes of Acute Gastritis

Dietary indiscretion or intolerance (non-allergic and allergic)

Foreign bodies, e.g., bones, toys, hairballs

Drugs and toxins, e.g., NSAIDs, corticosteroids, heavy metals, antibiotics, plants, cleaners, bleach

Systemic disease, e.g., uremia, liver disease, hypoadrenocorticism

Parasitic, e.g., *Ollulanus, Physalloptera* spp.

Bacterial, e.g., bacterial toxins,?*Helicobacter*

Possibly viral

221.4.2 Clinical Findings

Vomiting of sudden onset is the principal clinical sign. In some instances it is accompanied by hematemesis or melena and a variable degree of systemic abnormality. The history may reveal access or ingestion of spoiled food, garbage, toxins, medications, or foreign bodies. Signs of toxicity may be evident, such as jaundice and pallor with zinc ingestion, salivation or defecation with organophosphates toxicity or mushroom ingestion, or salivation and oral ulceration with chemical ingestion.

221.4.3 Diagnosis

A diagnosis of acute gastritis is usually based on clinical findings and the response to symptomatic treatment. A specific diagnosis may be sought if the patient has access to foreign objects or toxins, is systemically unwell, or has hematemesis, melena, or vomiting that fails to respond to symptomatic therapy, or other signs of more serious disease (see above). Laboratory testing in most animals with primary acute gastritis reflects mild dehydration, and is often not performed in the absence of a suspicion of more serious disease. Abdominal radiographs can be taken to detect foreign objects or gastrointestinal obstruction. Further diagnostics such as ultrasonography and endoscopy are rarely indicated as most animals with simple gastritis respond to symptomatic therapy.

221.4.4 Treatment

Therapy for uncomplicated acute gastritis is symptomatic and supportive and includes fluids, dietary restriction and modification, mucosal protectants or adsorbents, and possibly antacids.

221.4.4.1 Fluid Therapy

Small amounts of oral fluids, given little and often, can be given in the face of vomiting, with the volume increasing as vomiting subsides. Subcutaneous administration of an isotonic balanced electrolyte solution may be sufficient to correct mild fluid deficits (<5%) but is insufficient for patients with moderate to severe dehydration. Patients requiring intravenous fluids should undergo a more extensive diagnostic evaluation.

221.4.4.2 Dietary Restriction and Modification

Where vomiting is acute, oral intake is discontinued for at least 24 hours. Small amounts of a liquid diet can be offered in the face of vomiting to maintain GI barrier function and to determine if vomiting has resolved. A bland diet (non-spicy, fat restricted), either homemade (e.g., boiled chicken and rice, low-fat cottage cheese, and rice [1:3]) or commercial (usually fat restricted and rice based), is then introduced (fed little and often) with a gradual transition made back to a normal diet over a week or so.

221.4.4.3 Protectants/Adsorbents

Bismuth-subsalicylate, kaolin-pectin, activated charcoal and magnesium, aluminum-and barium-containing products are often administered in acute vomiting or diarrhea to bind bacteria and their toxins and to coat the gastrointestinal mucosa. These agents are probably safer and more efficacious than antibiotics or motility modifiers in acute gastroenteritis. Pepto bismol (1 mL/5 kg PO TID), bismuth subcitrate, kaolin-pectin (1 to 2 mL/kg PO TID) and sucralfate (0.25 to 1 g PO TID) are often employed. Acid-reducing drugs such as H_2-receptor antagonists can be administered but are usually reserved for patients with signs of gastric erosion or ulceration (melena/hematemesis) or persistent gastritis as described below.

Table • 221-2 Association of Gastric Ulceration and Erosion with Specific Diseases

GASTRIC PROBLEM	RELATED DISEASES
Metabolic/Endocrine	Hypoadrenocorticism, uremia, liver disease, mastocytosis, d.i.c. Hypergastrinemia and other APUDomas
Inflammatory	Gastritis
Neoplastic	Leiomyoma, adenocarcinoma, lymphosarcoma
Drug-induced	Nonsteroidal and steroidal anti-inflammatories
Hypotension	Shock, sepsis
Idiopathic	Stress, spinal surgery, exercise induced (sled dogs)

The author generally avoids anti-emetics in patients with acute gastritis to enable response to therapy to be ascertained. Patients who continue to vomit require further investigation.

221.4.5 Prognosis

The prognosis for uncomplicated acute gastritis is usually complete recovery.

221.5 GASTRIC EROSION AND ULCERATION

Gastric erosions and ulcers are associated with a number of primary gastric and non-gastric disorders (Table 221-2). Clinical signs range in duration and severity, from acute to chronic and mild to life threatening. The pathomechanisms underlying gastric damage can be broadly attributed to impairment of the gastric mucosal barrier (defined above) through direct injury, interference with gastroprotective prostaglandins (PGE_2), mucous or bicarbonate, decreased blood flow, and hypersecretion or gastric acid.

Perhaps the most predictable recipe for gastric erosion is the combination of a non-steroidal anti-inflammatory and a glucocorticoid, either alone, or in combination with intervertebral disk disease.[30]

Nonsteroidal anti-inflammatory drugs cause direct mucosal damage and interfere with prostaglandin synthesis.[9] Flunixin meglumine, aspirin, and ibuprofen have all been associated with erosions in healthy dogs. To circumvent toxicity caused by the inhibition of "friendly prostaglandins" (PGE_2), drugs that preferentially block "inducible" cyclooxygenase (COX-2) have been developed. These COX-2 selective agents, such as carprofen, meloxicam, derccoxib, and potentially etodolac, are less ulcerogenic in normal dogs.[31,32] However, even COX-2 selective drugs such as meloxicam are ulcerogenic in combination with dexamethasone,[33] and their safety in sick animals remains to be determined.

High doses of glucocorticoids alone, such as dexamethasone and methylprednisolone, have also been associated with gastric erosions[34] but the mechanisms by which they induce damage are not clear. Unlike NSAIDs, their effects are not ameliorated by PGE_2 analogs.[35]

Hypersecretion of gastric acid in response to histamine release from mast cell tumors, and gastrin from gastrinomas has also been clearly implicated as a cause of gastroduodenal ulceration and esophagitis in dogs and cats.

Renal failure, hepatic failure, hypoadrenocorticism, and hypotension are frequently proposed as risk factors for gastric erosion or ulceration, although few details have been published on the pathogenesis, frequency, or severity of gastric damage in these conditions. In a recent study of dogs with renal failure, ulceration was present in only 1 of 28 dogs. The predominant findings in these dogs were mucosal edema, vasculopathy, and mineralization that correlated to the degree of azotemia and calcium phosphorous product.[36]

Sled dogs in the Iditarod are prone to develop gastric erosions and/or ulcers.[37] This finding is similar to exercising humans and horses in whom the pathogensis is not understood but is responsive to acid suppression.

Erosions and ulcers are also a sequela of gastric cancer and gastritis and are discussed elsewhere in this chapter.

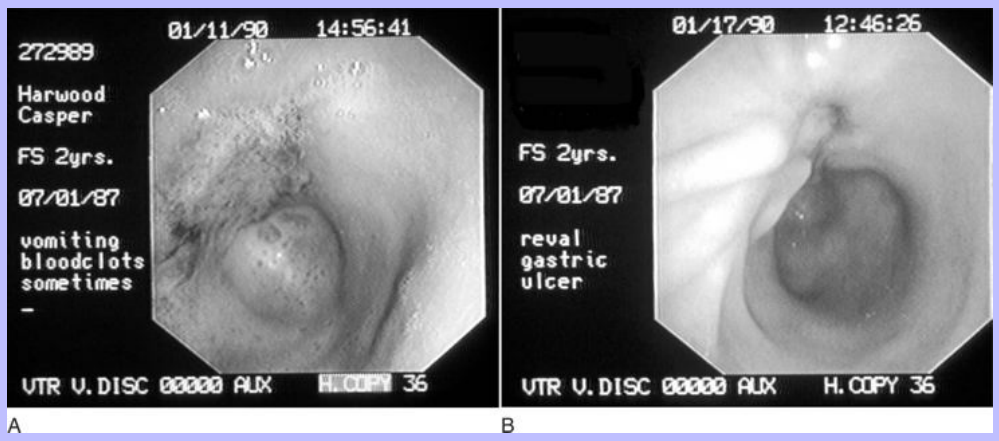
221.5.1 Clinical Findings

Vomiting, hematemesis, and melena may be present in patients with gastric erosions or ulcers. Pale mucous membranes, abdominal pain, weakness, inappetance, hypersalivation (potentially associated with esophagitis as a consequence of gastric acid hypersecretion), and evidence of circulatory compromise are more variably present. Access to toxins and drugs, particularly NSAIDs, should be determined.

Clinicopathologic testing is directed at identifying diseases associated with gastric erosions and ulcers (see Table 221-2) and the consequences of erosion/ulceration. The CBC may reveal anemia that is initially regenerative but can progress to become microcytic, hypochromic, and minimally regenerative. When accompanied by thrombocytosis and decreased iron saturation or low serum ferritin, these findings are characteristic of chronic bleeding and iron deficiency. Lack of a stress leukogram and eosiniphilia in dogs is supportive of hypoadrenocorticism. Eosinophilia could also be consistent with dietary allergy, eosinophilic gastroenteritis, mastocytosis, or a hyperseosinophilic syndrome. A neutrophilic leukocytosis and a left shift may indicate inflammation or possible gastric perforation. Examination of a buffy coat smear may help to detect mastocytosis.

Biochemistry and urinalysis may reveal findings consistent with dehydration (azotemia and hypersthenuria), renal failure (e.g., azotemia and isosthenuria), hepatic disease (e.g., increased liver enzymes or bilirubin; decreased cholesterol, albumin, BUN), or hypoadrenocorticism (i.e., Na^+:K^+ ratio <27:1). It will also identify electrolyte and acid base abnormalities associated with vomiting and GI ulceration. The presence of a metabolic alkalosis, hypochloremia, hypokalemia, and acid urine is consistent with upper GI obstruction (physical or functional) or a hypersecretory state. Testing should be performed to detect abnormalities in primary and secondary hemostasis that may be associated with GI bleeding. Serum gastrin and potentially histamine concentrations can be evaluated where acid hypersecretion is suspected as a cause of ulceration.

Figure 221-5 Gastric ulceration caused by ibuprofen ingestion before and after (1 week) treatment with cimetidine and sucralfate. (Images courtesy of The Ohio State University.)



221.5.2 Diagnosis

221.5.2.1 Diagnostic imaging

Plain radiographs are not usually helpful in diagnosing gastric erosions or ulcers but may help to rule out other causes of vomiting, such as foreign bodies, peritonitis, and gastric perforation. Contrast radiographs may reveal filling defects but do not allow detailed mucosal evaluation or sampling.

Ultrasonography can be performed to evaluate the gastric wall for thickening associated with ulcers and masses and also helps to rule out non-gastric causes of vomiting. The information provided by radiography and ultrasound is complementary to endoscopic evaluation, which is the diagnostic test of choice (Figure 221-6).

Endoscopy allows the direct evaluation of gastric damage and mucosal sampling. NSAID-associated ulcers tend to be found in the antrum and are not usually associated with marked mucosal thickening or irregular edges (Figure 221-5). This contrasts with ulcerated tumors that frequently have thickened edges and surrounding mucosa (Figure 221-17, *A*). Ulcers should be biopsied at the periphery to avoid perforation. Endoscopic biopsies are not ideal for diagnosing infiltrative gastric tumors and several biopsies from the

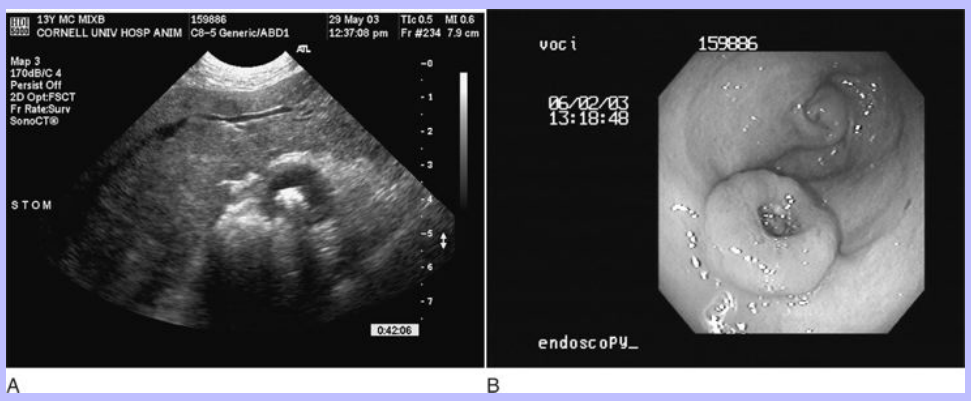
same site are usually taken to enable sampling of deeper tissue. Endoscopic guided fine-needle aspirates, with use of a needle and tubing in the biopsy channel, can also be used to sample deep lesions. Even with this approach the diagnosis may be missed, and surgical biopsy required for a definitive diagnosis.

The combination of mucosal erosion or ulceration, antral mucosal hypertrophy, copious gastric juice, and esophagi-tis is highly suggestive of a gastric hypersecretory state (Figure 221-7). It is prudent to measure gastric pH and serum gastrin in patients with gastric erosion/ulceration that is not associated with drugs or gastric tumors. Dogs with mast cell tumors and hyperhistaminemia-induced acid hyper-secretion have low serum gastrin concentrations. [38] Finding a combination of gastric pH less than 3 and a high serum gastrin concentration prompts further investigation of gastrinoma by secretin stimulation test, ultrasonography (liver and pancreas), and pentertreotide scintigraphy. [21]

1317

1318

Figure 221-6 Ultrasonography and endoscopy provide complementary information. The ultrasonogram **(A)** shows a mass projecting into the lumen of the stomach of a dog presented for the investigation of vomiting and hyperglobulinemia (IgA). Endoscopy **(B)** confirmed the presence of a mass and enabled a biopsy diagnosis of gastric plasmacytoma. (Images courtesy of Cornell University, Ithaca, NY.)



221.5.3 Treatment

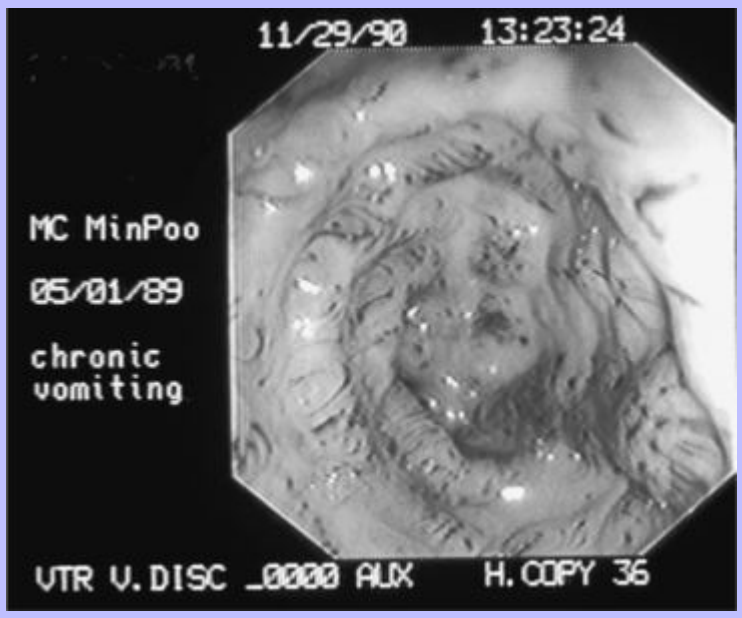
Treatment of gastric erosions and ulcers is directed at the underlying cause, which ensures adequate hydration and perfusion, including blood transfusion if needed, and restoring electrolyte and acid base disturbances. Additional support is directed at shoring up the gastric mucosal barrier by enhancing mucosal protection and cytoprotection, and decreasing gastric acid secretion. Where vomiting is persistent, antiemetics may help to reduce fluid loss, discomfort, and the risk of esophagitis.

221.5.4 Fluid Therapy

The rate of fluid administration depends on the presence or absence of shock, the degree of dehydration, and the presence of diseases (e.g., cardiac or renal), which predispose to volume overload. Patients with a history

of vomiting who are mildly dehydrated are usually responsive to crystalloids (e.g., LRS or 0.9% NaCl) at a rate that will provide maintenance and replace both deficits and ongoing losses over a 24-hour period. Potassium depletion is often a consequence of prolonged vomiting or anorexia, and most polyionic replacement fluids contain only small amounts of potassium. Therefore KCl is added to parenteral fluids on the basis of serum levels.

Figure 221-7 Gastric erosion and mucosal hypertophy in a dog with gastrinoma. (Courtesy of The Ohio State University.)



Patients with signs of shock require more aggressive support. The volume deficit can be replaced with crystalloids at an initial rate of 60 to 90 mL/kg/h, then tailored to maintain tissue perfusion and hydration. Colloid solutions can also be used to treat animals in shock to reduce the amount of crystalloid required (e.g., Hetastarch, hemaccel at 10 to 20 mL/kg IV over 4 to 6 hours). Plasma, colloids, packed cells, or whole blood is occasionally required to treat severe hypoproteinemia or anemia, which can develop in vomiting animals with severe ulceration or HGE.

Central venous pressure monitoring and evaluation of urine output are necessary in patients with severe GI disease, particularly those complicated by third space losses of fluid into the gut or petitoneum.

The effect of vomiting on acid-base balance is hard to predict and therapeutic intervention to correct acid-base imbalances should be based on blood gas determination. Where severe metabolic acidosis is present (pH <7.1, HCO^{3-} <10 mmol/L), sodium bicarbonate (1 mmol/kg) can be given under careful supervision for the development of worsening hypokalemia, and hypocalcemia, and CSF acidosis. Further bicarbonate supplementation is based on repeated blood gas analysis. Metabolic alkalosis usually responds to replacing volume deficit, chloride, and potassium with IV 0.9%NaCl+KCl. Diagnostic investigations should initially center on ruling out upper GI obstruction. The administration of anti-secretory drugs such as H_2 antagonists may help to limit Cl^--efflux into gastric juice.

221.5.4.1 Reducing Acid Secretion and Providing Mucosal Protection

Pharmacologic inhibition of acid secretion (see Figure 221-3) can be effected by blocking H_2 (cimetidine, ranitidine, famotidine), gastrin (proglumide), and acetylcholine (atropine, pirenzipine) receptors, and by inhibiting adenyl cyclase (PGE analogs) and H^+/K^+ ATPase (e.g., omeprazole).[39] Long-acting somatostatin analogs such as octreotide directly decrease the secretion of gastrin and gastric acid.

Decreasing gastric acid secretion with an H_2 receptor antagonist has been shown to promote mucosal healing in dogs with a variety of experimentally induced ulcers and erosions (see Figure 221-5). Famotidine is an attractive choice as it does not inhibit P450 enzymes and can be given once daily. The additional prokinetic activity of ranitidine or nizatidine (mediated by anticholinesterase activity) may make them good choices in the face of delayed gastric emptying associated with defective propulsion.[25] In patients with severe or persistent gastric ulceration that is refractory to H_2 antagonists, more complete inhibition of gastric acid secretion can be achieved with a H^+/K^+-ATPase inhibitor such as omeprazole (0.2 to 0.7 mg/kg SID PO—dogs). Omeprazole is the initial drug of choice in patients with acid hypersecretion secondary to mast cell tumors and gastrinoma (Zollinger-Ellison syndrome). Omeprazole has been shown to have few long-term side effects in dogs, but it should be used with caution in patients with liver disease and reviewed for interactions with drugs such as cisapride.

1318

1319

In sled dogs with exercise-associated gastric hemorrhage treatment with omeprazole significantly reduced mean gastric severity score compared to placebo but also was associated with increased frequency of diarrhea (omeprazole 54%, placebo 21%).[37] The authors recommended further investigation of diarrhea associated with omeprazole treatment before omeprazole can be recommended for routine prophylactic treatment in these athletes.[37]

The combination of omeprazole and the long acting somatostatin analog Octreotide effectively reduced vomiting in a dog with gastrinoma (Octreotide 2 to 20 µg/kg SC TID).[40] Octreotide can also be employed to rapidly decrease gastric acid secretion in patients discovered to have large ulcers at endoscopy and may also be useful for controlling gastric bleeding (see human studies).

221.5.4.2 Mucosal Protectants

The PGE_2 analog, misoprostol, protects against NSAID-induced erosions in dogs at doses that do not inhibit acid secretion (3 to 5 µg/kg PO TID in dogs) and may be given to dogs receiving chronic NSAIDs for arthritis.[41,42] The main side effect of misoprostol is diarrhea and it should not be given to pregnant animals.

The mucosal protectant polyaluminum sucrose sulfate (sucralfate) binds to areas denuded of mucosal epithelium regardless of the underlying cause and is useful for treating gastric erosions and ulcers and esophagitis. Sucralfate can be given to patients receiving injectable antacids, but it may compromise absorption of other oral medications and is probably best separated from these by 2 hours or so.

In contrast to the efficacy of misoprostol and H_2 antagonists in preventing NSAID-induced erosions, the prophylactic administration of various combinations of misoprostol, cimetidine, and omeprazole has not been shown to prevent gastric erosions in dogs with or without intervertebral disk disease receiving

high-dose glucocorticoids.[34,43,44] However, these drugs may speed healing of gastric lesions in these patients. Sucralfate is probably the drug of choice for treating GI ulceration in patients receiving high doses of corticosteroids because it is not dependent on the premise that acid is causing or delaying healing.

Mast cell tumors are also worth considering separately as gastric ulceration is a frequent and severe complication. Mast cell tumors are thought to cause vomiting via the central effects of histamine on the CRTZ and the peripheral effects of histamine on gastric acid secretion (with resultant hyperacidity and ulceration). Treatment of mastocyosis with H_1 and H_2 histamine antagonists (e.g., diphenhydramine and famotidine) should reduce the central and peripheral effects of histamine. Corticosteroids are used to decrease tumor burden. Where acid hypersecretion is present, or is suspected, it is likely best managed with proton pump inhibitors (e.g., omeprazole 0.2 to 0.7 mg/kg SID). Somatostatin analogs may also be useful for controlling refractory gastric acid hypersecretion (Octreotide 2 to 20 μg/kg SC TID).[21]

221.5.4.3 Antiemetics

Antiemetics can be used where vomiting is severe or compromising fluid and electrolyte balance, or causing discomfort.[39] The initial agent used in dogs is usually metoclopramide, which antagonizes D_2-dopaminergic and $5HT_3$-serotonergic receptors and has cholinergic effects on smooth muscle (1 mg/kg/24h CRI IV). Phenothiazine derivatives such as chlorpromazine and prochlorperazine are antagons of α_1 and α_2-adrenergic, H_1-and H_2-histaminergic, and D_2-dopaminergic receptors in the vomiting center and CRTZ and are used if metoclopramide is ineffective and the patient is normotensive. Nonselective cholinergic receptor antagonists (other than the M_1 specific antagonist-pirenzipine) such as atropine, scopolamine, aminopentamide, and isopropamide are generally avoided as they may cause ileus, delayed gastric emptying, and dry mouth.

221.5.4.4 Antibiotics and Analgesia

Prophylactic antibiotic cover (e.g., cephalosporins, ampicillin) may be warranted in animals with shock and major GI barrier dysfunction. Leukopenia, neutrophilia, fever, and bloody stools are additional indications for prophylactic antibiotics in animals with vomiting or diarrhea. Initial choices in these situations include ampicillin or a cephalosporin (effective against gram-positive and some gram-negative and anaerobic bacteria), which can be combined with an aminoglycoside (effective against gram-negative aerobes) when sepsis is present and hydration status is adequate. Enrofloxacin is a suitable alternative to an aminoglycoside in skeletally mature patients at risk of nephrotoxicity from an aminoglycoside.

Analgesia can be provided using opioids like buprenorphine (0.0075 to 0.01 mg/kg IM).

Surgery may be required when the cause of ulceration is unclear or to resect large non-healing ulcers or those about to perforate.

221.6 GASTRIC DILATATION AND VOLVULUS

Gastric dilatation and gastric dilatation and volvulus are characterized by the dramatic distension of the stomach with air. With volvulus the stomach twists about its axis, moving dorsally and left of the fundus. Both dilatation and dilatation and volvulus cause caudal caval obstruction and impair venous return to the heart. This results in hypovolemic shock that can be exacerbated by devitailization of the gastric wall, splenic torsion or avulsion, congestion of the abdominal viscera, endotoxic shock, and DIC.

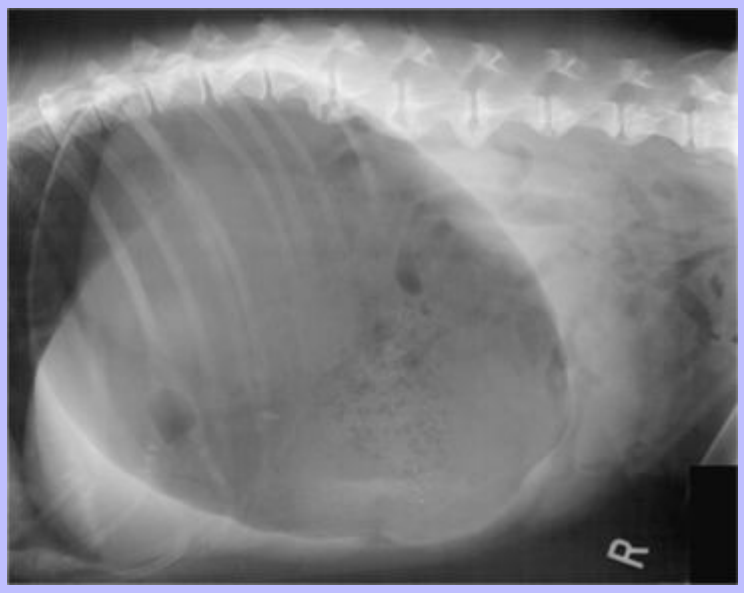
No single cause of gastric dilatation (GD) or dilatation and volvulus (GDV) has been identified. Large breed dogs with deep chests such as akita, bloodhound, collie, great Dane, Irish setter, Irish wolfhound, Newfoundland, Rottweiler, Saint Bernard, standard poodle, and Weimaraner are at greater risk. Cumulative incidence of GDV has been estimated at 6% for large breed and giant breed dogs. The lifetime risk is influenced by breed, ranging from of 3.9% for Rottweilers to 39% in great Danes.[45] In large breed and giant dogs, factors significantly associated with an increased risk of GDV include increasing age, having a first-degree relative with a history of GDV, having a faster speed of eating, once daily feeding, and having a raised feeding bowl and aerophagia.[46,47] The personality of the dogs may also have an impact, with happier dogs having a decreased incidence.[48]

Analysis of gastric gas supports aerophagia as the cause of distension, with dilatation explained by an inability to eructate or empty air into the intestines. Studies in dogs with GDV recovering from gastropexy suggest that abnormal electrical activity and gastric emptying may be related to the development of gastric dilatation.[49] The interrelationship of volvulus and gastric distension is unclear, although the length of the hepatogastric ligament may facilitate torsion.

1319

1320

Figure 221-8 Survey radiograph of gastric dilatation (R lateral). The fundus is distended with air. (Courtesy of Cornell University, Ithaca, NY.)

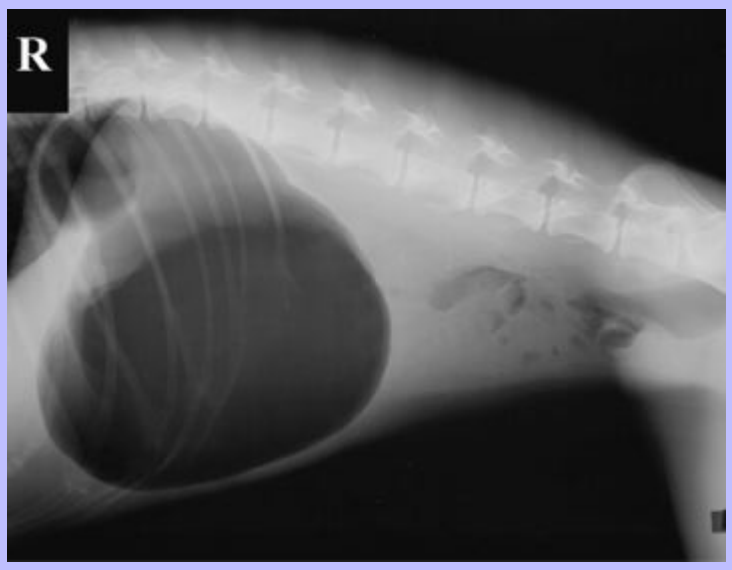


221.6.1 Diagnostic Features

A history of non-productive retching, salivation, abdominal distention, weakness, or collapse raises the possibility of gastric dilatation or volvulus, particularly in large breed and deep-chested dogs. Physical findings usually include abdominal distension and tympany, tachycardia, and mucosal pallor. Hypothermia, depression, and coma may be seen when shock is severe. Cardiac arrythmias such as ventricular premature beats or ventricular tachycardia may be detected on the initial examination or develop up to 72 hours after presentation.

Radiography is usually performed after fluid support and decompression and helps to distinguish simple dilatation from dilatation and volvulus. Right and left lateral recumbent views are usually acquired. Dilatation is associated with gas distension and on a right lateral position air is present in the fundus (Figure 221-8). With volvulus the pylorus moves dorally and left and the stomach is compartmentalized. On a right lateral radiograph the fundus is viewed as a large ventral compartment with the smaller, gas-filled pylorus located dorsally and separated from the fundus by a band of soft tissue, forming the “the Popeye's arm” sign (Figure 221-9). Loss of abdominal contrast may indicate gastric rupture or bleeding from avulsed splenic vessels, whereas increased contrast due to pneumo-peritoneum suggests gastric rupture.

Figure 221-9 Survey radiograph of gastric dilatation and volvulus (GDV). With gastric volvulus, the pylorus moves dorsally, cranially, and to the left. It is easiest to detect GDV in the right lateral view, where the pylorus is viewed as the smaller air-filled compartment dorsal to the larger air-filled fundus and seperated from the fundus by a soft tissue density. (Images courtesy of Cornell University, Ithaca, NY.)



221.6.2 Clinicopathologic Findings

Hematologic changes are often restricted to an increase in hematocrit. A variety of acid-base and electrolyte disturbances have been observed in dogs with GDV.[50,51] Metabolic acidosis and hypokalemia were the most common abnormalities in one study and occurred in 15 out of 57 and 16 out of 57 dogs, respectively.[50] Metabolic acidosis is likely due to tissue hypo-perfusion, anaerobic metabolism, and the accumulation of lactic acid.[50] Metabolic alkalosis may also occur and may be related to the sequestration of gastric acid or vomiting.[50]

Respiratory acidosis and alkalosis have been variably observed and reflect hypoventilation or hyperventilation, respectively. The variable nature of acid-base and electrolyte abnormalities in dogs with GDV indicates that fluid therapy should be individualized on the basis of blood gas and electrolyte measurements. Monitoring and correction of acid-base abnormalities are important because they may predispose to cardiac arrythmias and muscle weakness.

Coagulation abnormalities are usually consistent with disseminated intravascular coagulopathy (thrombocytopenia, increased D-dimer or FDPs, reduced ATIII, prolongation of the APTT).

221.6.2.1 Treatment

Fluid support and gastric decompression are the most important emergency treatments.

221.6.2.2 Fluid Support

Fluid therapy has traditionally consisted of shock doses of LRS (60 to 90 mL/kg/h) given via large-bore catheters into the cephalic or jugular veins. Experimental studies that have compared crystalloids (60 mL/kg, followed by 0.9% NaCl 20 mL/kg/h) with hypertonic saline (7% NaCl in 6% dextran, 5 mL/kg, followed by 0.9% NaCl 20 mL/kg/h) in dogs with GDV-induced shock, indicate that hypertonic saline maintains better myocardial performance, higher heart rate, and lower systemic vascular resistance than crystalloid.[52] The resuscitative dose of hypertonic saline was delivered in 5 to 10 minutes versus an hour for cystalloid. Fluid therapy should be aggressively monitored by frequent measurement of blood pressure, heart rate, PCV, and total solids and urine output. Potassium and bicarbonate are best administered on the basis of blood gas and electrolyte measurements. Hypokalemia is common after fluid therapy and 30 to 40 mEq KC l/L should be added to fluids after the initial shock dose.

221.6.2.3 Gastric Decompression

Decompression can be performed by oragastric intubation with a well-lubricated stomach tube, or a 16-g catheter can be used to trocarize the stomach. Oral decompression can also be performed after trocarization. Decompression should be maintained until surgery. Sedation with butorphanol (0.5 mg/kg IV) or oxymorphone (0.1 mg/kg IV) and diazepam (0.1 mg/kg slow IV) may be necessary to pass a stomach tube.

221.6.2.4 Adjunct Therapy for Endotoxic Shock and Reperfusion Injury

Adjunct therapy frequently includes prednisolone sodium succinate (10 mg/kg IV) or dexamethasone sodium phosphate (10 mg/kg IV) for shock, and broad-spectrum antibiotics such a cephalosporin in combination with a fluroquinolone to circumvent bacterial translocation and endotoxemia. Some clinicians advocate flunixin meglumine for endotoxic shock, but the author does not.

The administration of agents to decrease lipid peroxidation (U70046F) and chelate iron (desferoxamine) has decreased mortality attributed to reperfusion injury in dogs with experimental GDV.[53,54] These agents are best given before reper-fusion occurs, that is, prior to untwisting a torsion.

221.6.2.5 Cardiac Arrythmias

Cardiac arrhythmias such as ventricular premature complexes and ventricular tachycardia are relatively frequent (approximately 40% of patients) and may or may not contribute to mortality.[55,56] The arrhythmias can develop up to 72 hours after presentation and are considered a consequence of electrolyte, acid base, and hemostatic abnormalities, as well as due to reperfusion injury. Arrhythmias should be treated if they are associated with weakness or syncope, as well as if persistent ventricular tachycardia at rates greater than 150 beats per minute are demonstrated. The arrythmias are managed by correcting underlying acid-base electrolyte and hemostatic disturbances and administering lidocaine either as a bolus (1 to 2 mg/kg IV) or continuously (up to 50 to 75 µg/kg/min) and procainamide (10 mg/kg IM q6h and then orally if effective) where persistent. It is important that plasma concentration of K^+ and Mg^{2+} are normalized to enable effective antiarrythmic therapy (see Chapter 202).

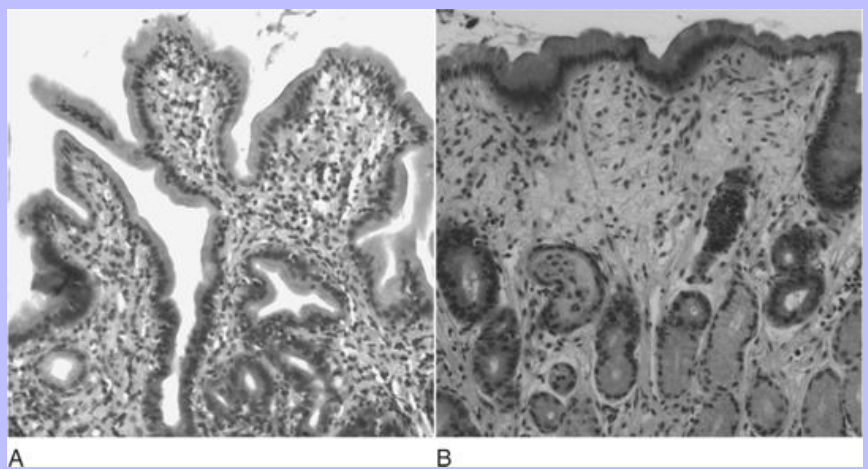
221.6.2.6 Surgery

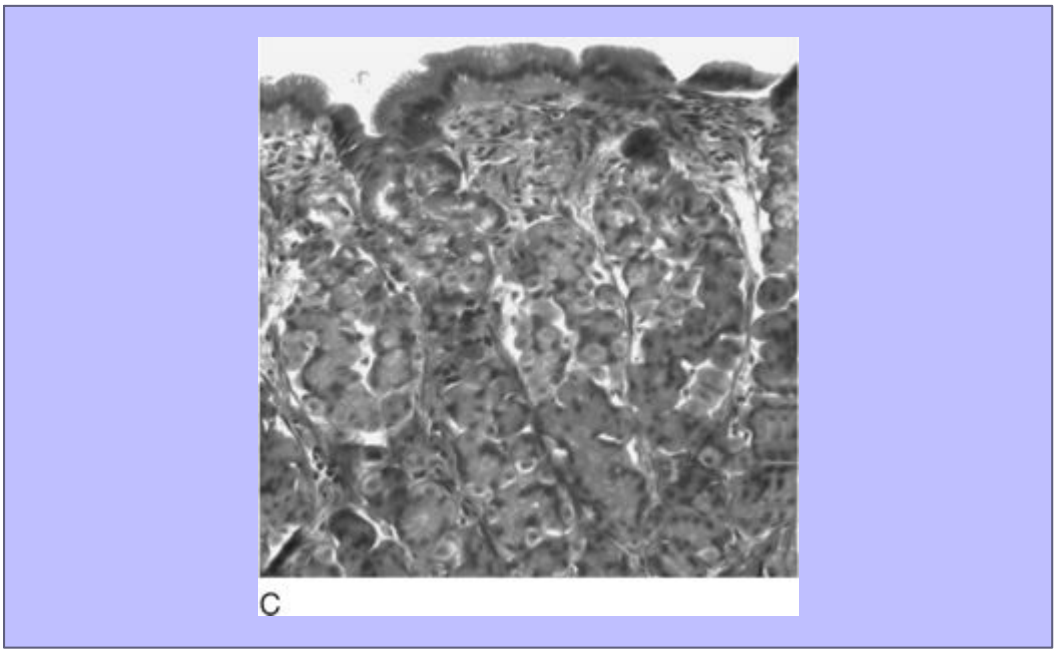
The aims of surgery are to reposition the stomach and spleen and to perform a gastropexy to enable short-term decompression and prevent recurrence. Surgery is complicated by the presence of gastric necrosis, which requires partial gastrectomy, and avulsion or torsion of the spleen, which may require resection or removal.

221.6.3 Prognosis

Mortality rate for dogs with gastric dilatation and volvulus is approximately 15%.[56] Dogs with gastric necrosis, gastric resection or splenectomy have a higher mortality rate (>30%).[55–57]

Figure 221-10 Grading schemes for gastritis. **A.** A visual analog cartoon system proposed by Happonen et al, 1998, and **B.** A standardized photograpic scale for atrophy, fibrosis and cellular infiltrate. (Courtesy Wiinberg, Simpson and MacDonough.)





The presence of gastric necrosis can be predicted by measuring plasma lactate concentration, with [lactate] greater than 6 mmol/L yielding a specificity of 88% and a sensitivity of 66% for necrosis.[57]

221.6.4 Prophylaxis

The recurrence rate of GD/GDV has been estimated at 11% over 3 years in one study, with median survival of 547 versus 188 days for dogs with a gastropexy versus those without.[58]

Prophylactic gastropexy in Great Danes, Irish Setters, Rottweilers, standard poodles, and Weimariners reduced mortality from as little as 2.2-fold in Rottweilers to as much as 29.6-fold in great Danes.[45]

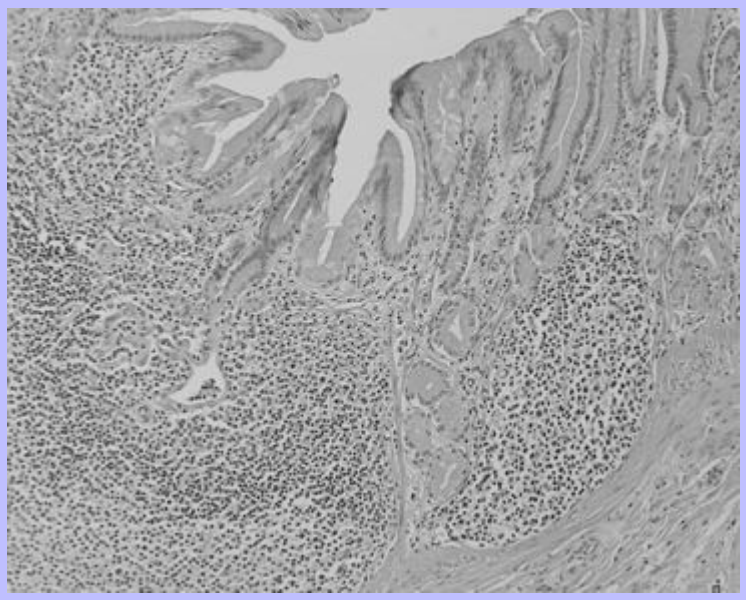
221.7 CHRONIC GASTRITIS

Gastritis is a common finding in dogs, with 35% of dogs investigated for chronic vomiting and 26% to 48% of asymptomatic dogs affected.[59,60] The prevalence in cats has not been determined. The diagnosis of chronic gastritis is based on the histologic examination of gastric biopsies and it is usually subclassified according to histopathological changes and etiology.

221.7.1 Histopathologic Features of Gastritis

Gastritis in dogs and cats is usually classified according to the nature of the predominant cellular infiltrate (eosinophilic, lymphocytic, plasmacytic, granulomatous, lymphoid follicular), the presence of architectural abnormalities (atrophy, hypertrophy, fibrosis, edema, ulceration, metaplasia), and their subjective severity (mild, moderate, severe). A standardized visual grading scheme has been proposed by Happonen et al[60] and has been adapted for pathologists[61] (Figure 221-10).

Figure 221-11 Lymphoid follicle hyperplasia and lymphoplasmacytic gastritis in a cat with *H. felis* infection.



The most common form of gastritis in dogs and cats is mild to moderate superficial lymphoplasmacytic gastritis with concomitant lymphoid follicle hyperplasia (Figure 221-11). Eosinophilic, granulomatous, atrophic, and hyperplastic gastritis are less common.

221.7.2 Etiology

Despite the high prevalence of gastritis an underlying cause is rarely identified, and in the absence of systemic disease, ulcerogenic or irritant drugs, gastric foreign objects, parasites (*Physalloptera* and *Ollulanus* spp.), and in rare instances fungal infections (*Pythium insidiosum, Histoplasma* spp.), it is usually attributed to dietary allergy or intolerance, occult parasitism, or a reaction to bacterial antigens, or unknown pathogens. Treatment is often empirical but can serve to define the cause of gastritis, such as diet responsive, antibiotic responsive, steroid responsive, or parasitic.

Although the basis of the immunologic response in canine and feline gastritis is unknown, recent studies in experimental animals have shed light on the immunologic environment in the gastrointestinal tract and reveal a complex interplay between the GI microflora, the epithelium, immune effector cells such as lymphocytes and macrophages, and soluble mediators such as chemokines and cytokines.[46,62] In health, this system avoids active inflammation by antigen exclusion and the induction of immune tolerance. The development of intestinal inflammation in mice lacking the cytokines IL-10, TGFβ, or IL-2 indicates the central importance of cytokines in damping down mucosal inflammation. In many of these murine models GI inflammation only develops in the presence of indigenous intestinal microflora, leading to the hypothesis that spontaneous mucosal inflammation may be the result of a loss of tolerance to the indigenous GI microflora. The role of these mechanisms in outbred species such as the dog and cat remains to be determined, but clearly loss of tolerance to bacterial of dietary antigens should be considered.

The epithelial cell is also emerging as a "general" in the inflammatory response, with gram-negative or pathogenic bacteria inducing proinflammatory cytokine (e.g., IL-8, IL1-β) secretion from epithelial cells, whereas commensal or bacteria such as *S. fecium* or *Lactobacillus* spp. induce the production of the immunomodulatory cytokines TGFB or IL-10.[62] The pro-inflammatory cytokines produced by epithelial cells are modulated by the production of IL-10 from macrophages and potentially by the epithelial cells themselves.[63] In this context, dogs with lymphoplasmacytic gastritis of undetermined etiology showed a correlation between the expression of the immunomodulatory cytokine IL-10 and proinflammatory cytokines (IFN-γ, IL-1β, IL-8).[61] Simultaneous expression of IL-10 and IFN-γ mRNA has also been observed in the intestines of beagle dogs (lamina propria cells and the intestinal epithelium) in the face of a luminal bacterial flora that was more numerous than that of control dogs.[64] Thus it is tempting to visualize a "homeostatic loop" consisting of proinflammatory stimuli and responses, countered by immunomodulation and repair, with an imbalance in either of these arms manifested as gastritis.

The importance of unknown pathogens in the development of mucosal inflammation is best demonstrated by the gastric bacterium *Helicobacter pylori*, a gram-negative bacterium, which chronically infects more than half of all people worldwide.[13] Chronic infection of human adults with *H. pylori* is characterized by the infiltration of polymorphonuclear and mononuclear cells and the up-regulation of pro-inflammatory cytokines and the chemokine IL-8. Mucosal T cells in infected individuals are polarized toward the production of gamma interferon (IFN-γ), rather than IL-4 or IL-5 indicating a strong bias toward a T_H-1 type response).[65,66] This sustained gastric inflammatory and immune response to infection appears to be pivotal for the development of peptic ulcers and gastric cancer in people.[67]

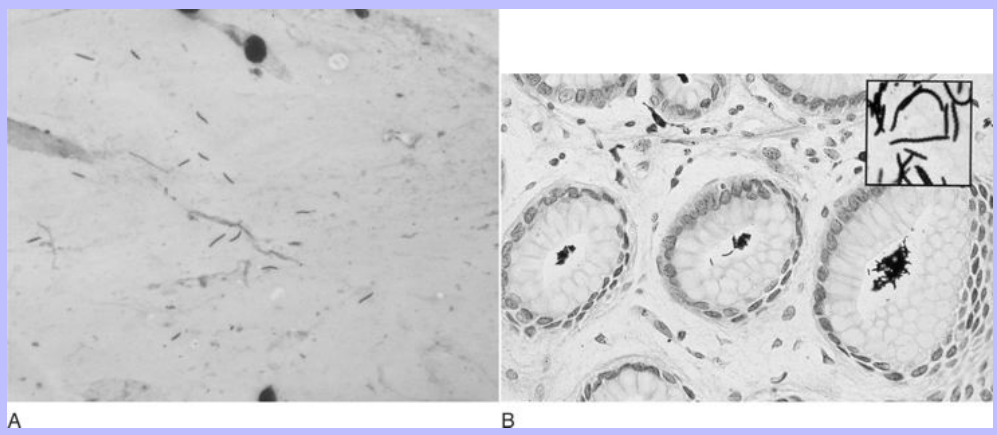
There is also a high prevalence of gastric *Helicobacter* spp. infection in dogs (67% to 100% of healthy pet dogs, 74% to 90% of vomiting dogs, 100% of laboratory beagles) and cats (40% to 100% of healthy and sick cats).[68–70] In contrast to people, in whom *Helicobacter pylori* infection predominates, dogs and cats are colonized by a variety of large spiral organisms (5 to 12 μ) (Figure 221-12). In cats from Switzerland, United States, and Germany, *Helicobacter heilmannii* is the predominant species, with *Helicobacter bizzozeronii* and *Helicobacter felis* much less frequent. In dogs from Finland, Switzerland, the United States, and Denmark *H. bizzozeronii* and *H. salomonis* are most common followed by *H. heilmanni* and *H. felis. H. bilis* and *Flexispira rappini* have also been described. Cats can also be colonized by *H. pylori* (2 to 5 μ) but infection has been limited to a closed colony of laboratory cats.

Ownership of dogs and cats has been correlated with an increased risk of infection of *H. heilmannii* in people.[71] Case reports have also suggested the transmission of *Helicobacter* spp. from pets to man. Recent studies clearly confirm that dogs and cats harbor *H. heilmannii*, but the subtypes of *H. heilmannii* present in dogs and cats (types 2 and 4) are of minor importance (approximately 15% of cases) to humans, who are predominantly colonized by *H. heilmannii* type 1 (the predominant *Helicobacter* sp. in pigs).[72]

The effect of eradicating *Helicobacter* spp. on gastritis and clinical signs, the main form of evidence supporting the pathogenic role of *H. pylori* in human gastritis, has not been thoroughly investigated to date in dogs and cats. An uncontrolled treatment trial of dogs and cats with gastritis and *Helicobacter* spp. infection showed that clinical signs in 90% of 63 dogs and cats responded to treatment with a combination of metronidazole, amoxicillin, and famotidine, and that 14 of the 19 animals re-endoscoped had resolution of gastritis and no evidence of *Helicobacter* spp. in gastric biopsies.[73]

Controlled clinical trials are required to confirm these observations but have been hampered by a much higher apparent recrudescence or re-infection rate than the 1% to 2% per year observed after treatment of *H. pylori*-infected people. With such limited information from eradication trials, most current knowledge about the pathogenicity of *Helicobacter* spp. for dogs and cats comes from the evaluation of animals with and without infections and clinical signs, and a small number of experimental infections. 1322 1323

Figure 221-12 *Helicobacter* spp. visualized on **(A)** an impression smear (Diff-Quick stain) and **(B)** endoscopic biopsy (Steiner stain).



The large *Helicobacter* species found in dogs an cats do not attach to the epithelium but colonize the superficial mucus and gastric glands, particularly of the fundus and cardia, and may also be observed intracellularly.[68,69] Degeneration of gastric glands, with vacuolation, pyknosis, and necrosis of parietal cells is more common in infected than uninfected animals. Inflammation is generally mononuclear in nature and ranges from mild to moderate in severity. Gastric lymphoid hyperplasia is common and can be extensive in dogs and cats infected with *Helicobacter* spp. (particularly when full thickness gastric biopsies are evaluated). In addition to this local gastric immune response, a systemic response characterized by increased circulating anti-*Helicobacter* IgG has been detected in sera from naturally infected dogs and cats. However, the gastritis observed in cats and dogs infected with large HLOs is generally less severe than that observed in *H. pylori* infected humans (where neutrophilic aggregates, and moderate to severe gastritis, are commonly encountered), and gastro-intestinal ulcers, gastric neoplasia, or changes in serum gastrin or acid secretion have not been associated with *Helicobacter* spp. infection in dogs and cats.

These differences between people, dogs, and cats may be attributed to differences in the virulence of the infecting *Helicobacter* spp., or the host response. Studies that address this issue indicate that *H. pylori* evokes a more severe pro-inflammatory cytokine and cellular response in dogs and cats than natural or experimental infection with large *Helicobacter* spp.[74,75] The limited mucosal inflammatory response and absence of clinical signs in the vast majority of dogs and cats infected with non-*H. pylori Helicobacter* spp., despite significant antigenic stimulation (evidenced by seroconversion and lymphoid follicle hyperplasia) suggest that large gastric *Helicobacter* spp. are more commensal than pathogenic. With this in mind, it is interesting to speculate that it is the loss of tolerance to gastric *Helicobacter* spp., rather than the innate pathogenicity of these bacteria, that explains the development of gastritis and clinical signs in some dogs and cats. However, much still remains to be learned about the role of *Helicobacter* spp. in canine and feline gastritis.

221.7.3 Clinical Findings

The major clinical sign of chronic gastritis is vomiting of food or bile. Decreased appetite, weight loss, melena, or hematemesis is variably encountered. The concurrent presence of dermatologic and gastrointestinal signs raises the likelihood of dietary sensitivity.[76] Access to toxins, medications, foreign bodies, and dietary practices should be thoroughly reviewed. The signalment should not be overlooked as it may increase the probability that chronic gastritis is the cause of vomiting. Hypertrophy of the fundic mucosa is frequently associated with a severe enteropathy in basenjis[77] and stomatocytosis, hemolytic anemia, icterus, and polyneuropathy in Drentse Patrijshond.[78] Hypertrophy of the pyloric mucosa is observed in small brachycephalic dogs such as Lhasa apso and is associated with gastric outflow obstruction (see Delayed Gastric Emptying and Motility Disorders). Atrophy of the gastric mucosa that may progress to adenocarcinoma has been reported in Lundehunds with protein-losing gastroenteropathy.[79]

Young, large breed, male dogs in the Gulf states of the United States may have granulomatous gastritis caused by *Pythium* spp. with infection more prevalent in fall, winter, and spring.[80] Physical examination is often unremarkable. Abdominal distension may be related to delayed gastric emptying caused by obstruction or defective propulsion. Abdominal masses, lymphadenopathy, or ocular changes may be encountered in dogs with gastric fungal infections.

221.7.4 Diagnosis

A biochemical profile, complete blood count, urinalysis, and T_4 (cats) should be performed as a basic screen for metabolic, endocrine, infectious, and other non-GI causes of vomiting, as well as the acid base and electrolyte changes associated with vomiting, outflow obstruction, or acid hypersecretion. Clinicopathologic tests are often normal in patients with chronic gastritis.

Eosinophilia may prompt the consideration of gastritis associated with dietary hypersensitivity, endoparasites, or mast cell tumors. Hyperglobulinemia and hypoalbuninemia may be present in basenjis with gastropathy/enteropathy, or dogs with gastric pythisosis. Panhypoproteinemia is a feature of gastro-enteropathy in Lundehunds, moderate to severe generalized inflammatory bowel disease, GI lymphoma, and GI histoplasmosis. More specific testing, such as an ACTH stimulation test, or serology for *Pythium insidiosum*, is performed based on the results of these initial tests. Determination of food specific IgE has not been shown to be useful in the diagnosis of dietary sensitivity in dogs or cats. The utility of noninvasive tests, such as serum pepsinogen and gastric permeability to sucrose, used to diagnose gastritis in people has not been determined in dogs and cats.

1323 1324

Abdominal radiographs are frequently normal in dogs and cats with gastritis but may show gastric distention or delayed gastric emptying (food retained more than 12 hours after a meal). Contrast radiography may reveal ulcers or thickening of the gastric rugae or wall but has largely been supersceded by the combination of ultrasonography to detect mural abnormalities and endoscopy to observe and sample the gastric mucosa.[22]

Endoscopic examination enables the visualization of foreign bodies, erosions, ulceration, hemorrhage, rugal thickening, lymphoid follicle hyperplasia (evident as mucosal pock marks), increased mucus or fluid (clear or bile stained), and increased or decreased mucosal friability. Discrete focal or multifocal mucosal nodules may be observed with *Ollulanus* spp. infection.

Gastric phycomycosis can be associated with irregular masses in the pyloric outflow tract and may prompt serologic testing by ELISA, Western blotting, and culture of fresh gastric biopsies. Parasites such as *Physalloptera* spp. may be observed as 1-to 4-cm worms. Large amounts of bile stained fluid is suggestive of duodenogastric reflux-associated gastritis, whereas lots of clear fluid my indicate hypersecretion of gastric acid. Gastric fluid can be aspirated for cytology (*Helicobacter* spp., parasite ova or larvae) and pH measurement. Impression smears of gastric biopsies are an effective way of looking for *Helicobacter* spp. (5 to 12 μ spirals) and are more sensitive than the biopsy urease test (*Helicobacter* spp. produce urease). Serum gastrin should be measured in the face of unexplained gastric erosions, ulcers, fluid accumulation, or mucosal hypertrophy.

The endoscopic procedure of dribbling dietary antigens onto the gastric mucosa to ascertain the presence of food allergy has not been useful in dogs or cats: it is highly subjective, detects only immediate hypersensitivity, and does not correlate with the results of dietary elimination trials.[76] The stomach should be biopsied even when it looks grossly normal (usually three biopsies from each region-pylorus, fundus, and cardia). Thickened rugae may require multiple biopsies, and a full-thickness biopsy is often required to differentiate gastritis from neoplasia or fungal infection and to diagnose submucosal or muscular hypertrophy. The results of gastric ultrasonography can help to forewarn the clinician of these possibilities and are complement to the endoscopic findings.

Gastric sections should be stained with H&E for evaluation of cellularity and architecture, and modified Steiner stain for gastric spiral bacteria (Figure 221-12, *B*). Further special stains, such as Gomori's methenamine silver, are indicated if pyogranulomatous inflammation is present to detect fungi. Masson's trichrome can be used to highlight gastric fibrosis, whereas sirius red and alcian blue help to reveal eosinophils and mast cells, respectively. Immunocytochemistry can be employed to help distinguish lymphoma from severe lymphocytic gastritis. Mucin staining has been performed in Lundehunds with gastric atrophy and showed an abnormal presence of mucus neck cells and pseudo-pyloric metaplasia.[81]

The interpretation of gastric biopsies has important implications for patient care because biopsy findings are often used to guide treatment. For example, moderate lymphoplasmacytic gastritis without *Helicobacter* spp. infection is often treated with corticosteroids, whereas mild lymphoplasmacytic gastritis may be treated with a change in diet. As the histopathologic evaluation of gastric biopsies has not been standardized, the prudent clinician should carefully review histologic sections to get a feel for the pathologist's interpretation. Even with optimum evaluation similar histologic changes can be observed in patients with different underlying etiologies, so well-structured treatment trials often form the basis of an etiologic diagnosis.

221.7.5 Treatment

Treatment of gastritis initially centers on the detection and treatment of underlying metabolic disorders and the removal of drugs, toxins, foreign bodies, parasites, and fungal infections.

221.7.5.1 Parasitic Gastritis

Ollulanus tricuspis is a microscopic worm (0.7 to 1 mm long, 0.04 mm wide) that infects the feline stomach.[82] Its predominant cat-to-cat transmisison is through ingestion of vomitus. It can also undergo internal autoinfection with worm burdens reaching up to 11,000 per stomach. Mucosal abnormalities range from none, to rugal hyperplasia, and nodular (2 to 3 mm) gastritis.

Histologic findings include lymphoplasmacytic infiltrates, lymphoid follicular hyperplasia, fibrosis, and up to 100/hpf globular leukocytes. *Ollulanus* spp. are not detected by fecal examination and require evaluation of gastric juice, vomitus, or histologic sections for larvae or worms. Gastric lavage and xylazine-induced emesis have been described to aid diagnosis. Treatment with fenbendazole 10 mg/kg PO SID 2d may be effective.

Physalloptera spp. are about 2 to 6 cm long worms that are sporadically detected in the stomachs of dogs and cats. *Physalloptera rara* are most commonly described and appear to be primarily a parasite of coyotes. Diagnosis is difficult as worm burden is often low and the eggs are transparent and difficult to see in sugar floatation. Treatment with pyrantel pamoate (5 mg/kg PO: dogs single dose; cats two doses 14 days apart) may be effective. Control of infection may be difficult due to the ingestion of intermediate hosts, such as cockroaches and beetles, and paratenic hosts, such as lizards and hedgehogs.

Given the difficult diagnosis of *Ollulanus* and *Physalloptera* spp., empirical therapy with an anthelminthic such as fenbendazole may be warranted in dogs and cats with unexplained gastritis.

Gastric infection with *Gnathostoma* spp. (cats), *Spirocerca* spp. (dogs), and *Aonchotheca* spp. (cats) has been associated with gastric nodules that have been treated by surgical resection of affected gastric tissue.[83]

221.7.5.2 Gastric Pythiosis

The presence of transmural thickening of the gastric outflow tract (Figure 221-13, *D*) and histology that indicates pyogranulomatous inflammation raise the possibility of infection with fungi such as *Pythium insidiosum*.[80] Special staining (Gomoris methenamine silver), culture, serology, and PCR of infected tissues can be used to help confirm the diagnosis. Treatment consists of aggressive surgical resection combined with itraconazole (10 mg/kg PO SID) and terbinafine (5 to 10 mg/kg PO SID) for 2 to 3 months post-surgery. ELISA titers of pre-and post-treatment samples may show a marked drop during successful treatment and drugs can be stopped. Medical therapy is continued for another 2 to 3 months if titers remain elevated. The prognosis is poor and fewer than 25% of afflicted animals are cured with medical therapy alone.[80]

221.7.5.3 Helicobacter-Associated Gastritis

The general lack of knowledge of the pathogenicity of gastric *Helicobacter* spp. has meant that veterinarians are faced with the dilemma of either treating or ignoring spiral bacteria observed in biopsies from patients with chronic vomiting and gastritis. In light of their pathogenicity in man, ferrets, cheetahs, and mice, it would seem prudent that eradication of gastric *Helicobacter* spp. is attempted prior to initiating treatment with immunosuppressive agents to control gastritis. However, this must be decided on an individual basis. For example, in the patient with a lymphoplasmacytic infiltrate of the stomach and small intestine with a concomitant gastric *Helicobacter* spp. infection, should one treat for inflammatory bowel disease, *Helicobacter,* or both? 1324 1325

The author recommends treating only symptomatic patients that have biopsy-confirmed *Helicobacter* spp. infection and gastritis. Current treatment protocols are based on those found to be effective in humans infected with *H. pylori*. An uncontrolled treatment trial of dogs and cats with gastritis and *Helicobacter* spp. infection showed that clinical signs in 90% of 63 dogs and cats responded to treatment with a combination

of metronidazole, amoxicillin, and famotidine, and that 74% of 19 animals re-endoscoped had no evidence of *Helicobacter* spp. in gastric biopsies.[73]

Unfortunately these promising results regarding the eradication of *Helicobacter* spp. have not been borne out by more controlled studies in asymptomatic *Helicobacter*-infected dogs and cats. Treatment combinations that have been critically evaluated are (1) amoxicillin (20 mg/kg PO BID 14d), metronidazole (20 mg/kg PO BID 14d), and famotidine (0.5 mg/kg PO BID 14d) in dogs[84]; (2) clarithromycin (30 mg PO BID 4d), metronidazole (30 mg PO BID 4d), ranitidine (10 mg PO BID 4d), and bismuth (20 mg PO BID 4d) (CMRB) in *H. heilmannii* infected cats[85] and (3) azithromycin (30 mg PO SID 4d), tinidazole (100 mg PO SID 4d), ranitidine (20 mg PO SID 4d) and bismuth (40 mg PO SID 4d)(ATRB) in *H. heilmannii*-infected cats.[85] Re-evaluation of infection status at 3 days (dogs) or 10 days (cats) after treatment revealed six of eight dogs and 11 of 11 CMRB and four of six ATRB-treated cats to be *Helicobacter* spp. free on the basis of histology and urease testing (dogs) or ^{13}C-urea breath test (dogs and cats).[85,86] However, at 28 days (dogs) or 42 days (cats) after completing antimicrobial therapy, eight of eight dogs and four of eleven cats that received CMRB, five of six cats that received ATRB were found to be re-infected. A transient effect of combination therapy (amoxicillin 20 mg/kg PO TID 21d, metronidazole 20 mg/kg PO TID 21d, and omeprazole 0.7 mg PO SID 21d) on bacterial colonization has also been observed in six cats with *H. pylori* infection.

Further analysis of gastric biopsies from infected dogs and *H. pylori* infected cats using PCR and *Helicobacter*-specific primers revealed persistence of *Helicobacter* DNA in gastric biopsies that appeared negative on histology and urease testing. These studies suggest that antibiotic regimens that are effective against *H. pylori* in people may only cause transient suppression, rather than eradication, of gastric *Helicobacter* spp. in dogs and cats.

The author has recently employed the combination of amoxicillin (20 mg/kg PO BID), clarithromycin (7.5 mg/kg PO BID) and metronidazole (10 mg/kg PO BID) for 14 days to eradicate *Helicobacter pylori* infection in cats. Further controlled trials of antibiotic therapy in infected dogs and cats, particularly symptomatic patients with gastritis and *Helicobacter* spp. infection, are clearly required before guidelines regarding the treatment of gastric *Helicobacter* spp. in dogs and cats can be made.

221.7.5.4 Chronic Gastritis of Unknown Cause

Lymphocytic plasmacytic gastritis of unknown cause is common in dogs and cats. It may be associated with similar infiltrates in the intestines, particularly in cats (who should also be evaluated for the presence of pancreatic and biliary disease). The cellular infiltrate varies widely in severity and it may be accompanied by mucosal atrophy or fibrosis, and less commonly hyperplasia.

Patients with mild lymphoplasmacytic gastritis are initially treated with diet. The diet is usually restricted in antigens to which the patient has been previously exposed, such as a lamb-based diet if the patient has previously been fed chicken and beef, or contains hydrolyzed proteins (usually chicken or soy) that may be less allergenic than intact proteins. Many of these diets are also high in carbohydrate and restricted in fat, which facilitates gastric emptying, and may contain other substances such as menhaden fish oil or antioxidants that may alter inflammation.

The test diet is fed exclusively for a period of about 2 weeks while vomiting episodes are recorded.[76] If vomiting is improved a challenge with the original diet is required to confirm a diagnosis of food

intolerance. The introduction of a specific dietary component to the test diet, such as beef, is required to confirm dietary sensitivity. If vomiting is unresponsive the patient may be placed on a different diet for another 2 weeks, usually the limit of client tolerance, or started on prednisolone (1 to 2 mg/kg/day PO, tapered to every other day at the lowest dose that maintains remission over 8 to 12 weeks).

Patients with moderate to severe lymphoplasmacytic gastritis are usually started on a combination of a test diet and prednisolone. If the patient goes into remission they are maintained on the test diet while prednisolone is tapered and potentially discontinued. Antacids and mucosal protectants are added to the therapeutic regimen if ulcers or erosion are detected at endoscopy or if hematemesis or melena is noted.

If gastritis is unresponsive to diet, prednisolone, and antacids, additional immunosuppression may be indicated. Gastric biopsies should be carefully re-evaluated for evidence of lymphoma. In dogs immunosuppression is usually increased with azathioprine (PO2 mg/kg SID for 5d then EOD, on alternating days with prednisolone). Chlorambucil may be a safer alternative to azathioprine in cats (PO) and has been successfully employed in the management of inflammatory bowel disease and small cell lymphoma (see below). Prokinetic agents such as metoclopramide, cisapride, and erythromycin can be used as an adjunct where delayed gastric emptying is present. These are discussed below.

Diffuse eosinophillic gastritis of undefined etiology is usually approached in a similar fashion to lymphoplasmacytic gastritis. The presence of eosinphilia, dermatologic changes, and eosinophilic infiltrates may be even more suggestive of dietary sensitivity. In cats it should be determined if it is part of a hypereosinophilic syndrome. Treatment for occult parasites, dietary trials, and immunosuppression can be carried out as described above. Focal eosinophilic granulomas can be associated with parasites or fungal infection that should be excluded prior to immunosuppression with corticosteroids.

221.7.5.5 Atrophic Gastritis

Atrophic gastritis in dogs and cats is often associated with a marked cellular infiltrate (see Figure 221-10). In people atrophy is associated with *Helicobacter* spp. infection and inflammation, and immune-mediated destruction.[87] Gastric disease is often not discovered until the patient presents with pernicious anemia secondary to cobalamin deficiency caused by a lack of gastric intrinsic factor. In people, atrophic gastritis, intestinal metaplasia of the gastric mucosa, and hypochlorhydia are thought to precede the development of gastric cancer.[88] The host inflammatory response is also thought to contribute to the development of atrophy and pro-inflammatory IL-1β and IL-10 gene polymorphisms in people are associated with increased inflammation, gastric atrophy, hypochlorhydria, and gastric cancer.[89,90]

Atrophic gastritis has been infrequently described in dogs and cats but does share some similarities with people. Atrophy has been associated with gastric adenocarcinoma in Lundehunds[81] and in dogs with lymphoplasmacytic gastritis of undetermined cause atrophy correlates with the expression of mRNA for IL-1β and IL-10 and the presence of neutrophils. However, there is no clear evidence that lymphoplasmacytic gastritis progresses to atrophy and gastric cancer in dogs or cats,[91] and the role of *Helicobacter* spp. or antigastric antibodies in the development of atrophy in dogs and cats remains to be determined.

1325

1326

In contrast to humans, dogs and cats with atrophic gastritis have not been reported to develop cobalamin deficiency. This is probably because the pancreas, rather than the stomach, is the main source of intrinsic factor in these species. Achlorhydria has been described in dogs and may enable the prolifera-tion of bacteria in the stomach and upper small intestine, although this has not been proven. The treatment of

atrophic gastritis has received limited attention, but *Helicobacter* spp. eradication and immunosuppression have been effective in people.

221.7.5.6 Hypertrophic Gastritis

Hypertrophy in the fundic mucosa is uncommon and is often part of the breed-specific gastropathies or gastroenteropathies mentioned above (Figure 221-13). Concurrent hypergastrinemia should prompt consideration of underlying hepatic or renal disease, achlorhydria, or gastrin-producing tumors, which should be pursued appropriately. Basenji gastoenteropathy is variably associated with fasting hypergastrinemia and exaggerated secretin stimulated gastrin, and anecdotal reports suggest that affected basenjis may respond to antimicrobial therapy. Antral hypertrophy of brachycephalic dogs causes outflow obstruction and is treated with surgery (see below).

221.8 DELAYED GASTRIC EMPTYING AND MOTILITY DISORDERS

Disorders of gastric motility can disrupt the storage and mixing of food and its expulsion into the duodenum.[25] Normal gastric motility is the result of the organized interaction of smooth muscle with neural and hormonal stimuli. Delayed gastric emptying is the most commonly recognized manifestation of gastric motility disorders. Rapid gastric emptying and motility disorders associated with retrograde transit of bile or ingesta are less well defined.

Delayed gastric emptying is caused by outflow obstruction or defective propulsion (Table 221-3) and is usually suspected by the vomiting of food at least 8 and often 10 to16 hours after a meal.

221.8.1 Diagnosis

Vomiting of food some time after ingestion (more than 8 hours) is the most common sign. Vomiting may be projectile with pyloric stenosis. Abdominal distension, weight loss, melena, abdominal discomfort, distention, bloating, and anorexia are more variably present.

The signalment and history may be helpful narrowing down the cause. Development of vomiting at weaning raises the possibility of pyloric stenosis. Access to foreign bodies, bones, and medications is of obvious relevance to outflow obstruction. Brachycephalic, middle-aged, small breed dogs, such as shih tzus, seem predisposed to the syndrome of hypertrophic pylorogastropathy, where vomiting is secondary to pyloric outflow obstruction caused by hypertrophy of the pyloric mucosa and/or muscularis.[92,93] Gastric neoplasia is usually detected in older animals, and weight loss, hematemesis, and pallor may be present. Gastric pythiosis is more prevalent in young large breed dogs in the Gulf states of the United States. Large breed, deep-chested dogs are more prone to GDV that may have an underlying problem with gastric emptying (see GD/GDV above).

A thorough physical examination is performed to detect causes of vomiting such as string foreign bodies, or intestinal masses or thickenings, non-gastrointestinal (GI) causes, including thyroid (nodules-cats), liver (jaundice, hepatomegaly) or kidney disease (renomegaly, lumpy or small), and the systemic effects of vomiting, such as dehydration and weakness.

Table • 221-3 Causes of Delayed Gastric Emptying

Outflow Obstruction
Congenital stenosis
Foreign bodies
Hypertrophy of pyloric mucosa
Granuloma
Polyps
Neoplasia
Extragastric masses
Defective Propulsion
Gastric disorders
Gastritis
Ulcers
Neoplasia
Gastroenteritis
Peritonitis
Pancreatitis
Metabolic (hypokalemia, hypocalcemia, hypoadrenocorticism)
Nervous inhibition (trauma, pain, stress?)
Dysautonomia
GDV
Surgery
Drugs (e.g., anticholinergics, narcotics)
Idiopathic

The diagnostic approach is to confirm delayed gastric emptying and to detect causes of gastric outflow obstruction that may require surgery, and non-gastric disorders associated with defective propulsion. Historical and physical findings are combined with clinicopathologic testing, plain radiographs, and ultrasonography.

Hematology, serum biochemistry, urinalysis, fecal analysis (e.g., parasites, parvo), and serology (e.g., FelV) are employed to detect non-GI causes of vomiting or delayed gastric emptying and to determine the consequences of vomiting. Laboratory findings vary depending on the severity of vomiting and completeness of pyloric obstruction and the presence of disorders associated with blood loss or inflammation. The CBC is often normal, but anemia may accompany gastric ulcers or neoplasia. Hyperglobulinemia may be present where outflow obstruction is secondary to fugal granuloma. The presence of hypochloremia, hypokalemia, and metabolic alkalosis, with or without aciduria, should increase suspicion of an upper GI obstruction or potential hypersecretion of gastric acid.

Radiographs are essential to confirm the retention of food or fluid in the stomach longer than 8 hours, and often 12 to 16 hours, after a meal, and to detect extra gastric disorders such as peritonitis. Ultrasound may detect mural thickening or irregularity of the stomach suggestive of neoplasia, granuloma, or hypertrophy. Ultrasound may also reveal radiolucent foreign objects and detect non-gastric causes of delayed emptying, such as pancreatitis. Contrast radiography can be used to detect mural abnormalities and to confirm a suspicion of gastric obstruction where plain radiographs are inconclusive (Figure 221-14). However, endoscopy is usually favored over radiographic procedures for confirming gastric outflow obstruction and gastric and duodenal causes of decreased propulsion (e.g., ulcers, gastritis) (see Figure 221-13). Measurement of gastric pH and serum gastrin can help to differentiate idiopathic hypertrophic pylorogastropathy from hypertrophy associated with hypergastrinemia. Pancreatic polypeptide-producing tumors may also be associated with mucosal hypertrophy. Endoscopy is hampered by the recent administration of barium so it is

1326 1328

often performed first. Endoscopic biopsy is limited to the superficial mucosa and surgical biopsy is frequently required to achieve a definitive diagnosis of granulomatous, neoplastic, or hypertrophic conditions.

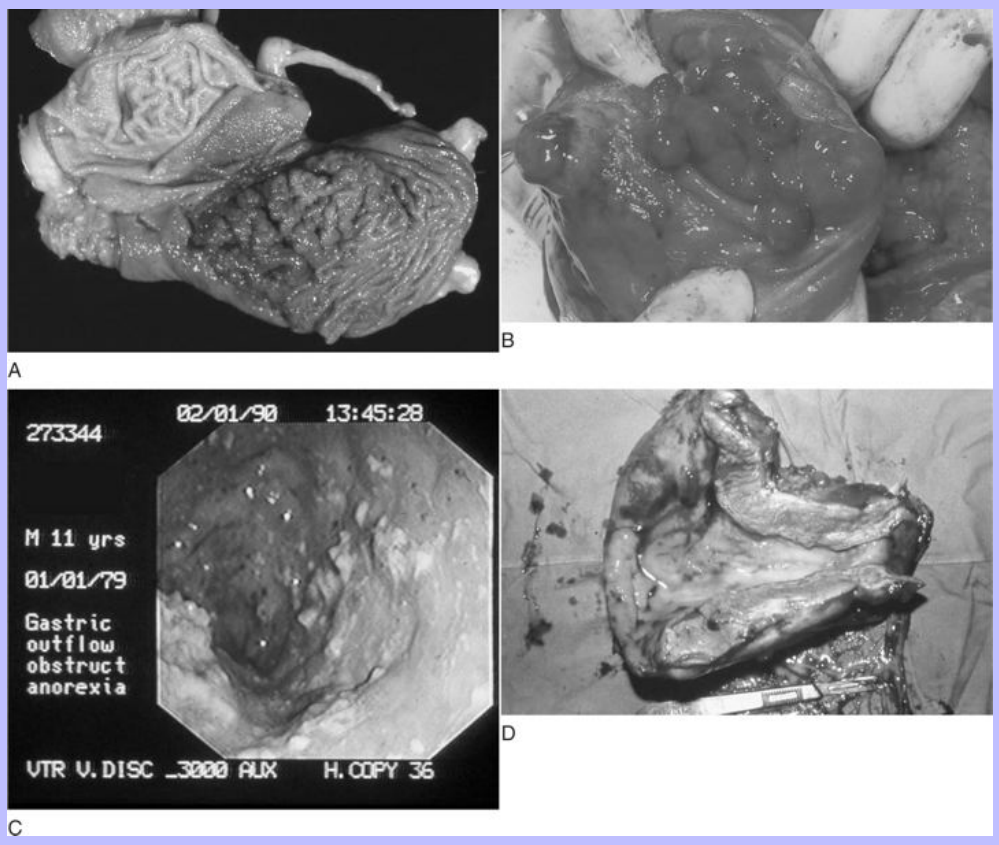


Figure 221-13 Gross appearance of hypertrophic gastropathies. **A,** Diffuse fundic hypertrophy; **B,** multifocal fundic hypertrophy; **C,** antral mucosal hypertrophy (idiopathic hyperplastic pylorogastropathy in a brachycephalic dog); **D,** thickening of the pyloric outflow tract due to *Pythium* spp. (*A, B,* and *D,* Courtesy of Cornell University; *C,* courtesy of The Ohio State University.)

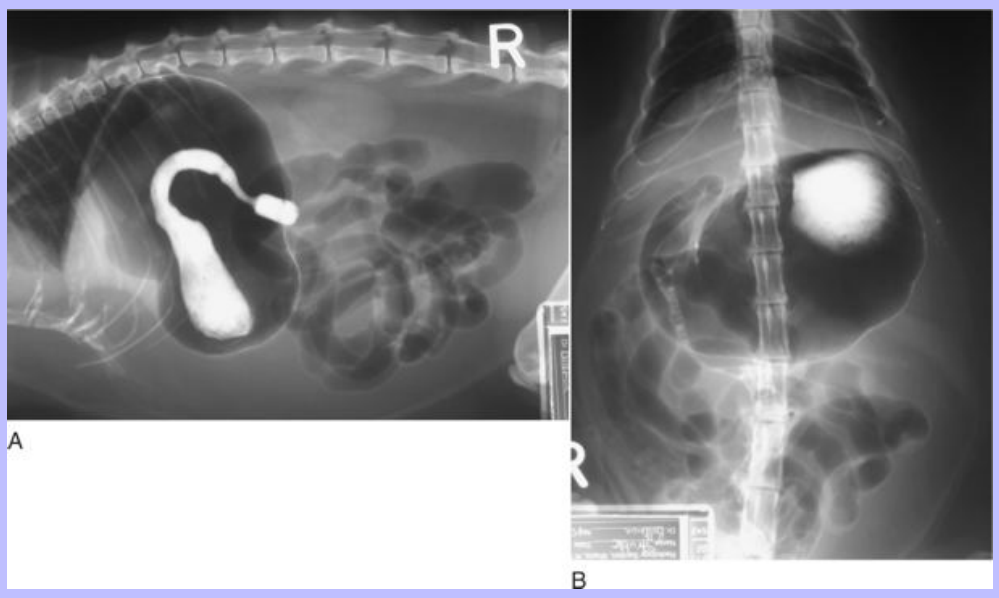
Figure 221-14 Marked gastric dilation and retention of liquid barium in a 12-year-old domestic short hair cat. Full thickness gastric biopsies showed submucosal infiltration with neutrophils and lymphocytes. (Courtesy of Cornell University.)



More sophisticated procedures to directly evaluate gastric emptying and motility are usually employed to determine if vomiting is due to an undefined gastric motility disorder and to optimize prokinetic therapy (Table 221-4).[25,26] Radiographic contrast procedures are readily available but are hampered by the wide variability in emptying times for barium in liquid or meal form. The administration of barium impregnanted polyspheres (BIPS) is a simplified contrast procedure suited to routine clinical practice as it requires many fewer radiographs than traditional barium series and is standardized in terms of test performance and interpretation but its utility in clinical patients remains to be determined. Scintigraphic techniques are generally considered the most accurate way to evaluate emptying but are restricted to referral institutions. Ultrasound can be useful for detecting gastric wall abnormalities and measuring contractile activity. A test employing the labeled ^{13}C-octanoic acid has been evaluated in people and dogs and found to reflect gastric emptying (the values are longer than scintigraphy as ^{13}C-octanoate has to be absorbed and metabolized before $^{13}CO_2$ is liberated).

Table • 221-4 A Review of Methods for Assessment of the Rate of Gastric Emptying in the Dog and Cat[26]

METHOD	SPECIES	TEST MEAL	n	GASTRIC HALF EMPTYING TIME (t½)*
Radioscintigraphy	Dog	Eggs, starch +glucose	27	66 min (median), 45–227 min (95% CI)
		Beef baby food +kibble	6	4.9 ±1.96 hours (mean ±sd)
		Liver	4	About 2 hours
		Canned dog food +egg	6(18 tests)	172 ± 17 min (mean ±se)
		Canned dog food +egg	7(14 tests)	285 ± 34 min (mean ± sd); 294 ±39 min (mean ±sd)
		Canned dog food	6	77 min (mean)
	Cat	Dry cat food	10	2.47 ±0.71 hours (mean ±sd)
		Liver +cream	6(15 tests)	163 ± 11 min (mean ±se)
		Canned cat food	20	2.69 ±0.25 hours (mean ±sd)
		Dry cat food	20	3.86 ±0.24 hours (mean ±sd)
		Eggs	10	330 min (median), 210–769 min (range)
Radiography		Dry dog food +radio-opaque solids	10	3.5 hours (median), 1–6 hours (range)
		Canned dog food +egg +BIPS	6(18 tests)	Small BIPS 416 ± 81 min (mean ±se)
	Dog	Canned dog food +BIPS	20	Small BIPS 6.05 ± 2.99 hr (mean ±sd) Large BIPS 7.11 ± 3.60 hr (mean ±sd)
		Kibble +BIPS	8	Small BIPS =8.29 ± 1.62 hr (70% of dogs ± se) Large BIPS =29.21 ± 18.31 hr (70% of dogs ±se)
		Kibble +liquid barium	9(27 tests)	Total gastric emptying time =7–15 hr (range)
		Kibble +liquid barium	4	Total gastric emptying time =7.6 ± 1.98 hr (mean ±se)
	Cat	Canned cat food +BIPS	10	Small BIPS 6.43 ± 2.59 hr (mean ±sd) Large BIPS 7.49 ± 4.09 hr (mean ±sd)
		Canned cat food +BIPS	6	Small BIPS-7.7 hr (median), 3.5–10.9 hr (range) Large BIPS-8.1 hr (median), 5–19.6 hr (range)
		Canned cat food +BIPS	10	Small BIPS-5.36 hr (median) Large BIPS-6.31 hr (median)
		Cat food +liquid barium	8	Gastric emptying time =11.6 ± 0.9 hr (mean ±sd)
Gastric Emptying	Cat	Canned cat food	6	Peak ^{13}C-excretion =56.7 ± 9.8 min (mean ±sd)
Breath Test	Dog	Bread, egg +margarine	6(18 tests)	3.43 ± 0.50 hr (mean ±sd)

* Gastric emptying rate is expressed as gastric half emptying time, unless otherwise stated. (Reproduced with permission of Wyse et al, *JVIM* 2003,17:604–621.)

221.8.2 Treatment

Treatment of gastric emptying disorders is directed at the underlying cause. Gastric ulcers, erosions, and inflammation should be investigated and managed medically as described above. Foreign bodies are removed either endoscopically or surgically. Pyloric stenosis, polyps, and hypertrophic gastro-pathy that is not associated with hypergastrinemia are managed surgically. When hypertrophic gastropathy, ulcers or erosions,

or excessive gastric juice is encountered at endoscopy, intravenous H_2-antagonists can be given during the endoscopic procedure to try to prevent postoperative perforation or esophagitis. Neoplasia, polyps, and granulomas may require extensive gastric resection and Billroth procedures.

1328

1329

Dietary modification to facilitate gastric emptying may be beneficial irrespective of cause.

Small amounts of semi-liquid, protein-and fat-restricted diets fed at frequent intervals may facilitate emptying, such as an “intestinal disease diet” blended with water and mixed with an equal volume of boiled rice.

In nonobstructive situations gastric emptying can be enhanced and duodenogastric reflux inhibited by prokinetic agents such as metoclopramide, cisapride, erythromycin, or ranitidine.[25,39,94] The choice of prokinetic depends if a central antiemetic effect is required (e.g., metoclopramide), if a combined antacid prokinetic is indicated (e.g., ranitidine), or if treatment with one agent has been ineffective or caused adverse effects (e.g., behavioral changes with metoclopramide). Metoclopramide (0.2 to 0.5 mg/kg PO SC TID) has central antiemetic properties in addition to its prokinetic activity in the stomach and upper GI tract and is frequently an initial choice in patients with underlying metabolic diseases associated with vomiting and delayed gastric emptying.

However, metoclopramide may only facilitate the emptying of liquids and is less effective in promoting organized gastroduodenal and intestinal motility than cisapride. Cisapride (0.1 to 0.5 mg/kg PO TID) has no central antiemetic effects but is generally more potent in promotion of the gastric emptying of solids than metoclopramide, but it does have more drug inter-actions and its availability is limited. Erythromycin (dog: 0.5 to 1.0 mg/kg PO TID, between meals) releases motilin and acts at motilin receptors and mimics phase III of the interdigestive migrating myoelectric complex (MMC) promoting the emptying of solids. Niaztidine and ranitidine (0.25 to 0.5 mg/lb PO TID) have prokinetic activity attributed to an organophosphate-like effect.

No controlled trials in dogs and cats have evaluated the efficacy of different prokinetics in different disease states, and treatment is usually based on a best guess/least harmful basis. Where true prokinetic activity is required, cisapride and erythromycin appear to be the most efficacious.[25] Treatment trials with prokinetics should probably be structured to last between 5 and 10 days to determine benefit. A diary of clinical signs and the objective assessment of gastric emptying using the tests described above, before and after therapy helps to optimize treatment. Combination therapy, such as erythromycin and cisapride, is not recommended due to the potential for adverse drug interactions. The prognosis for patients with delayed gastric emptying depends on the cause.

A suspected motility disorder characterized by duodenogastric reflux is thought to account for a syndrome known as the bilious vomiting syndrome. Affected dogs usually vomit early in the morning. Remission may be achieved by feeding the animal late at night. Prokinetic agents may also be employed.

221.9 GASTRIC NEOPLASIA

Gastric neoplasia represents less than 1.0% of all reported canine and feline neoplasms.[95] Malignant tumors are more common than benign tumors and most types of gastric neoplasms have been reported to occur more frequently in males, except adenomas, which occur more frequently in females.[95] Other gastric malignancies reported are leiomyosarcoma, lymphosarcoma, fibrosarcoma, rare anaplastic sarcomas, and gastric extramedullary plasmacytoma. Table 221-5 summarizes the prevalence, breed predisposition, and distribution of gastric tumors in dogs.

221.9.1 Benign Tumors

Benign tumors of the stomach include leiomyomas and less frequently, adenomatous polyps. Canine gastric leiomyoma is a tumor of old dogs, median age 16 years, and many are discovered incidentally at necropsy or when they are presented for GI bleeding and microcytic anemia (Figure 221-15).

Table • 221-5 Characteristics of Gastric Neoplasia in Dogs

TUMOR	MOST COMMON LOCATION	MEDIAN AGE (YEARS)	REPORTED BREED PREDISPOSITION
Adenocarcinoma	Pyloric antrum, lesser curvature	10	Belgian shepherd Rough Collie Staffordshire Bull terrier Lundehund
Leiomyoma	Cardia	16	Beagle
Leiomyosarcoma		7	none
Lymphosarcoma	Diffuse	10	none

Adenomatous polyps are rare in dogs but have been reported as either raised, sessile or pedunculated, single or multiple growths in the stomach. The most common site is the terminal pyloric antrum and although most are discovered incidentally, they may also cause signs of gastrointestinal upset with vomiting (Figure 221-16). In humans, adenomatous polyps are generally regarded as possible premalignant lesions and changes considered focally malignant have been found in dogs. Benign GI neoplasia in the cat occurs at a much lower frequency than in the dog, where up to 36% of all GI neoplasia is reported to be benign.

221.9.2 Malignant Tumors

221.9.2.1 Adenocarcinoma

Malignant adenocarcinoma is the most common gastric neoplasm in dogs and accounts for 47% to 72% of all canine gastric malignancies.[96–99] Gastric adenocarcinoma is extremely rare in cats. The peak age of dogs with gastric carcinomas has been reported to be from 11 to 12 years with a range of 3 to 13 years and an average age of 9.1 to 10 years. A breed predilection for gastric carcinoma in related Belgian shepherd dogs and rough collie and Staffordshire bull terrier has been suggested, although the majority of studies show no significant breed predilections. Lundehunds with atrophic gastritis seem overrepresented, and gastric atrophy and inflammation may precede tumorigenesis as it does in humans.[79,88]

1329
1330

Figure 221-15 An ulcerated gastric leiomyoma in the cardia of a dog. (Courtesy of The Ohio State University.)

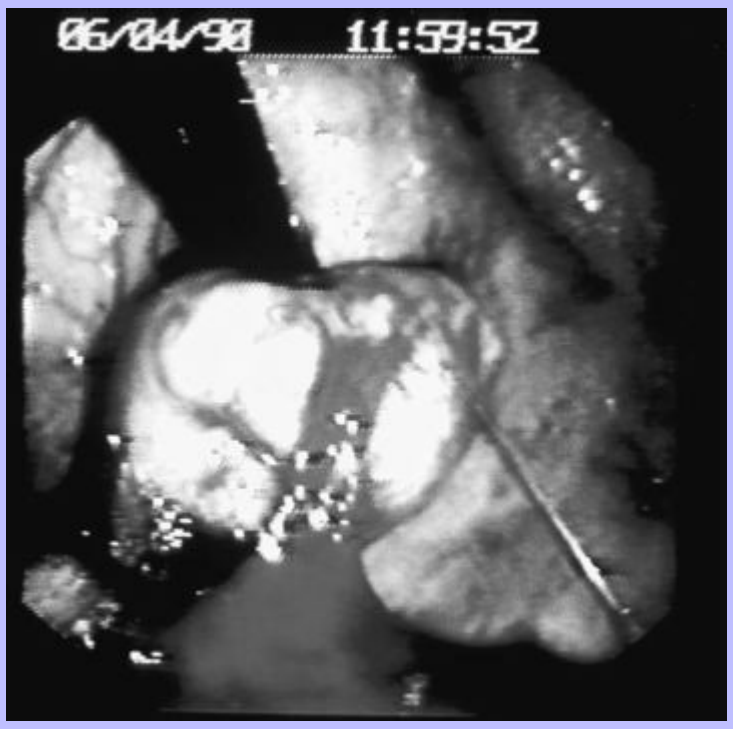


Figure 221-16 Adenomatous polyp in the pyloric outflow tract of a dog. (Courtesy of University of London.)

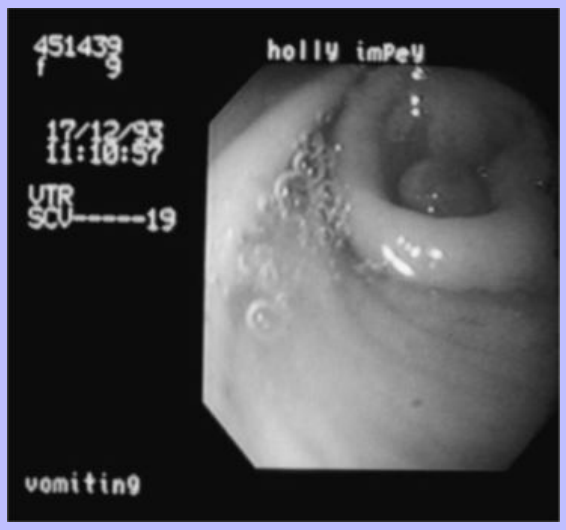
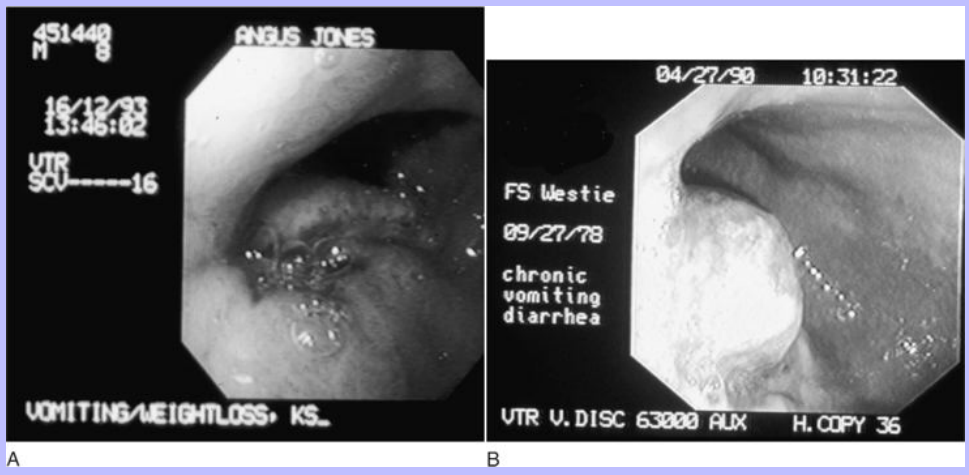


Gastric carcinomas of dogs occur most commonly in the lesser curvature and pyloric region as annular or stenosing lesions and metastasis is frequent with involvement of lymph nodes, lung, and liver (Figure 221-17). Carcinomas can be further divided into three morphologic patterns of distribution: (1) Diffusely infiltrating non-ulcerating lesions that involve most of the stomach and are consistent with the "leather bottle" appearance described in man, (2) Localized, raised thickened plaque usually containing a raised, excavating central ulcer, and (3) Raised, polypoid, sessile lesion projecting into the lumen of the stomach.

Figure 221-17 Endoscopic appearance of diffuse **(A)** and focal **(B)** gastric adenocarcinoma in a dog. (Courtesy of The Ohio State University.)



Two histologic types of gastric carcinoma exist in man: the diffuse and intestinal or tubular type. The diffuse type consists of widespread random infiltrates of neoplastic cells dispersed between stromal elements of the gastric wall. The intestinal type is characterized by a tubular, glandular structure. These same two classifications have been shown to exist in dogs with the diffuse type being more common.

221.9.2.2 Lymphosarcoma

The most common gastrointestinal neoplasm in both cats and dogs is lymphosarcoma, although it most often involves several segments of the intestinal tract. In canine lymphosarcoma (LSA) or lymphoma originating in the gastric submucosa the tumor type can be described as diffuse or nodular with the diffuse infiltrate being more common (Figure 221-18). Involvement of the liver, regional lymph nodes, small intestine, and bone marrow is common. Feline gastric lymphoma is not associated with FelV infection and has been recently categorized as large cell or small cell, with small cell lymphoma being more localized to the GI tract and carrying a much better prognosis than large cell lymphoma.[100]

In both dogs and cats, lymphocytic-plasmacytic inflammation has been found to precede or coexist with gastric LSA, and it has been suggested that lymphocytic-plasmacytic enteritis (LPE) is a prelymphomatous change in the GI tract. The development of gastric lymphoma in response to chronic antigenic stimulation

and inflammation is exemplified by gastric MALT lymphoma in people with *H. pylori*-associated gastritis. Whether a similar situation is present in dogs and cats remains to be determined.

221.9.2.3 Leiomyosarcoma

Leiomyosarcomas are slow growing tumors of smooth muscle origin. The median age for of affected dogs is greater than 10 years. Intestinal leiomyosarcoma has been found to be more common in female dogs and a predilection was reported in the German shepherd breed. However, neither breed nor sex predilection has been reported for gastric leiomyosarcoma.[101] In one study, dogs with leiomyosarcoma of the spleen, stomach, small intestine, and cecum were grouped together with 79% showing no evidence of metastases at surgery and 64% survived longer than 2 weeks.[101] Invasion of the gastric wall by leiomyosarcomas and lymphosarcomas is often diffuse. These tumors may cause ulceration, grossly resembling adenocarcinomas or appear as discrete masses. The median survival of these dogs was 10 months (range 1 month to 7 years). Of the stomach/small intestine group, 29% died of leiomyosarcoma eventually. Leiomyosarcoma and leiomyoma have been associated with paraneoplastic hypoglycemia and seizures presumed due to the production of insulin-like growth factors.[102]

221.9.3 Clinical Findings

The most common clinical signs associated with gastric neoplasia are chronic vomiting, weight loss, anorexia, diarrhea, and hematemesis, melena, or pallor if ulceration is present. Some dogs will also show abdominal

pain or a distended abdomen. With GI lymphoma, the onset of clinical signs is often insidious and gradually increases in severity, becoming refractory to symptomatic treatment.

221.9.4 Diagnosis

Survey radiographs may be completely normal or suggest focal gastric wall thickening, an abdominal mass, or evidence of peritonitis, rupture of a viscus, splenomegaly, hepatomegaly, or lymphadenopathy.

Ultrasonography may reveal mural thickening or irregularities that forewarn the endoscopist the lesion may be more submucosal or muscular than superficial. Lympadenopathy or regional metasasis may be evident.

Gastroscopy is able to efficiently detect most gastric tumors and has largely replaced contrast radiography. Lymphosarcoma is seen as a diffuse, smooth, or cobblestone-like thickening of the rugae with a mucosa that is pink or white and may have scattered petechial or ecchymotic hemorrhages. Gastric carcinomas tend to be focal dark pink to red masses that may appear slightly pedunculated. Discolored purple to black areas indicate hemorrhage, whereas yellow to brown foci often represent necrotic ulcers. In some cases, lesions may be submucosal and the endoscopist gets the impression that something is indenting the stomach or the wall seems less distensible or thick.

Several biopsy samples should be taken from suspicious areas and masses should be biopsied multiple times in the same place to get deeper into tissue as gastric tumors may have superficial necrosis, inflammation, and ulceration. These centers of ulcers and craters should be avoided, taking biopsies at the periphery to avoid perforation. Surgical biopsies should be taken where the gross endoscopic appearance does not match the histologic diagnosis, such as a large focal gastric mass with an endoscopic biopsy result of lymphoplasmacytic gastritis.

When endoscopy is not available contrast radiography may be useful with features of gastric neoplasia including thickening of the gastric wall, filling defects and derangement of normal rugal pattern, and delayed gastric emptying with retention and irregular pooling of barium. Surgery is then performed to sample the affected area.

221.9.5 Treatment

Except for lymphosarcoma, surgery is the most common form of treatment for gastric cancer. Resection may be curative if the affected area is localized or if the tumor is benign. If a widespread area is involved, a partial gastrectomy or antrectomy followed by gastroduodenostomy (Billroth I) may be attempted. However, many patients are presented at a late stage of disease and the lesions are often too extensive to resect. Gastric adeoncarcinoma often metastasizes and regional lymph nodes and liver should be inspected and biopsied. Even with surgery the prognosis for malignant gastric neoplasia is poor, with most patients dying within 6 months from recurrent or metastatic disease. Leiomyosarcoma is an exception and carries a good to excellent prognosis if the mass is surgically resectable. Even if gross metastasis is evident at surgery, a favorable outcome may be achieved because the tumor is slow growing. Survival in dogs with stomach, small intestinal, splenic, and cecal leiomyosarcoma ranges from 0 to 47 months after surgery and the median survival is 12.5 months.[101]

Gastrointestinal lymphosarcoma has a poor prognosis in dogs.[103] In cats the prognosis depends if the tumor is small or large cell. Small cell lymphomas achieve substantial remission when treated with chlorambucil and

prednisolone.[100] Large cell lymphoma is treated with combination cyclical chemotherapy and carries a much poorer prognosis.

222 CHAPTER • 222 Diseases of the Small Intestine

Edward J. Hall

Alexander J. German

The small intestine (SI) must be capable of performing digestive and absorptive functions while simultaneously protecting the body from a multitude of environmental threats. Thus it is the largest and most complex immunologic organ in the body, and armed with an understanding of its immunologic role, the clinician will be better able to understand and treat many intestinal diseases.

Considering the complex, paradoxical roles of the small intestine, minor daily variations in stool quality must be considered normal. *Diarrhea,* a significant increase in the frequency, fluidity, or volume of feces, is the cardinal sign of SI malfunction. However, diarrhea may also be a manifestation of disease elsewhere in the gastrointestinal (GI) tract or even in other organ systems (Box 222-1). Furthermore, diarrhea is not present in all cases of SI disease, and many other signs of SI disorder are nonspecific and may be overlooked (Box 222-2). Nevertheless, an understanding of normal SI function, in particular the small intestine's role as an immunologic organ, allows a logical approach to diagnosis and treatment.

222.1 STRUCTURE AND FUNCTION OF THE SMALL INTESTINE

222.1.1 Normal Structure

222.1.1.1 Gross Structure

The small intestine runs from the pylorus of the stomach to the ileocolic valve (Figure 222-1, *A*). It is divided anatomically into three arbitrary segments: the proximal duodenum (Figure 222-2), the jejunum, and the distal ileum.[1]

222.1.1.2 Microstructure

The small intestine is in essence a tube connected to the external environment (Figure 222-1, *B*). Its basic cross-sectional structure of serosa, muscularis, submucosa, and mucosa is present throughout (Figure 222-1, *C*) but varies in proportions, reflecting the varying functions of each region.

The *mucosa* is the most clinically important layer of the intestine. It is responsible for secretion and absorption and serves as a barrier. It comprises the epithelium and the lamina propria and is modified by gross folds and fingerlike processes, the *villi* (see Figure 222-1, *C*). Mucosal capillaries are fenestrated; in conjunction with a central villus lymphatic (*lacteal*), they carry away protein-rich tissue fluid. Loss of epithelial integrity permits leakage of the protein-rich fluid and the development of a protein-losing enteropathy (PLE). The lamina propria contains aggregates of lymphoid tissue and nonaggregated immunocytes (see Gastrointestinal Immune System).

222.1.2 Functional Anatomy

222.1.2.1 Surface Area of the Small Intestine

The surface area of the small intestine is increased almost 600-fold, compared with that of a simple tube, by folds in the mucosal wall (~3 fold), cylindrical projections into the intestinal lumen called villi (~10 fold), and microscopic microvilli on the surface of each epithelial cell (~20 fold) (see Figure 222-1). Villus atrophy or even just microvillar damage is likely to produce profound malabsorption and diarrhea.

222.1.2.1.1 Box • 222-1 Causes of Diarrhea

222.1.2.1.1.1 Gastrointestinal Disease

Primary small intestinal disease

Primary large intestinal disease

Dietary-induced causes (food poisoning, gluttony, sudden change of diet)

Gastric disease

- Achlorhydria*
- Dumping syndromes*

Pancreatic disease

- Exocrine pancreatic insufficiency
- Pancreatitis
- Pancreatic neoplasia

Liver disease

- Hepatocellular failure
- Intrahepatic and extrahepatic cholestasis

222.1.2.1.1.2

Nongastrointestinal Disease

Polysystemic infection (e.g., distemper, leptospirosis, infectious canine hepatitis in dogs; FIP, FeLV, FIV in cats)

Endocrine disease

- Hypoadrenocorticism
- Hyperthyroidism†
- Hypothyroidism
- APUDomas (gastrinoma or Zollinger-Ellison syndrome)*

Renal disease

- Uremia
- Nephrotic syndrome

Miscellaneous

- Toxemias (pyometra, peritonitis)
- Congestive heart failure
- Autoimmune disease
- Metastatic neoplasia
- Various toxins and drugs

* Rare conditions.

† Rare in dogs only.

APUD, amine precursor uptake and decarboxylation tumor

FeLV, feline leukemia virus

FIP, feline infectious peritonitis

FIV, feline immunodeficiency virus

222.1.2.1.2 Box • 222-2 Clinical Signs of Small Intestinal Disease

222.1.2.1.2.1 Primary Sign

Diarrhea (increase in frequency, volume, and consistency of bowel movements)

222.1.2.1.2.2 Secondary Signs

Vomiting

Weight loss and/or failure to thrive

Hematemesis

Melena

Altered appetite (inappetence/anorexia)

Polyphagia, coprophagia, pica

Abdominal discomfort, pain

Abdominal distension

Borborygmi and flatus

Halitosis

Dehydration

Polydipsia

Ascites and edema

Shock

222.1.2.2 Crypt-Villus Unit

A villus and its associated crypts comprise the functional unit of the small intestine (see Figure 222-1, *D*). Crypts continually produce undifferentiated epithelial cells, mainly enterocytes. After further division of daughter cells as they pass up the crypt, cells undergo a final division before differentiating into immature enterocytes.

222.1.2.3 Mucosal Epithelial Cells

The intestinal surface is covered by an epithelial cell monolayer. Enterocytes predominate, interspersed mainly with mucus-secreting goblet cells. The epithelial basement membrane is permeable to nutrients, and by expressing glycoproteins, called *laminins,* it promotes enterocyte adhesion, growth, polarization, and differentiation through interaction with integrins expressed by enterocytes.[2]

Crypt cells have a potent secretory capacity. However, as enterocytes migrate to the villus tip, maturation involves loss of secretory activity and the development of digestive and absorptive properties. The duration of migration from crypt to villus tip is 3 to 5 days in dogs and cats. The majority of enterocytes are exfoliated at the tips of the villi.

Goblet cell density in the mucosa varies, being highest in the ileum. The cells secrete protective mucus and novel trefoil peptides, which act as growth factors. Endocrine-and paracrine-secreting epithelial cells, as well as transforming growth factors α and β (TGFα) and epidermal growth factor (EGF), have important trophic activities. Receptors for EGF on the luminal and basolateral surfaces of enterocytes suggest they respond both to blood-borne EGF and to luminal EGF secreted from salivary and pancreatic tissue or delivered in milk.

222.1.2.4 Enterocytes

The *mucosal barrier* is formed by the intestinal epithelium; tight junctions encircle the lateral aspects of enterocytes, excluding antigens and bacteria. Effete enterocytes are shed from the villus tip (see Figure 222-1, D), but the integrity of the tight junctions is probably loosest in the crypts, where fluid secretion occurs.

Enterocyte function dictates normal digestion and nutrient absorption. Function depends on the polarity of the enterocyte, involving a specialized portion of the cell membrane on the luminal surface, the *microvillar membrane (MVM)*. The MVM, also called the *brush border* because of its microscopic appearance (see Fig. 222-1, *E* and *F*), consists of thousands of parallel cylindrical processes, the microvilli, bearing digestive enzymes and specific carrier proteins (see Figure 222-1, *F*). Maximum enzyme and transport activities are expressed in the midvillus region. As enterocytes migrate to the villus tip, enzymes are cleaved from the brush border by bacterial and pancreatic proteases and released into the lumen to form the succus entericus, which is thus not a true secretion.

Enterocyte metabolism is geared toward the production of brush border proteins and the transfer of nutrients from the lumen to the blood. Basolateral cell membranes export sodium from the cell via energy-dependent sodium-potassium adenosine triphosphatase (Na/K ATPase). Water can follow osmotically, or compensatory sodium influx at the luminal surface can drive carrier-mediated nutrient absorption. Natural inhibition of glycolysis in enterocytes facilitates the transfer of glucose from the lumen to the blood. Enterocytes can utilize ketone bodies, but their major energy source is glutamine. Both are derived from the lumen, which explains the decline in villus structure, epithelial integrity, and absorptive function in starvation and anorexia and therefore the clinical importance of attempting to maintain enteral nutrition.[3]

Brush border enzyme activities are variable, tending to be highest in the proximal SI and declining in an aborad gradient. Digestive enzymes, especially disaccharidases and transport proteins, may be inducible in response to the composition of the diet. This has been shown in dogs[4] but not in cats,[5] perhaps reflecting

the carnivorous nature of cats. A sudden change in diet in dogs may cause diarrhea through transient intolerance until either existing enterocytes upregulate expression of specific enzymes and carriers or new enterocytes expressing induced proteins differentiate, thus rendering the diarrhea self-limiting.

222.1.3 Digestion

Major dietary constituents must be hydrolyzed from their initial polymeric structure to monomers to be transported across the MVM. This is largely achieved in the SI by bile salts and luminal enzymes. The intestine provides the optimum environment in terms of solute, temperature, and pH. Most enzymes are secreted by the pancreas, and exocrine pancreatic insufficiency (EPI) is a major cause of malabsorption. Normally only terminal digestion is performed by MVM enzymes; the reserve capacity called into function after significant intestinal resection probably represents both increases in brush border protein expression and compensatory hypertrophy of the remaining tissue (see Short Bowel Syndrome).

Lactose is found almost exclusively in dairy products, and its hydrolysis by brush border lactase is most important in the nursing animal. At weaning, activities of lactase decline, especially in cats,[5] and animals may become lactose intolerant, although congenital lactase deficiency has not been demonstrated in dogs or cats.

222.1.4 Absorption

Digested nutrients are delivered to the body across the mucosal barrier and then via the lymphatics or bloodstream. Uptake can occur by passive diffusion or by active or facilitated carrier-mediated transport. Receptor-mediated endocytosis enables the uptake of small amounts of a specific intact nutrient, such as cobalamin. Endocytosis of small, antigenic peptides is of no nutritional significance but is crucial to the mucosal immune response.

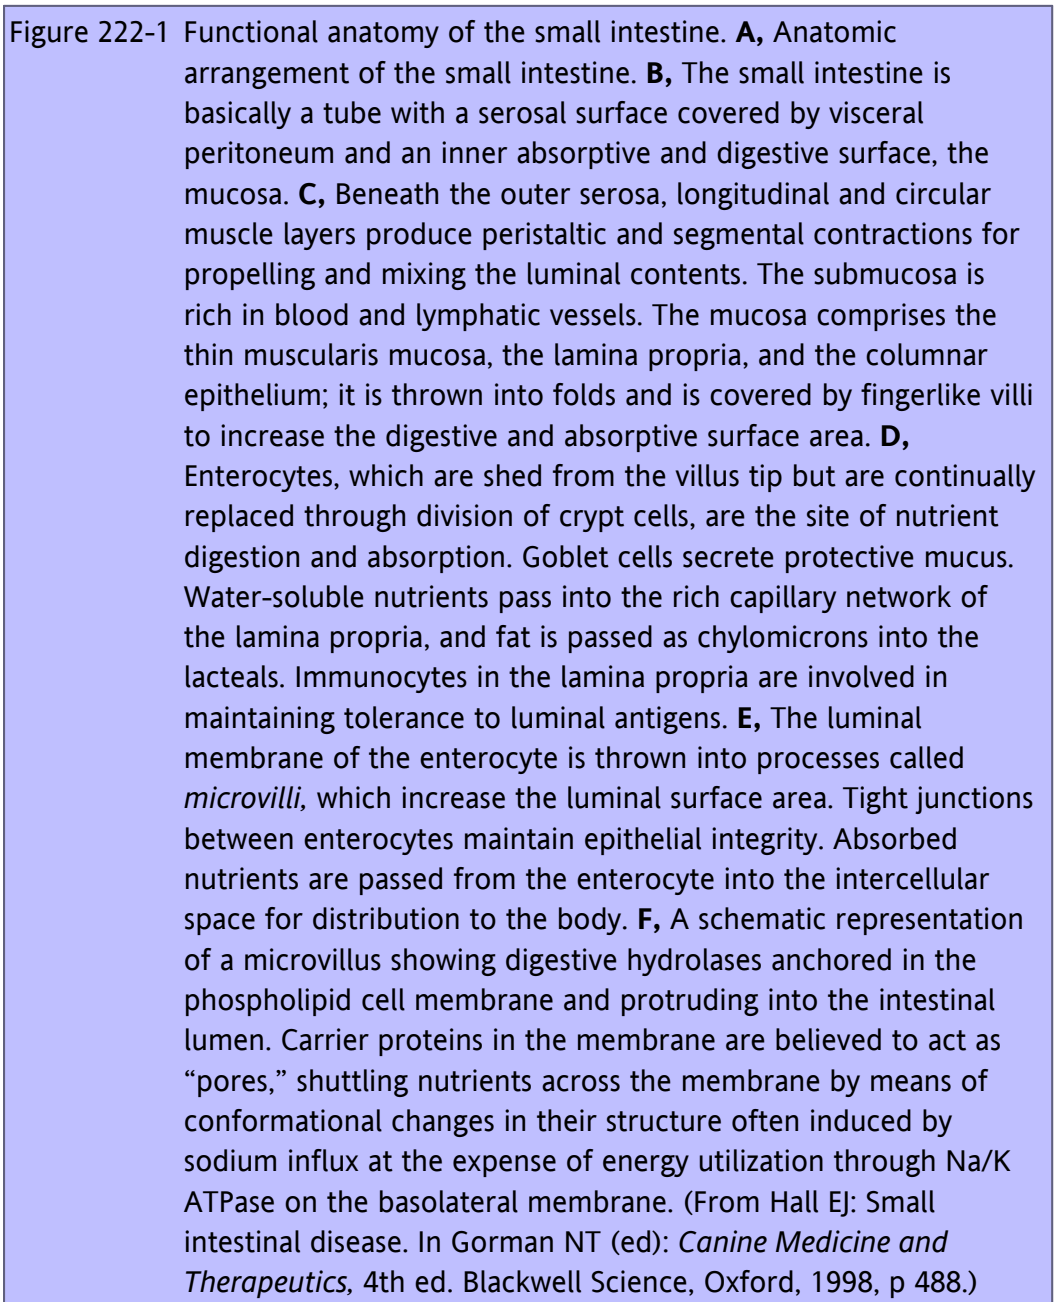

Figure 222-1 Functional anatomy of the small intestine. **A,** Anatomic arrangement of the small intestine. **B,** The small intestine is basically a tube with a serosal surface covered by visceral peritoneum and an inner absorptive and digestive surface, the mucosa. **C,** Beneath the outer serosa, longitudinal and circular muscle layers produce peristaltic and segmental contractions for propelling and mixing the luminal contents. The submucosa is rich in blood and lymphatic vessels. The mucosa comprises the thin muscularis mucosa, the lamina propria, and the columnar epithelium; it is thrown into folds and is covered by fingerlike villi to increase the digestive and absorptive surface area. **D,** Enterocytes, which are shed from the villus tip but are continually replaced through division of crypt cells, are the site of nutrient digestion and absorption. Goblet cells secrete protective mucus. Water-soluble nutrients pass into the rich capillary network of the lamina propria, and fat is passed as chylomicrons into the lacteals. Immunocytes in the lamina propria are involved in maintaining tolerance to luminal antigens. **E,** The luminal membrane of the enterocyte is thrown into processes called *microvilli,* which increase the luminal surface area. Tight junctions between enterocytes maintain epithelial integrity. Absorbed nutrients are passed from the enterocyte into the intercellular space for distribution to the body. **F,** A schematic representation of a microvillus showing digestive hydrolases anchored in the phospholipid cell membrane and protruding into the intestinal lumen. Carrier proteins in the membrane are believed to act as "pores," shuttling nutrients across the membrane by means of conformational changes in their structure often induced by sodium influx at the expense of energy utilization through Na/K ATPase on the basolateral membrane. 222.1.4.1 Carbohydrate Absorption

Glucose is transported across the MVM with energy expenditure by the basolateral Na/K ATPase on the sodium-glucose cotransporter protein SGLT 1. The glucose transporter GLUT 5 on the MVM allows facilitated diffusion of fructose and D-xylose. Fructose uptake in cats is low, which perhaps explains why the xylose absorption test is unhelpful in cats. GLUT 2 on the basolateral membrane of enterocytes shuttles glucose, galactose, and fructose out of the enterocyte by facilitated diffusion.

222.1.4.2 Protein Absorption

L-amino acids are absorbed on stereo-specific carriers by sodium-linked active transport.

222.1.4.3 Lipid Absorption

The products of fat digestion are absorbed by passive diffusion from mixed micelles. The limiting factor, assuming normal pancreatic function, is the intestinal surface area, and villus atrophy is likely to cause fat malabsorption.

222.1.4.4 Fat-Soluble Vitamins

Vitamins A, D, E, and K are solubilized in mixed micelles before passive diffusion across the brush border. Fat malabsorption associated with inadequate amounts of bile salts (i.e., biliary obstruction), lymphangiectasia, or severe villus atrophy may result in vitamin deficiency.

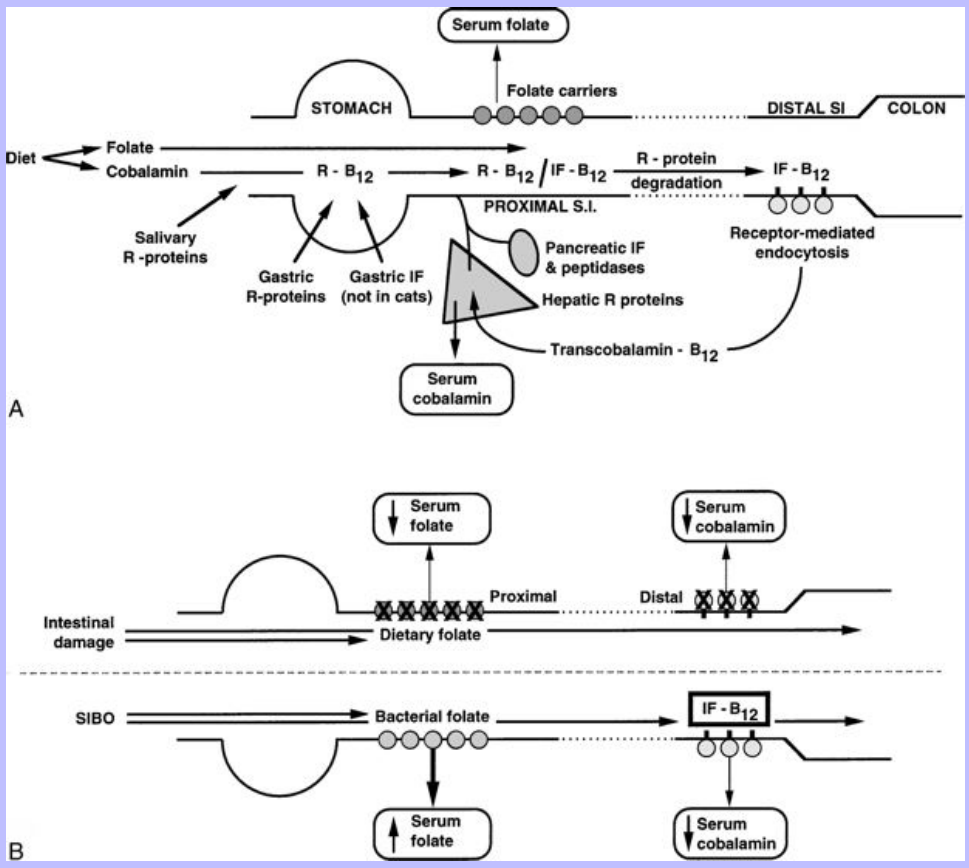
222.1.4.5 Water-Soluble Vitamins

Water-soluble B vitamins are absorbed by a variety of passive, facilitated, and active mechanisms. The absorptive mechanisms for folic acid and vitamin B_{12} are complex (Figure 222-3, *A*) and important clinically because they may be helpful in determining the site and nature of the intestinal disease (Figure 222-3, *B*).

Folic acid is absorbed in the proximal SI through a carrier-mediated process at low luminal concentrations. 1335

Cobalamin (vitamin B_{12}) is absorbed by means of receptor-mediated endocytosis in the ileum, in a complex process that permits intact cobalamin absorption and exclusion of potentially harmful analogs. Intrinsic factor (IF) promotes cobalamin absorption in the ileum; IF-bound cobalamin passes to the ileum, where the complex binds specific receptors and undergoes endocytosis. The source of IF is the stomach and pancreas in dogs and solely the pancreas in cats.[6,7] Cats and dogs have less capacity to store cobalamin than do humans, and severe cobalamin malabsorption can deplete the vitamin's stores in cats and dogs within a month. 1336

Figure 222-3 Diagrammatic representation of the absorption of folate and cobalamin. **A,** In normal intestine, folate is absorbed in the proximal SI by means of carrier-mediated diffusion, and cobalamin is absorbed in the ileum through receptor-mediated endocytosis. **B,** In diseased intestine, proximal and distal mucosal damage causes folate and cobalamin malabsorption, respectively; bacterial overgrowth may cause an increase in folate uptake because of bacterial folate synthesis and a decrease in cobalamin uptake because of bacterial binding.



222.1.5 Intestinal Motility

Slow wave motion and segmental and peristaltic contractions of the SI are generated by the co-ordinated contraction of smooth muscle in response to spontaneous electrical activity modulated by co-ordinated neurohumoral and neurochemical molecules.[8] Many of these neurohumoral and neurochemical molecules are also involved in the regulation of intestinal secretion and absorption and the mucosal immune response.[9]

Intestinal motility in the fasted state in dogs is characterized by three phases. A cycle comprising a quiescent phase (lasting about 1 hour), minor contractile activity (15 to 40 minutes), and migrating myoelectric complexes (MMCs) (4 to 8 minutes) is repeated approximately every 3 hours.[10] The short MMC phase is a period of intense contractile activity that sweeps undigested food, secretions, desquamated cells, and bacteria down the intestine. This process is known as the "intestinal housekeeper" wave and is induced by motilin secretion. The pattern of intestinal motility in cats is different, but a migrating spike complex correlates with the MMC.

In the fed state, the pattern of motility is most similar to phase two fasting motility. Its duration is determined by the nature of the diet, with fats and fiber prolonging it. Segmental contractions slow intestinal transit and ensure mixing and digestion of nutrients, and peristalsis propels ingesta. Reduced segmental motility may lead to rapid transit, and decreased peristalsis delays transit, conditions manifesting clinically as diarrhea and ileus, respectively.

222.1.6 Fluid Balance

The ability of the intestine to absorb fluid and electrolytes varies according to the site, with water absorption becoming increasingly efficient distally. The net amount of fluid and electrolytes in the GI tract reflects a balance between absorption and secretion, with net absorption in health.

1336

1337

222.1.6.1 Intestinal Secretion

Intestinal secretion, a function of villus crypt cells, is believed to occur by electrogenic transport of chloride across the basolateral membrane into the enterocyte and by chloride efflux through chloride channels in the MVM. Passive flux of water follows chloride secretion into the intestinal lumen.

222.1.6.2 Absorption

In a 20-kg dog, approximately 2.7L of fluid (oral intake, stomach juice, saliva, pancreatic juice, bile, and SI secretion) is presented to the SI each day. The jejunum absorbs 50%, the ileum, 75%, and the colon, 90% of the fluid volume presented to it, leaving 0.05 L in feces.[11] This gradient in absorptive ability is a function of enterocyte pore size, membrane potential difference, and the type of transport processes associated with each intestinal segment.[12] The site of the enterocyte on the villus is also important; villus enterocytes absorb, whereas crypt cells secrete.

The absorption of water is passive and follows transport of solutes across the GI epithelium by one of three processes: passive absorption, active absorption, or solvent drag.

222.1.6.2.1 Jejunum

Because the jejunum is highly permeable, passive transport provides the major contribution to sodium (Na) and chloride (Cl) movement in this segment.

222.1.6.2.2 Ileum

In the ileum, sodium is absorbed predominantly through neutral NaCl absorption.

222.1.6.2.3 Colon

Colonic absorption is important in SI disease, because it compensates for fluid losses. Furthermore, patients with SI disease may present with signs of large intestinal (LI) dysfunction, because the colonic reserve capacity may be overwhelmed. In addition, products from the SI, such as hydroxylated fatty acids and deconjugated bile acids, stimulate colonic secretion.

222.1.6.3 Control of the Absorption and Secretion of Water and Electrolytes

Fluid balance is largely an autonomous process regulated by the neurocrine systems in the submucosal plexus.[12] Vasoactive intestinal polypeptide (VIP) and acetylcholine are major mediators of secretion; at the cellular level they increase intracellular calcium and cyclic adenosine monophosphate (cAMP), inhibit neutral sodium and chloride absorption, and facilitate transcellular chloride efflux. Many bacterial agents exert diarrheogenic effects by increasing intraenterocytic cAMP. The principal regulators of absorption—noradrenaline, somatostatin, and opioids—lower intracellular cAMP and calcium concentrations and stimulate neutral NaCl absorption and thereby can have therapeutic antidiarrheal effects.

222.1.7 Bacterial Flora

The normal SI bacterial flora is a diverse mixture of aerobic, anaerobic, and facultatively anaerobic bacteria. Common aerobes include *Staphylococcus* spp., *Streptococcus* spp., Enterobacteriaceae, *Escherichia coli, Bacillus* spp., *Proteus* spp., *Pasteurella* spp., *Corynebacterium* spp., *Lactobacillus* spp., and *Enterococcus* spp. Frequent anaerobes are *Clostridium* spp. and *Bacteroides* spp.

The flora increases in number from duodenum to colon. Factors maintaining this aboral gradient are luminal patency, motility, substrate availability, bacteriostatic and bacteriocidal secretions (e.g., gastric acid, bile, and pancreatic secretions), and an intact ileocolic valve. Abnormalities or dysfunction of any of these factors may lead to quantitative or qualitative abnormalities in the flora.

Quantitative bacteriology performed on samples of undiluted intestinal juice has revealed bacterial counts in healthy cats range from 10^2 to 10^8 colony-forming units (CFU) per milliliter of total bacteria in the proximal small intestine.[13,14] These numbers are considerably higher than the less than 10^5 CFU/mL reported in healthy humans and subsequently extrapolated to dogs. However, no consensus exists as to what constitutes a normal SI flora count in healthy dogs; some studies suggest that the proximal SI of healthy dogs can harbor up to 10^9 CFU/mL total bacteria.[15] Therefore the cutoff for normal flora in dogs and cats cannot be extrapolated from humans, and descriptions of small intestinal bacterial overgrowth (SIBO) in dogs using the cutoff value of 10^5 may be spurious.[15]

The resident bacterial flora is an integral part of the healthy SI and influences a wide variety of parameters, such as villus size, enterocyte turnover, brush border enzyme turnover, and intestinal motility. The digestion and assimilation of fats, carbohydrates, proteins, amino acids (e.g., taurine), and vitamins (e.g., cobalamin and folate) are also affected by bacteria.

The presence of a stable enteric flora is important for preventing colonization by pathogens; it also stimulates the development of the enteric immune system. The host response to a bacterium is likely to be as important as

the intrinsic pathogenicity of the organism. Loss of tolerance to the normal bacterial flora may precipitate intestinal inflammation, abnormal intestinal function, and perhaps even neoplasia. Inability to tolerate a normal bacterial flora may explain antibiotic-responsive enteropathy in German shepherd dogs (see Small Intestinal Bacterial Overgrowth).

The SI flora is relatively resistant to dietary changes. Studies using different diets or the addition of fructo-oligosaccharides to the diet have failed to demonstrate significant effects on the number or type of bacteria in the proximal SI of dogs,[16,17] but some effects have been seen on the colonic flora in cats.[18] Given the intimate inter-relationship of a healthy intestine with its flora, indiscriminate use of anti-biotics in dogs and cats with diarrhea or gastroenteritis is ill-advised and may enhance antibiotic resistance. Although the consequences of inappropriate antibiotic therapy are often mild and self-limiting, postantibiotic salmonellosis has had fatal consequences in cats.[19]

222.1.8 ## Gastrointestinal Immune System

The SI mucosa has a general barrier function (Box 222-3); however, it must also generate a protective immune response against pathogens while remaining "tolerant" of harmless environmental antigens such as commensal bacteria and food. Despite recent advances in our understanding of the structure of and interactions in the immune system, it is still unclear what prompts the SI to respond to or to become tolerant of a particular antigen.

Mucosal-associated lymphoid tissue

222.1.8.2 Structure of the Mucosal Immune System

The gut-associated lymphoid tissue (GALT) consists of inductive and effector sites.[20] Inductive sites comprise Peyer's patches (PPs), isolated lymphoid follicles, and the mesenteric lymph nodes (MLNs); effector sites comprise the intestinal lamina propria (LP) and epithelium. Such a distinction is not absolute, however, and the functions of these different sites overlap.

The PPs are the main sites of induction of the immune response and may also function as sites of B-lymphocyte development. The PP consists of an overlying follicle-associated epithelium (FAE), a subepithelial dome (SED), multiple B-cell follicles, and interfollicular regions. Within the FAE is a specialized population of antigen transport cells (microfold cells or M cells), which act as portals through which the underlying immune cells receive antigen. The MLNs receive afferent lymph from the intestine and are also important in the generation of immune responses.

The LP consists of a matrix of connective tissue with a prominent immune cell component. A large leukocyte population, composed principally of lymphocytes (intraepithelial lymphocytes [IELs]), also exists between enterocytes. Accumulating evidence indicates that *cross-talk* (two-way immunoregulatory signals mediated by cytokines and adhesion molecules) occurs between IELs and enterocytes.[21]

222.1.8.3 Cells and Molecules of the Mucosal Immune System

222.1.8.3.1 Lymphocytes

B lymphocytes are present in the Peyer's patches and the lamina propria. In the PPs they are found predominantly in follicular regions. In the LP, B cells are largely represented by plasma cells, mostly of the IgA isotype. Most plasma cells are present around the intestinal crypts, and the numbers vary along the length of the small intestine.[22]

In the SI, most *T lymphocytes* are of the conventional alpha/beta type.[23] An evolutionarily older (gamma/delta) T-cell population also exists and is considered a primitive first-line defense.[23] T lymphocytes can be further subdivided on the basis of expression of cell surface markers, in particular CD4 and CD8 molecules. CD4+ T cells (classical “helper” T cells) recognize antigenic peptide presented by major histocompatibility complex class II (MHC II) molecules, whereas CD8+ T cells (usually cytotoxic cells) are MHC class I restricted.

In the canine LP, T cells are most numerous in the upper villus regions and are mostly the alpha/beta, CD4+ phenotype.[22–24] However, in the feline LP, CD8+ T cells outnumber the CD4+ population.[25] Most LP lymphocytes are highly differentiated, which implies that they receive continuous antigenic and mitogenic stimulation, probably from the endogenous microbial flora.

The T cells in the intestinal epithelium (i.e., IELs) are a heterogeneous population; most are CD8+ cells, which may be of either the alpha/beta or the gamma/delta phenotype, depending on the species. Known functions of IELs include cytolytic activity and cytokine production, which suggests that these cells play roles in epithelial surveillance and the maintenance of mucosal immune homeostasis.

222.1.8.3.2

Dendritic cells

Dendritic cells (DCs) function predominantly as antigen-presenting cells and can be found in both inductive (PP) and effector (LP) tissues. In effector tissues their main function is antigen sampling, whereas in inductive sites they are responsible for generating acquired immune responses. Follicular dendritic cells (FDCs) are a unique population of cells[26] that take up and store antigen to provide continued stimulation to memory B cells. Immature DCs can efficiently acquire and process antigen but cannot present it or initiate immune responses.[27] Conversely, mature DCs cannot take up or process antigen but are efficient at antigen presentation and lymphocyte stimulation.[27]

222.1.8.3.3

Other immune cells

Macrophages are present in the PP and LP. Their functions include phagocytosis, antigen presentation, and immunoregulatory roles. They secrete cytokines, chemokines, and inflammatory mediators, including tumor necrosis factor-α (TNF-α), eicosanoids, and leukotrienes. Neutrophils are present in small numbers, although their numbers increase with mucosal inflammation. Both mast cells (MCs) and eosinophils can be found in the LP; they also actively produce chemical mediators (e.g., histamine, heparin, eicosanoids, and cytokines). Mast cells express the high-affinity IgE receptor (FceRI), which can bind IgE, causing MC degranulation and release of inflammatory mediators.[28] In dogs, eosinophils are a prominent population in the LP, especially in the crypts. Eosinophils[22] may have proinflammatory roles, especially in allergic processes, because they are a rich source of proinflammatory mediators, cytokines, and chemokines.[28] Triangular cross-talk may occur among eosinophils, MCs, and T cells.

222.1.8.3.4

Enterocytes

In addition to absorptive functions, enterocytes have important immune functions. First, they are an important component of the mucosal barrier, controlling uptake of antigens. Second, they may be capable of antigen presentation, through expression of MHC II and nonclassical antigen-presenting molecules. In dogs, MHC II is expressed by enterocytes, most abundantly in crypt epithelium.[29] In contrast, MHC II is largely absent from the intestinal epithelium of cats, except in regions adjacent to Peyer's patches.[25] Third, enterocytes can produce inflammatory mediators, chemokines, and cytokines and may regulate immune responses in both epithelial and LP compartments. Cross-talk between enterocytes and IELs may also occur through cell to cell interactions (e.g., between E-cadherin expressed on the enterocyte and the integrin $alpha_{\varepsilon}/beta_{7}$, expressed by IEL).[30]

222.1.8.3.5

Enteric neurons

The SI also contains a well-developed nervous system with extensive ramification in both inductive and effector sites.[31] These neurons can release immunoactive neuropeptides (including substance P and VIP), which can cause *neurogenic* inflammation. Bidirectional communication may also exist, in which release of mediators by immune cells (e.g., mast cells) can generate axon reflexes and thereby perhaps modulate intestinal motility, secretion, and absorption.

222.1.8.3.6

Cytokines

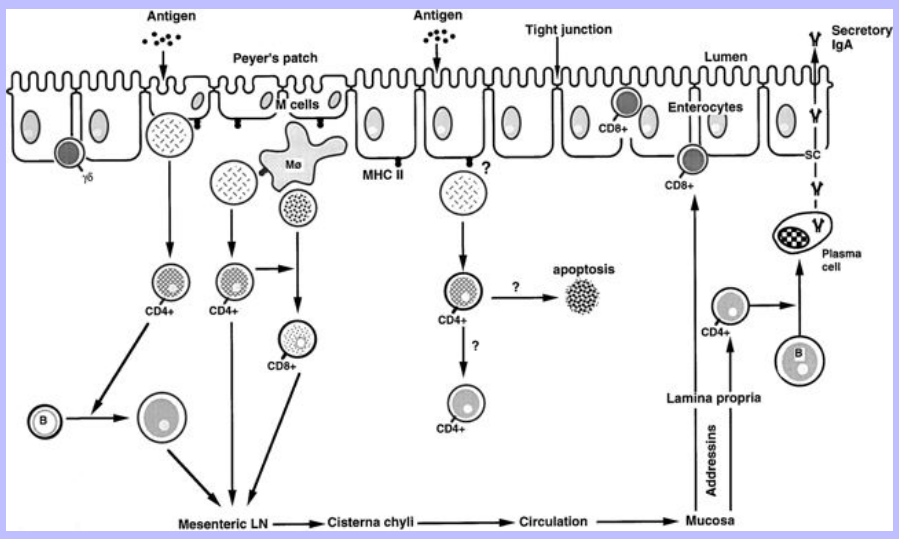
A large array of cytokines is present in the SI, and these cells can be grouped into proinflammatory, immunoregulatory, and chemokinetic types.[32] CD4+ T cells are a major cytokine-producing cell population. Different CD4+ T-cell populations have different patterns of cytokine secretion and can differentially regulate distinct arms of the immune system (e.g., humoral and cell mediated). *In vitro,* two principal populations of CD4+ T cells exist: a T helper 1 (Th1) population (which produces interleukin-2 [IL-2], interferon-γ [IFN-γ], and TNF-β), and a T helper 2 (Th2) population (which produces IL-4, IL-5, IL-6 and IL-10).[33] Other populations with downregulatory functions also have been identified, which predominantly secrete TGF-β or IL-10.[34] Many other cell types also may produce cytokines (see above) and, consequently, an overall cytokine "milieu," which determines the predominant type of immune response that develops, is created.

222.1.8.4

Homing of Lymphocytes in Gut-Associated Lymphoid Tissue

To mount an effective immune response, lymphocytes must traffic between the inductive and the effector sites. Such homing pathways are mediated by complex leukocyte-endothelial interactions. Those governing 1338
recirculation to mucosal tissues are distinct from systemic tissues,[35] because differential expression of 1339
homing receptors (addressins) determines the specificity of homing. Virtually all naïve mucosal lymphocytes can home to the PPs, MLNs, and other nodes in the body. In contrast, mucosal memory lymphocytes home preferentially to effector sites in the GALT.

Figure 222-4 Diagrammatic representation of the mucosal-associated lymphoid tissue, showing M cells in a Peyer's patch sampling luminal antigen, presentation of the antigen to the associated lymphoid tissue, priming of B and T cells, and their circulation to the lamina propria, with subsequent IgA secretion.



Tissue migration of cells from the blood vessel is a multistage process involving a number of molecular interactions. The most important interaction for mucosal lymphocytes occurs between $alpha_4$/$beta_7$ on the lymphocyte and mucosal addressin cell adhesion molecule-1 (MAdCAM-1) on the endothelial cell.[23]

Inflammation causes increased activation of both lymphocytes and endothelial cells, which alters the expression of both homing receptors and vascular addressins. Enhanced expression of MAdCAM-1 leads to increased recruitment of specific mucosal lymphocytes, whereas expression of other vascular addressins (e.g., E-selectin, P-selectin and peripheral node addressin) can lead to recruitment of a broader range of lymphocyte specificities.[36]

A final factor important to the homing of lymphocytes is the chemokines and their receptors.[37] Because chemokine receptors can be selectively expressed on different CD4+ T cell subsets (Th1 versus Th2), the chemokine milieu of a particular tissue determines which T-helper cell types (and which other immune cell subsets) are recruited.

222.1.8.5 Acquired Immune Responses of Gut-Associated Lymphoid Tissue

Acquired immune responses develop after a series of steps involving antigen uptake, presentation to naïve lymphocytes, costimulation by helper cells, clonal expansion, homing to effector sites, and performance of effector functions. The specific mechanisms involved are described in detail elsewhere.[38]

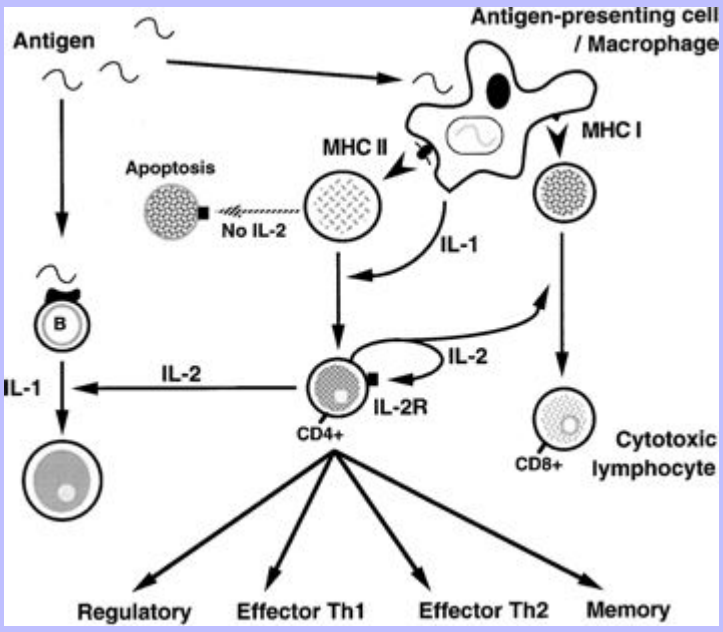
222.1.8.5.1 Antigen uptake and presentation

Most antigen uptake occurs through the M cells of the Peyer's patches; the antigen then is transported to macrophages and dendritic cells in the subepithelial dome (Figure 222-4). Macrophages and DCs act as antigen-presenting cells (APCs), presenting antigen, in the context of MHC II molecules, to lymphocytes (Figure 222-5). Enterocytes may also be capable of taking up antigen and presenting it to T cells.

1339

1340

Figure 222-5 Activation of mucosal CD4+ T cells by antigen presentation in association with major histocompatibility complex (MHC) class II molecules; the result is either clonal expansion into memory and effector cells or apoptosis, depending on the synthesis of interleukin-2 receptor (IL-2R) and IL-2. CD8+ T cells are activated by antigen presentation in association with MHC class I molecules and, under the influence of CD4+ T cell–derived cytokines, develop into intraepithelial lymphocytes. γδT cells also form a part of the intraepithelial cell compartment.



222.1.8.5.2 B-cell responses

The primary function of the B lymphoid lineage is generation of humoral immune responses, and the synthesis of IgA predominates in the intestinal mucosa. In the PP follicles, antigen on the surface of DCs stimulates B cells through the B-cell receptors (secretory immunoglobulin M [sIgM] and immunoglobulin D [IgD]). Costimulation to B cells is provided by CD4+ T cells, which enables the B cells to undergo clonal expansion. During the process of B-cell development, a switch occurs such that the effector cells are capable of producing a single immunoglobulin class (e.g., IgG, IgE, and IgA). The switching process is assisted by CD4 T-helper cells, which produce cytokines such as TGF-β, IL-4, and IFN-γ (for IgA, IgE, and IgG switching, respectively).

After class switching, B cells undergo further expansion and then traffic to effector sites to differentiate terminally into plasma cells. After synthesis, IgA (and to a lesser extent IgM) is released and then

transported into the intestinal lumen by the polymeric immunoglobulin receptor (pIgR) on the enterocytes.[39] This complex passes through the enterocyte and is delivered across the microvillar membrane. On the luminal surface, the extracellular fragment of the pIgR is cleaved, forming *secretory component* (*SC*), which associates with pIgA and protects it from degradation in the intestinal lumen. The main function of sIgA is immune exclusion; that is, to bind its respective antigen and neutralize it. Immune exclusion limits the amount of antigen absorbed into the intestinal mucosa and thus the amount available to stimulate active immune responses. This helps maintain tolerance (see below) and protects the mucosa from antigen invasion.

Responses to parasites also occur through generation of antigen-specific plasma cells. These cells, found in the mesenteric lymph nodes, produce IgE that binds to the FcεRI on mucosal mast cells. When subsequently exposed to antigen, MC degranulation occurs and the associated parasite is expelled. Inappropriate IgE responses to food antigens also can be generated, providing a potential mechanism for food allergy.

222.1.8.5.3 Cytotoxic lymphocyte responses

Cytotoxic lymphocyte (CTL) responses are present in the SI mucosa, and their main function is to remove tumor cells or cells infected with intracellular bacteria, viruses, or parasites. CD8+ alpha/beta T cells, the main cytotoxic cells, are generated in a manner similar to B cells except that the former are found in interfollicular regions. Again, help is provided by CD4+ T cells, under the influence of cytokines such as IFN-γ. CD4+ cells themselves can participate in cytotoxicity, and γ/δ IELs may also be cytotoxic.

222.1.8.6 Mucosal Tolerance

The above descriptions relate to specific immune responses to pathogens, but such responses are the exception rather than the rule, and the default mucosal response to antigens is tolerance. This is not surprising, given that the majority of luminal antigens are derived from innocent dietary components or endogenous microflora. Generation of active immune responses to such ubiquitous molecules is both wasteful and potentially harmful, because it could lead to uncontrolled inflammation. Although the mechanisms by which mucosal tolerance actually occurs have been well characterized, the fundamental question of what prompts GALT tolerance or an immune response remains unresolved.

Mucosal tolerance can result either from anergy/deletion (apoptosis) of antigen-specific T cells or from active suppression by antigen-specific suppressor cells (secreting downregulatory cytokines, including IL-10 and TGF-β).[40]

The CD4+ α/β T-cell subsets that mediate active suppression either produce downregulatory cytokines (e.g., TGF-β or IL-10)[34,40] or achieve their effect through cell to cell interactions (e.g., through CD25+, IL-2 receptor). However, any cell capable of producing similar cytokine profiles could play a role and therefore tolerance could arise from the effects of CD8+ T cells, macrophages, stromal cells, and enterocytes. Furthermore, because TGF-β and IL-10 are also important in IgA production, generation of mucosal tolerance potentially could occur in parallel to specific IgA responses, which help to maintain tolerance through immune exclusion.

222.1.8.7 Mucosal Immune System Response or Tolerance

As mentioned previously, the mucosal immune system is prompted either to generate specific immune responses (e.g., toward a pathogen) or to remain tolerant (e.g., to commensal bacteria or food components). The best current hypothesis for the determination of which effect occurs is the "danger theory,"[41] which is based on the supposition that the type of response depends on the context in which the antigen is presented.

The normal intestinal mucosa has an intact mucosal barrier and an environment dominated by downregulatory cytokines (e.g., IL-10 and TGF-β). Therefore most immune responses that develop are tolerance responses. Furthermore, the same cytokine milieu encourages IgA responses, which limit mucosal antigen exposure through immune exclusion.

However, when the mucosa is invaded by a pathogen or toxin, cell damage leads to the release of "danger signals," such as inflammatory mediators (e.g., prostaglandins, leukotrienes), proinflammatory cytokines (e.g., IL-1, IL-6, and TNF-α), and chemokines (e.g., IL-8). In this altered environment, the nature of the immune response generated changes from tolerance to an active immune response. This active response can be either Th1 dominated (e.g., cytotoxicity and IgG responses) or Th2 dominated (i.e., IGE responses). The powerful responses that develop aim to eliminate the pathogen completely, but the potential for bystander damage to host cells is great.

If the antigenic challenge is contained, the danger signals diminish, the mucosa enters a repair phase, and the normal "tolerogenic" environment returns. However, if the danger persists, either because the mucosal barrier remains breached and the pathogenic insult continues unabated or because of an inherent abnormality in the GALT, a state of chronic inflammation ensues. This may also lead to a breakdown in tolerance to harmless environmental antigens (food components and commensal bacteria) and inflammation. Chronic inflammation ultimately leads to histopathologic changes, which are similar regardless of the inciting cause.

222.2 PATHOPHYSIOLOGIC MECHANISMS IN INTESTINAL DISEASE

222.2.1 Motility Disorders

Alterations of intestinal motility as a primary cause of diarrhea have not yet been well characterized.[42] Irritable bowel syndrome may be associated with altered intestinal motility (see below). Secondary alterations in motility often occur, such as with intestinal obstruction, pseudo-obstruction, adynamic ileus, or inflammatory or infectious enteropathies. In malabsorption conditions, unabsorbed solutes decrease transit time because osmotically retained fluid causes intestinal distension and hypermotility. Hyperthyroidism decreases transit time in cats and causes diarrhea. Rapid waves of contractions have been demonstrated in enterotoxigenic diarrhea.

However, in most instances diarrhea is actually associated with intestinal hypomotility. Abnormal dilatation of the intestine caused by hypomotility or obstruction is known as *ileus*. *Adynamic ileus* is a transient and reversible functional obstruction of the intestine with a number of causes (Box 222-4). In enteric viral infections, for example, ileus is common, promoting diarrhea by stasis, which allows bacterial fermentation. Hypomotility and constipation are expected with hypothyroidism, but occasionally antibiotic-responsive diarrhea is found.[43]

Inflammatory causes

Peritonitis

Pancreatitis

Parvovirus

222.2.2 Luminal Disturbances

Lack of pancreatic enzymes in EPI or increased destruction of enzymes by acid hypersecretion (e.g., Zollinger-Ellison syndrome) or SIBO results in failure of digestion. Bacteria may also compete for nutrients (e.g., binding of cobalamin in SIBO).

Interruption of enterohepatic circulation and lack of bile salt micelles result in fat malabsorption and can be caused by portosystemic shunting, intrahepatic or extrahepatic cholestasis, bacterial deconjugation of bile salts

in the gut lumen, or ileal disease. Surgical resection of the ileum (e.g., with ileocolic intussusception) and inflammatory bowel disease (IBD) affecting the distal SI cause both bile salt and cobalamin malabsorption.

222.2.3 Villus Atrophy

Villus atrophy causes loss of intestinal surface area and results in malabsorption of fat. Also, carrier-mediated uptake is rate limited, because there is a finite number of nutrient transporters. Villus atrophy results in a loss of carriers critical to carbohydrate and protein digestion.

Atrophy is caused either by a decrease in the production of enterocytes or an increase in the rate of enterocyte loss. Infectious agents that damage enterocytes may infect the villus tip (e.g., rotavirus) or midvillus (e.g., coronavirus), causing cell loss and a mild to moderate diarrhea. Destruction of crypt cells (e.g., parvovirus infection) causes loss of enterocyte production, complete villus collapse, and severe diarrhea.

A persistently increased rate of enterocyte loss through immune-mediated mechanisms results in a compensatory increase in the crypt cell proliferation rate, and if the cell loss is matched by the increased proliferation, villus height does not decrease. However, a significant effect still is exerted on the digestive and absorptive ability of the SI, because prematurely lost mature enterocytes are replaced by immature, suboptimally functioning enterocytes. If enterocyte loss outpaces increased proliferation, villus atrophy results. If the initiating cause can be removed, villus atrophy is completely reversible. Cytotoxic drugs (e.g., vincristine) and parvovirus infection (which cause crypt arrest and destruction, respectively) can be devastating, causing complete villus and crypt collapse. However, assuming some stem cells survive the insult, regeneration is possible, although it is likely to take several days.

222.2.4 Enteroctye Dysfunction

Even if enterocytes are only damaged, the loss of brush border proteins still is often clinically important. Interference with enterocyte function can occur without histologic damage through the action of various bacterial secretions. Malnutrition and ischemia also impair function and increase epithelial permeability.

222.2.5 Microvillar Membrane Damage

The MVM is clearly damaged when overt histologic villus damage can be seen, but even without light microscopic changes, massive impairment of mucosal function can occur if the microvilli are damaged. Such damage is seen with enteropathogenic *Escherichia coli* infection or lectins, which cause a loss of surface area and brush border enzymes and carriers. Bacterial overgrowth is associated with subtle but specific damage to the membrane. Obligate anaerobes are very effective at degrading membrane glycoproteins or releasing brush border enzymes.[44]

222.2.6 Brush Border Membrane Disease

Primary brush border membrane diseases are biochemical abnormalities that occur in the absence of histologic damage. They are well characterized in humans, but equivalent defects in dogs and cats have rarely been demonstrated. Relative lactase deficiency does occur in dogs and particularly in cats.[5] Defects in ileal cobalamin–intrinsic factor complex uptake have been documented in giant schnauzers, collies, and beagles, resulting in cobalamin deficiency with consequent methyl-malonic aciduria.[45] Clinical signs include inappetence, failure to thrive, neutropenia, and anemia.

222.2.7 Mucosal Barrier Disruption

The mucosal barrier is crucial in maintaining oral tolerance and excluding pathogens. In animal models, malnutrition results in villus atrophy with increased transepithelial macromolecular absorption, abnormal mucin, and reduced IgA secretion.[46]

In the N-cadherin dominant negative chimaeric mouse, intestinal inflammation is restricted to regions of the gut where the mutant gene is expressed and consequently where epithelial integrity is disrupted because of a lack of expression of E-cadherin.[47]

Natural causes of decreased barrier function include luminal aggressive factors and endogenous inflammatory mediators such as IFN-γ (Box 222-5). Barrier damage may lead to entry of antigens, subsequent allergic and/or inflammatory reactions, and even translocation of bacteria into the circulation. Leakage of protein-rich tissue fluid in the opposite direction is also of clinical significance, causing a protein-losing enteropathy (PLE).

222.2.8 Hypersensitivity

Sensitization of a patient to a dietary antigen may provoke an IgE-mediated allergic reaction when the animal is next exposed. The release of numerous mast cell mediators (e.g., histamine, serotonin, heparin, interleukins) may have remote effects (e.g., pruritus, urticaria) and even generalized systemic effects (anaphylaxis). Mast cell mediators also have local effects on the intestine, acting directly on epithelium, muscle, and endothelium and indirectly through fibroblast and nerve activity.[48] They induce rapid changes in absorption and secretion, mucus secretion, epithelial and endothelial permeability, and gut motility, causing vomiting and diarrhea.

222.2.9 Mucosal Inflammation

Inflammation is a cellular and vascular response to a number of inciting causes, including infection, ischemia, trauma, toxins, neoplasia, and immune-mediated reactions. The normal mucosa is continually bombarded by a vast array of antigens derived from endogenous bacteria and food components and can be considered to be in a state of "controlled inflammation." Anything that overloads this system is likely to trigger uncontrolled inflammation.

Experimental models of gastrointestinal inflammation have allowed researchers to understand better the pathogenesis of mucosal inflammation and the mechanisms that trigger it (Table 222-1). These genetically engineered rodents have a variety of spontaneously arising or induced disruptions of the mucosal immune system that lead to chronic inflammation, the end results of which are histologically similar. The disruptions usually are induced in one of three ways: through disruption of the mucosal barrier (e.g., the N-cadherin dominant negative chimaeric mouse)[47]; through dysregulation of the mucosal immune system; or through disruption of the endogenous microflora. Disruption of the mucosal immune system, either through targeted deletion of cytokines (e.g., IL-2, IL-10, or TGF-β knockout mice) or through abnormalities in the CD4+ T-cell compartment, results in dysregulated immune responses and, consequently, uncontrolled mucosal inflammation.[49] Extracellular proteolysis by matrix metalloproteinases is critical in the pathogenesis of IBD in humans.[50]

Either mucosal barrier disruption or immune system dysregulation (or both) is required for the development of uncontrolled inflammation; however, the presence of an enteric flora is essential for expression of disease. In this regard, chronic intestinal inflammation generally does not develop when the rodent in these model systems is reared in a germ-free environment.[49] This demonstrates the importance of the endogenous flora in the pathogenesis of uncontrolled mucosal inflammation, as confirmed by studies showing that normal humans are tolerant to their own intestinal microflora but that this tolerance is broken in patients with IBD.[51]

Table • 222-1 Experimental Rodent Models of Chronic Intestinal Inflammation

CD, cluster of differentiation; IL, interleukin; HLA, human leukocyte antigen; MHC, major histocompatibility complex; SCID, severe combined immunodeficiency; TCR, T cell receptor; TGF, transforming growth factor.

222.2.10 Neoplasia

Solitary tumors can cause diarrhea, probably through the effects of partial obstruction, stasis of ingesta, and secondary bacterial overgrowth. More typically the tumor is associated with such signs as intestinal obstruction (i.e., vomiting, abdominal pain, absence of feces), bleeding, and cancer-associated anorexia. Mast cell tumors may cause duodenal perforation and peritonitis through histamine-mediated gastric acid hypersecretion. *1342*

1343

Diffuse tumors, such as lymphoma, that infiltrate the mucosa cause diarrhea. Malignant cells may simply obstruct blood and lymphatic flow, but enterocyte function is likely to be impaired or the mucosa may be ulcerated.

222.2.1.1 Nutrient Delivery Failure

After absorption nutrients are delivered to the body via blood and lymph; only lymphatic diseases are described in animals. Primary lymphatic obstruction (lymphangiectasia) that causes malabsorption may be idiopathic or may be associated with lymphangitis. Secondary lymphangiectasia is seen with lymphatic obstruction.

222.3 SMALL INTESTINAL DISEASE

222.3.1 Signs

222.3.1.1 Diarrhea

Diarrhea is an increase in fecal mass caused by an increase in fecal water and/or solid content. It is accompanied by an increase in frequency and/or fluidity and/or volume of feces. Yet it must be remembered that the absence of recognizable diarrhea does not preclude the possibility of significant SI disease.

Diarrhea can be classified in several ways (Box 222-6). These categories are not mutually exclusive, and they allow the problem to be viewed from different perspectives, facilitating diagnosis and the choice of appropriate treatment. A mechanistic approach is simple, and many SI diseases have a component of osmotic diarrhea, but even in a situation as simple as lactase deficiency, other mechanisms become involved (Figure 222-6). Osmotic diarrhea in lactose malabsorption causes intestinal distension, which induces peristalsis and rapid transit, and bacterial fermentation products in the colon cause secretion. Bacterial fermentation of unabsorbed solutes is often a complicating factor in malabsorption. The fecal pH is often low because of the production of volatile fatty acids, and some products of fermentation (e.g., hydroxylated fatty acids, unconjugated bile acids) can cause colonic inflammation and secretion, and therefore signs of LI diarrhea frequently accompany prolonged SI disease.

222.3.1.1.1 Osmotic diarrhea

Excess water-soluble molecules in the intestinal lumen retain water osmotically and overwhelm the absorptive capacity of the SI and colon (e.g., sudden diet change, overeating, and malabsorption). The diarrhea typically resolves when food or laxatives are withheld.

222.3.1.1.2 Secretory diarrhea

Stimulation of SI secretion such that the reserve absorptive capacity is overwhelmed results in diarrhea even though the absorptive ability of the SI and colon may not actually be impaired. Treatment with oral rehydration fluids containing glucose and amino acids (e.g., glycine) to increase water absorption is appropriate.

Figure 222-6 Diagrammatic representation of the mechanisms of diarrhea caused by lactase deficiency.

Chronic

Typically secretory diarrhea does not resolve with fasting but does not cause weight loss unless anorexia, vomiting, or additional SI damage is a factor. Morbidity and even mortality are associated with the dehydration that results from excessive fluid loss. Secretory diarrhea typically is caused by chemical toxins and toxins elaborated by enteric bacteria (Box 222-7). 1343 1344

222.3.1.1.2.2 Box • 222-7 Causes of Secretory Diarrhea

Bacterial enterotoxins and endotoxins (e.g., *Clostridium perfringens, Escherichia coli, Salmonella* spp., *Shigella* spp., *Yersinia enterocolitica*)

Unconjugated bile acids from bacterial fermentation

Hydroxylated fatty acids from bacterial fermentation

Giardia infection

Possibly hyperthyroidism

Laxatives (castor oil, dioctyl sodium sulfosuccinate, bisacodyl)

Cardiac glycosides

Amine precursor uptake and decarboxylation (APUD) neoplasms (excess vasoactive intestinal polypeptide, serotonin, prostaglandins, substance P)

Intestinal inflammation

222.3.1.1.3 Permeability (exudative) diarrhea

Intestinal inflammation can stimulate increased fluid and electrolyte secretion and impair absorption. Leakage of tissue fluid, serum proteins, blood, and mucus may occur from sites of inflammation, ulceration, or infiltration or if portal hypertension or lymphatic obstruction is present. Increased permeability severe enough to cause loss of plasma proteins in excess of their rate of synthesis results in a PLE.

222.3.1.2 Malabsorption

Failure of food assimilation is sometimes classified as primary failure to digest (maldigestion) or primary failure to absorb (malabsorption). However, such a classification is misleading, because failure of absorption is an inevitable consequence of failure to digest. The preferred use of the term *malabsorption* is to describe defective absorption of dietary constituent resulting from interference with the digestive and/or absorptive phases in the processing of that molecule.

Within this broad definition, the site of the primary abnormality may be found in the luminal, mucosal, or transport phase (Table 222-2). Also, the reserve capacity of the distal SI and colon may prevent overt diarrhea despite significant malabsorption and weight loss. The clinical manifestations of malabsorption, namely diarrhea, weight loss, and altered appetite (polyphagia, coprophagia, pica), are largely a result of the lack of nutrient uptake and the losses in feces. Animals are often systemically healthy and have an increased appetite unless an underlying neoplastic or a severe inflammatory condition is present. Only when the patient is quite malnourished or develops hypoproteinemia does it become ill.

222.3.1.3 Melena

The presence of dark, tarry, oxidized blood in feces, a condition called *melena,* reflects either swallowed blood or generalized or localized GI bleeding, which usually occurs proximal to the large intestine (Table 222-3). Medication with ferrous sulfate or bismuth subsalicylate (Pepto-Bismol) also can impart a black color to the feces. It has been estimated that the loss of 350 to 500 mg/kg of hemoglobin into the GI tract is required for melena to be visible.[52] The presence of microcytosis with or without thrombocytosis is suggestive of iron deficiency secondary to chronic blood loss. An increased blood urea nitrogen (BUN) to creatinine ratio (from bacterial digestion of blood) provides supporting evidence. Hypoproteinemia may indicate significant blood loss or the presence of a PLE.

Table • 222-2 Pathophysiologic Mechanisms of Malabsorption

MECHANISM	EXAMPLE
Luminal Phase	
Dysmotility	
Rapid intestinal transit	Hyperthyroidism
Defective substrate hydrolysis	
Enzyme inactivation	Gastric hypersecretion
Lack of pancreatic enzymes	Exocrine pancreatic insufficiency
Fat maldigestion	
Decreased bile salt delivery	Cholestatic liver disease, biliary obstruction
Increased bile salt loss	Ileal disease
Bile salt deconjugation	Bacterial overgrowth
Fatty acid hydroxylation	Bacterial overgrowth
Impaired release of CCK, secretin	Impairment of pancreatic secretion due to severe small intestine disease
Cobalamin malabsorption	
Intrinsic factor deficiency	Exocrine pancreatic insufficiency Giant schnauzer defect
Competition for cobalamin	Bacterial overgrowth
Mucosal Phase	
Brush border enzyme deficiency	
Congenital	Trehalase (cats)
Acquired	Relative lactose deficiency
Brush border transport protein deficiency	
Congenital	Intrinsic factor receptor
Acquired	Secondary to diffuse SI disease
Enterocyte defects	
Enterocyte processing defects	Abetalipoproteinemia
Reduction in surface area	Villus atrophy
Immature enterocytes	Increased enterocyte turnover
Mucosal inflammation	Inflammatory bowel disease
Transport Phase	
Lymphatic obstruction	
Primary	Lymphangiectasia
Secondary	Obstruction caused by neoplasia, infection, or inflammation
Vascular compromise	
Vasculitis	Infection, immune mediated
Portal hypertension	Hepatopathy, right heart failure, cardiac tamponade

The general approach to melena is to rule out bleeding diatheses, ingestion of blood, and underlying metabolic disorders before pursuing primary GI causes. Ultrasonography is particularly useful for detecting gastrointestinal masses and thickening. The next step for investigating upper GI blood loss is endoscopy. If the source of GI bleeding is still undetermined, tagged red cell scintigraphy, exploratory laparotomy, angiography, and enteroscopy may be used to localize the site.[53]

Table • 222-3 Causes of Melena

MECHANISM	SOURCE
Ingestion of blood	Oral, nasal, pharyngeal, or pulmonary bleeding
Coagulopathies	Thrombocytopenia, factor deficiencies, DIC
Gastrointestinal erosion/ulceration	
Metabolic	Uremia, liver disease
Inflammatory	Gastritis, enteritis, HGE
Neoplastic	Leiomyoma, adenocarcinoma, lymphosarcoma
Paraneoplastic	Mastocytosis, hypergastrinemia and other APUDomas
Vascular	A-V fistula, aneurysms, angiodysplasia
Ischemia	Hypovolemic shock, hypoadrenocorticism, thrombosis/infarction, reperfusion
Drug induced	Nonsteroidal and steroidal anti-inflammatory agents
Foreign objects	

APUD, amine precursor uptake and decarboxylation tumor; A-V, arteriovenous; DIC, disseminated intravascular coagulation

1344

1345

222.3.1.4 Borborygmi and Flatulence

Borborygmus is a rumbling noise caused by the propulsion of gas through the intestines. Swallowed air and bacterial fermentation of ingesta are the main causes of borborygmi and flatulence. Feeding a diet that is highly digestible, with a low fiber content (e.g., cottage cheese and rice in a 1:2 ratio) leaves little material present in the intestine for bacterial fermentation and can effect a cure in some cases. If borborygmi or flatulence continues despite dietary modification, the animal may be excessively aerophagic or may have malabsorption, especially if diarrhea or weight loss are also present.

222.3.1.5 Weight Loss or Failure to Thrive

General causes of weight loss are reduced nutrient intake, increased nutrient loss, and increased catabolism or ineffective metabolism. The history should reveal whether the type and amount of diet fed is adequate and whether anorexia, dysphagia, or vomiting is a potential cause. Weight loss or failure to thrive accompanied by diarrhea often is a feature of malabsorption, and the diagnostic approach is the same as for chronic diarrhea. However, diarrhea does not invariably accompany malabsorption that causes weight loss.

222.3.1.6 Protein-Losing Enteropathy

When SI disease is severe enough for protein leakage into the gut lumen to exceed protein synthesis, hypoproteinemia develops.[54] Chronic diarrhea associated with hypoproteinemia usually requires intestinal biopsy to define the cause of the PLE (Table 222-4). Nonintestinal diseases, which may potentially be associated with intestinal protein loss (e.g., portal hypertension), usually present with ascites before diarrhea. Hypoproteinemia associated with GI disease is much less common in cats than in dogs and most often accompanies GI lymphoma.

222.3.1.6.1 Clinical presentation

Breeds that appear to be predisposed to PLE are the basenji, lundehund, soft-coated wheaten terrier, Yorkshire terrier, and Shar Pei (see below). Clinical signs associated with PLE include weight loss,

diarrhea, vomiting, edema, ascites, and pleural effusion. Weight loss frequently is the predominant feature, and diarrhea is not invariably present, particularly with lymphangiectasia and focal intestinal neoplasia. Physical findings may include edema, ascites, emaciation, thickened intestines, and melena. Thromboembolism is a feature of some cases of PLE.

Table • 222-4 Protein-Losing Enteropathies

CAUSES	EXAMPLES
Lymphangiectasia	Primary lymphatic disorder, venous hypertension (e.g., right heart failure, hepatic cirrhosis)
Infectious	Parvovirus, salmonellosis, histoplasmosis, phycomycosis
Structural	Intussusception
Neoplasia	Lymphosarcoma
Inflammation	Lymphocytic-plasmacytic, eosinophilic, granulomatous
Endoparasites	*Giardia, Ancylostoma* spp.
Gastrointestinal hemorrhage	HGE, neoplasia, ulceration

HGE, hemorrhagic gastroenteritis

222.3.1.6.2 Diagnosis

The serum concentrations of both albumin and globulin are reduced in most patients with PLE. Exceptions are raised hyperglobulinemia with hypoalbuminemia found in histoplasmosis and immunoproliferative SI disease in the basenji (see below). Renal and hepatic causes of hypoalbuminemia are eliminated by assay of serum bile acids and urinary protein loss respectively. Hypocholesterolemia and lymphopenia are common in PLE. Hypocalcemia and hypomagnesemia are also reported.[55] Measurement of fecal loss of alpha$_1$-protease inhibitor may be a sensitive test for PLE.[56]

Survey abdominal radiographs often are normal in patients with PLE, but ultrasound scans may reveal intestinal thickening, mesenteric lymphadenopathy, or abdominal effusion. Thoracic radiographs may show pleural effusion, metastatic neoplasia, or evidence of histoplasmosis. Although intestinal function tests may confirm the presence of malabsorption, they rarely provide a definitive diagnosis, and intestinal biopsy is more appropriate. Because many intestinal causes of PLE are diffuse, endoscopy is the safer way to obtain biopsies, but surgical biopsy may be required to obtain a definitive diagnosis for lymphoma and for diseases that cause secondary lymphangiectasia (Box 222-8).

222.3.1.6.3 Treatment

Plasma transfusion may be indicated during the perioperative period when collecting biopsy specimens, and diuretics may reduce ascites. Spironolactone (1 to 2 mg/kg given orally twice daily) may be more effective than furosemide for treating ascites. Thromboembolism is a feature of some cases of PLE. Specific treatments are discussed later.

222.3.2 Diagnosis of Small Intestinal Disease

Most cases of diarrhea are acute, nonfatal, and self-limiting and require only symptomatic support without a definitive diagnosis. However, some cases are life-threatening, may have an infective potential for other animals, or may present a potential zoonotic risk to humans. If significant hypovolemia or dehydration is present, fluid and electrolyte deficits must be addressed simultaneously with the diagnostic effort. The extent

of diagnostic investigations required for acute diarrhea varies; investigations are appropriate if diarrhea is hemorrhagic, accompanied by systemic signs, or unresponsive to symptomatic treatment. By definition, chronic diarrhea is not self-limiting, and an etiologic diagnosis usually is required to allow specific treatment. Diagnostic approaches to acute and chronic diarrhea are discussed in detail elsewhere.

222.3.2.1 Box • 222-8 Relative Advantages of Endoscopic and Surgical Intestinal Biopsy

222.3.2.1.1 Endoscopy

Advantages

Minimally invasive

Allows visualization and biopsy of focal lesions

Permits multiple biopsies

Minimal adverse reactions

Allows steroids to be started early

Disadvantages

Requires general anesthesia

Permits access only to duodenum (and distal ileum?)

Allows only small, superficial (and crushed) biopsies

Requires expensive equipment

Technically demanding

222.3.2.1.2 Laparotomy

Advantages

Allows biopsy of multiple sites

Permits large, full-thickness biopsies

Allows inspection of other organs

Offers potential for corrective surgery

Disadvantages

Requires general anesthesia

Poses a surgical risk

Requires convalescence

Requires delay before steroids can be started

The aim of the diagnostic approach is to eliminate extra-intestinal diseases and to differentiate SI from LI disease (Table 222-5). The history (Boxes 222-2 and 222-9 and Table 222-6) and physical examination (Table 222-7) are crucial steps toward reaching a diagnosis and in some cases may be all that is required. Preliminary investigations may also include collection of baseline data (i.e., hematology, serum biochemistry, urinalysis, and fecal examination). Diagnostic imaging may be indicated, especially if a disease requiring surgical intervention is likely. Further investigations include exclusion of EPI, indirect tests of intestinal function and damage and, ultimately, direct examination of the SI by endoscopy or surgery with histologic examination of biopsies.

222.3.2.2 Fecal Examination

Fecal examinations are an important part of the investigation of SI disease. Tests such as quantification of fecal fat excretion are unsuitable for practice, and bacteriologic culture is sometimes of questionable value, but identification of parasites is important.

222.3.2.2.1 Direct smear

Staining of smears for undigested starch granules (Lugol's iodine), fat globules (Sudan stain), and muscle fibers (Wright's or Diff Quik stain) may indicate malab-sorption but is unreliable. Fungal elements and sporulating clostridia may be seen, but rectal cytology is more useful. Unstained wet mounts may be used to identify protozoal trophozoites.

Table • 222-6 Some Suspected and Confirmed Breed Susceptibilities to Small Intestinal Disease in Dogs and Cats

BREED	CONDITION
Basenji	Lymphocytic-plasmacytic enteritis (also called immunoproliferative disease)
Beagle	Cobalamin deficiency
Border collie	Cobalamin deficiency
German shepherd	Idiopathic antibiotic-responsive; inflammatory bowel disease (lymphoplasmacytic, eosinophilic)
Giant schnauzer	Defective cobalamin absorption
Irish setter	Gluten-sensitive enteropathy
Lundehund	Lymphangiectasia
Retrievers	Dietary allergy
Rottweiler	Susceptibility to parvovirus
Soft-coated wheaten terrier	Protein-losing enteropathy/nephropathy
Shar Pei	Lymphocytic-plasmacytic enteritis, cobalamin deficiency
Toy breeds	Hemorrhagic gastroenteritis
Yorkshire terrier	Lymphangiectasia

Enterotoxin production by *Clostridium perfringens* is a potential cause of diarrhea. The presence of a large number of clostridial endospores (more than 5 per oil field) on Diff Quik–stained smears may be suggestive, but a positive fecal enterotoxin assay (enzyme-linked immunosorbent assay [ELISA] or reverse passive latex agglutination) is more significant.

222.3.2.2.2 Fecal concentration methods

For detection of most parasites, fecal concentration methods are more rewarding (Figure 222-7). Examination of three fecal samples by zinc sulfate flotation is recommended to detect *Giardia* oocysts. A direct smear, sedimentation, or the Baermann technique can identify larvae of *Strongyloides* spp.

222.3.2.2.3 Bacteriologic examination

Routine culture of all bacteria from a fecal sample is of little value, but targeted evaluation for potential pathogens may be helpful. Culture of feces is indicated in animals with hemorrhagic diarrhea or pyrexia or with an inflammatory leukogram or neutrophils on rectal cytology. Identification of *Salmonella* spp., *Campylobacter jejuni,* and *Clostridium difficile* may be helpful, although the significance of a positive isolate should be interpreted in the light of the clinical history, because these organisms can be present in clinically healthy animals. Furthermore, although fecal flora might be representative of colonic bacterial populations, they do not necessarily reflect the SI flora and cannot be used to diagnose SIBO. *E. coli* can be cultured from most fecal samples, but only certain strains are pathogenic, and molecular probes have recently been used to detect pathogenicity markers of *E. coli* in small animal medicine.[57] However, the significance of a positive result needs further assessment, because these organisms can be isolated from both healthy and ill dogs. Feces can be cultured for fungi, such as *Histoplasma capsulatum,* but isolation is difficult and slow.

222.3.2.2.4 Virologic examination

Viral diarrhea is usually acute and self-limiting and does not require a positive diagnosis. Electron microscopy can be used to identify the characteristic viral particles of rotavirus, coronavirus, and parvovirus. A fecal ELISA for parvovirus is also available (see below).

Table • 222-7 Significant Physical Findings in Animals with Signs of a Small Intestinal Disorder

FINDINGS	INTERPRETATION
General	Rule out other systemic disease
Oropharynx	
Mucous membranes	Hydration status, cardiovascular status, anemia, icterus
Tongue	Linear foreign body
Cervical Region	
Thyroid gland	Thyroid nodule (hyperthyroidism)
Abdominal Palpation and Auscultation	
Palpation	Effusions, masses, bunching of intestinal loops, foreign bodies, abnormal accumulations of ingesta, associated pain, feces, lymphadenopathy, other systemic disease
Auscultation	Ileus, borborygmi
Rectal Examination	
Digital examination	Masses, foreign bodies, hemostatic disorders, dehydration
Collection of stool sample	Laboratory analysis, melena
Rectal mucosal scrape	Cytology
Cutaneous Examination	
Poor coat condition, scale	Malnutrition
Pruritus	Food hypersensitivity
Pedal pruritus	*Uncinaria stenocephala* infection (larval migration)

222.3.2.2.5 Giardia antigen

A commercially available ELISA can be used to detect *Giardia* antigen in feces.

222.3.3 Occult blood

These tests are used to search for intestinal bleeding from ulcerated mucosa and benign or malignant tumors. Unfortunately, all versions nonspecifically test for hemoglobin and are very sensitive, reacting with any meat diet and not just patient blood. Therefore the patient must be fed a meat-free diet for at last 72 hours for a positive result to have any reliability.[52,58]

222.3.3.1 Alpha$_1$-protease inhibitor

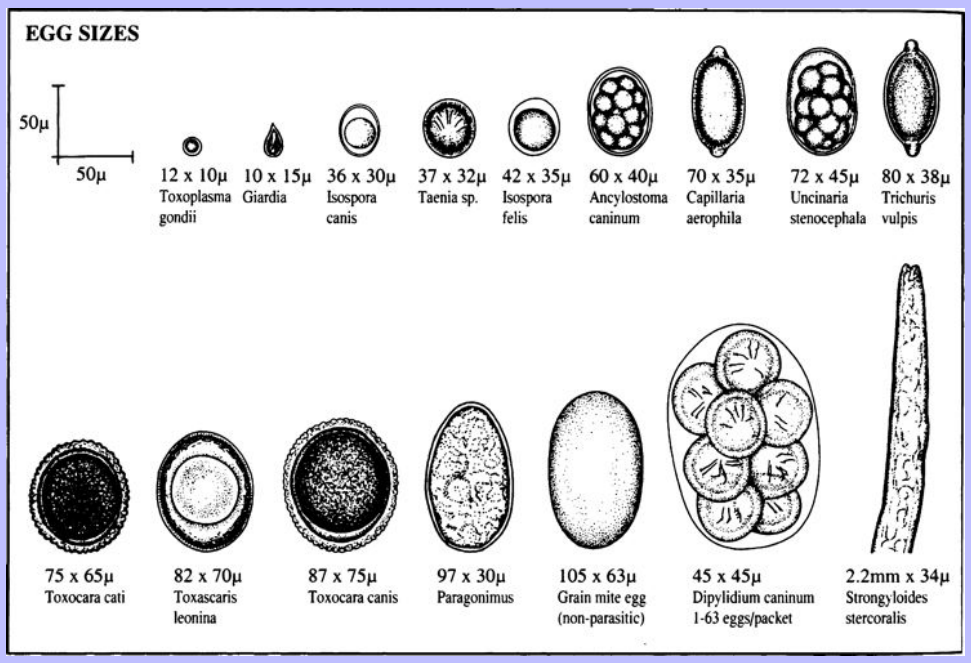
This test assays the presence in feces of a naturally occurring endogenous serum protein that is resistant to bacterial degradation if it is lost into the intestinal lumen. To improve diagnostic accuracy, three fresh fecal samples should be sampled. The assay is valid only if used on fecal samples collected after voluntary evacuation, because abrasion of the colonic wall during manual evacuation is enough to elevate

alpha$_1$-protease inhibitor (alpha$_1$-PI) concentrations. It appears to be of value for the diagnosis of PLE[59] and may prove to be more a sensitive marker than measurement of serum albumin for the detection of early disease.[60]

1347

1348

Figure 222-7 Identification of protozoan cysts and worm eggs that may be found in the feces of dogs and cats. (Hoechst-Roussel-Agri Vet Company, USA.)



222.3.3.2 Rectal cytology

At the end of the rectal examination, the rectal wall is mildly abraded, the gloved finger rolled on a microscope slide, and the smear stained. Although the result is often negative and, when positive, probably more representative of LI disease, an increased number of neutrophils may be suggestive of a bacterial problem, indicating the need for fecal culture. Clostridial endospore elements (*Histoplasma, Aspergillus, Pythium,* and *Candida* spp.) may be identified. The test is fast and simple but in all cases confirmatory tests are indicated.

222.3.4 Imaging

Until recently, imaging of the intestinal tract was limited to plain and contrast radiographs. This has been dramatically altered by the use of ultrasound and endoscopy. Scintigraphy, computed tomography (CT), and magnetic resonance imaging (MRI) scanning are rapidly being adopted, and “virtual endoscopy” by helical CT is becoming available.

222.3.4.1 Radiography

222.3.4.1.1 Survey radiographs

Plain radiographs are most useful in the investigation of primary vomiting, diarrhea associated with vomiting, abdominal pain, and palpable abnormalities. Diagnostic yield is improved if both lateral views are taken,[61] although a single lateral radiograph is all that is required if radiography is combined with ultrasonography. Generally the aim is the detection of (acute) surgical disease; these radiographs allow detection of foreign bodies, masses, obstructions, decreased serosal detail, free peritoneal gas, and ileus (Table 222-8).

Ileus is an abnormal dilatation of an immotile segment of intestine, and the differential diagnosis depends on whether it is localized or generalized and whether an accumulation of gas or fluid is present (Box 222-10). The usefulness of plain radiographs in malabsorption is minimal.

222.3.4.1.2 Contrast radiography

Since the introduction of abdominal ultrasonography and endoscopy, contrast radiographic studies have had limited value in the assessment of SI disease.

222.3.4.1.2.1 Barium follow-through examinations.

Studies using microfine barium suspensions can identify ulcers and irregular mucosal detail and may confirm the presence of radiolucent foreign bodies. Such studies are of limited use in identifying mural masses and partial obstructions, and they rarely provide more information than a good-quality survey film (Figure 222-8). Furthermore, although contrast studies allow assessment of the intestinal transit rate, they provide limited etiologic information, and dysmotility may occur secondary to other causes. Also, administration of barium may delay endoscopy for at least 24 hours.

222.3.4.1.2.2 Barium-impregnated polyethylene spheres (BIPS).

BIPS are solid-phase radiopaque markers that provide information on gastric emptying, intestinal transit, and obstructive disorders (Figure 222-8, *D*). Given that the transit time of BIPS is highly variable,[62] their use for transit studies is limited. However, they may be more helpful in the detection of obstructive disorders.

222.3.4.2 Ultrasonography

Transabdominal ultrasound examination of the SI is now a routine part of the investigation of intestinal disease. In the future, endoscopic ultrasound will allow the mucosal wall and adjacent viscera (e.g., pancreas) to be examined in more detail. A conventional ultrasound examination can detect layering of the wall, peristalsis, and luminal contents and can measure intestinal wall thickness.[63] It has excellent sensitivity for the detection of lesions such as intussusceptions,[64] masses,[65] radiolucent foreign bodies, intestinal wall thickening, and lymphadenopathy in chronic inflammatory and neoplastic enteropathies (Figure 222-9). Values for normal SI wall thickness have been reported for dogs and cats,[63] and thickness

decreases from proximal to distal. Ultrasound-guided fine needle aspiration for cytologic examination is possible. Disruption of the normal five-layered sonographic appearance (mucosal surface, mucosa, submucosa, muscularis, serosa) is typical of neoplasia, although loss of layering can also result from other infiltrative disorders and bowel wall edema. Intussusceptions are usually recognized in the transverse plane as multiple concentric rings[65] and longitudinally as a thick, multilayered segment.

Table • 222-8 Helpful Survey Abdominal Radiograph Findings in Patients with Intestinal Disease

FINDINGS	INTERPRETATION
Radiopaque foreign bodies	Visible on survey films
Ileus	Either adynamic/paralytic or obstructive (see Box 222-4)
Abnormal soft tissue shadow	Abdominal mass
Displacement of viscera	Abdominal mass, enlargement of intraperitoneal or retroperitoneal organ, rupture or hernia
Bunching of intestines	Excess intra-abdominal fat, large mass, adhesions, linear foreign body
Bowel wall thickness	Edema, infiltrative (inflammatory, neoplastic disease)
Bowel wall irregularity	Enteritis, neoplasia, ulcers
Loss of serosal detail	Emaciation and immaturity, peritoneal effusion (ascites in hypoproteinemiaand/or portal hypertension, peritonitis, carcinomatosis)

222.3.5 Special Tests

In cases of malabsorption, intestinal biopsy is usually necessary to obtain a definitive diagnosis. However, EPI should be ruled out before biopsy, because signs of malabsorption are nonspecific. It is also well recognized that biopsies from up to 50% of patients are considered normal by light microscopy. Therefore, usually before biopsy, a number of indirect tests are performed to assess for intestinal damage, altered permeability, and dysfunction.

222.3.5.1 Diagnosis of Exocrine Pancreatic Insufficiency

Because the signs of EPI cannot be distinguished from primary causes of SI, serum trypsin-like immunoreactivity (TLI) measurement must be performed in all cases.

222.3.5.2 Serum Folate and Cobalamin Concentrations

The assay of serum folate and cobalamin concentrations can be performed on the same serum sample taken for the TLI test. This assay has limited value in the diagnosis of SI diseases, but subnormal folate and cobalamin concentrations secondary to GI disease may be detected. Cobalamin deficiency is more common, and the response to treatment of the underlying GI disease may be suboptimal if this vitamin deficiency is not corrected. In dogs, the severe cobalamin deficiency recognized in several breeds has been linked to an IF-cobalamin receptor deficiency.[45,66] Cobalamin deficiency is a common sequel to small intestinal disease in cats,[67] and systemic metabolic consequences have been recognized. Determination of the serum folate and cobalamin concentrations is not recommended for the diagnosis of canine SIBO (see below).

222.3.5.3 Indirect Assessment of Intestinal Absorption

Attempts to assess intestinal function by measuring the mediated absorption of numerous substrates (e.g., lactose, glucose, vitamin A, D-xylose, triglyceride, and starch tolerance tests) are no longer performed because of a similar lack of sensitivity and specificity.

222.3.5.3.1 Xylose/3-O-methyl-D-glucose test

The differential absorption of these two sugars eliminates the nonmucosal effects that blight the xylose test, and initial results suggest that the test may be of value in dogs and cats.[68]

222.3.5.4 Intestinal Permeability

Intestinal permeability is an index of mucosal integrity and is assessed by measuring unmediated uptake of nondigestible probe markers. Tests use a nonmetabolizable probe marker that is excreted in the urine. The permeability probe chromium-51-labeled ethylenediamine tetra-acetic acid (^{51}Cr-EDTA) was used in original studies,[69] but the need for a γ-emitter limited its safe use.

Errors related to nonmucosal factors (including the gastric emptying rate, intestinal transit time, and completeness of urine collection) can be eliminated by concurrently measuring the absorption of two probes with different pathways of absorption (Figure 222-10). Calculation of their excretion ratio eliminates errors from extramucosal factors because both probes should be affected equally. The ratio, which is altered by villus atrophy or epithelial damage or both, offers a simple, sensitive diagnostic test.

1349

1350

Figure 222-8 Identification of an intestinal mass in a Siamese cat. **A,** Annular adenocarcinoma in the ileum demonstrated at laparotomy. **B,** Prior plain lateral radiograph showing a dilated loop of bowel associated with this caudal abdominal mass. **C,** Ventrodorsal radiograph after oral administration of barium suspension showing a dilated loop of SI in the midline, colonic filling, and narrowing of the intestinal lumen at the site of the mass. **D,** Ventrodorsal radiograph after oral administration of BIPS showing accumulation of the larger markers at the site of the partial obstruction caused by the mass. (Courtesy A.H. Sparkes.)

A 5-hour urine collection is performed after oral administration of two sugars. A number of candidates can be used for the probe molecules, and a mixture of one large simple sugar (e.g., lactulose, cellobiose, raffinose) and one small one (e.g., rhamnose, arabinose, mannitol) can be chosen. The cellobiose/mannitol excretion ratio and lactulose/mannitol ratio have been used in companion animals,[70] but with advances in the high-performance liquid chromatography (HPLC) assay of these sugars, the lactulose/rhamnose test has become the standard test of SI permeability.

222.3.5.5 Tests for Protein-Losing Enteropathy

Historically, intestinal protein loss has been detected by measuring the fecal loss of ^{51}Cr-labeled albumin.[71] The test is unpleasant to perform and potentially hazardous and has largely been discarded, although it remains the standard by which other tests, such as the assay of fecal alpha$_1$-PI (see above), are judged.

222.3.5.6 Breath Tests

Breath tests are used to assess bacterial metabolism in the GI tract. Bacteria synthesize a gas, which is absorbed and excreted in breath. Breath hydrogen tests have been used most extensively because mammalian cells cannot produce hydrogen, and therefore any that is measured must be bacterial in origin. Such tests can assess carbohydrate malabsorption, bacterial colonization of the SI, and oro-cecal transit time.

1350

1351

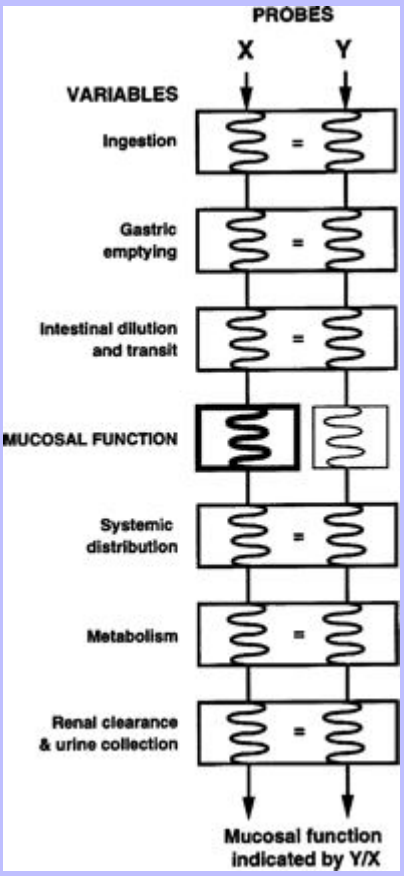
A variety of protocols has been used, including xylose to assess malabsorption, lactulose to assess oro-cecal transit, and a test meal to assess SI bacterial fermentation. Also, a number of recent studies have attempted to standardize the techniques for companion animals.[72–75] However, these techniques are not widely used even in referral centers.

Figure 222-10 Principle of differential permeability testing. Simultaneous administration of two probes selected to respond identically to each variable except mucosal permeability. The Y/X ratio provides a specific index of mucosal permeability. (Hall EJ: Small intestinal disease: Is endoscopic biopsy the answer? J Small Anim Pract 35:408, 1994.)



222.3.5.7 Unconjugated Bile Salts

The principle of the serum conjugated bile acids test is that conjugated bile salts secreted into the intestine in bile are deconjugated by certain bacterial species and absorbed by the SI. Therefore, in theory, increases in SI bacterial numbers might result in an increase in serum unconjugated bile acids (SUBA). Preliminary work suggested that the test was sensitive and specific for canine SIBO,[76] although a recent study has questioned its utility.[77]

222.3.5.8 Miscellaneous Tests

A number of tests for intestinal bacterial metabolites have been devised to detect SIBO. These include the nitrosonaphthol test, urinary indican excretion, bacterial release of sulfapyridine from sulfasalazine, and bacterial release of p-amino benzoic acid (PABA) from a bile salt conjugate (PABA-UDCA). However, none of these tests are widely used in companion animals.

222.3.6 Endoscopy

Flexible endoscopy allows gross examination of the SI mucosa and collection of tissue samples without the need for invasive surgery. The proximal small intestine can be viewed during gastroduodenoscopy (see Figure 222-2), and the distal SI often can be visualized by passing the endoscope retrograde through the ileocolic valve. Therefore only the midjejunum cannot be satisfactorily examined by routine endoscopy. However, given that most cases of malabsorption involve diffuse disease, this limitation may not be significant. Enteroscopy, which was developed in humans and which uses a much narrower, thinner endoscope, may allow examination of most of the jejunum.

Abnormal findings on gross endoscopic examination include mucosal granularity and friability, erosions/ulcers, retained food, mass lesions, and hyperemia/erythema. However, none of these characteristics is pathognomonic for particular disease conditions, and gross findings frequently do not correlate with those of the histopathologic examination. A milky white appearance or a milky exudate is suggestive of lymphangiectasia, and the presence of intraluminal parasites may be diagnostic in some cases.

222.3.7 Intestinal Biopsy

In most cases of acute diarrhea, a tissue diagnosis is not needed, and intestinal biopsy is never performed. 1351
However, in chronic diarrhea a definitive diagnosis often depends ultimately on histologic examination of 1352
intestinal tissue, although this procedure has major limitations (see below). Biopsy specimens are collected, either endoscopically or surgically. The clear advantages of endoscopy to the patient and client are balanced by a number of drawbacks (see Box 222-8), and the client should always be warned that surgical biopsy might ultimately be required for definitive diagnosis. A surgical option is also preferred if there is any possibility of extraintestinal disease or focal intestinal pathology. Biopsies should always be taken, even in the absence of gross abnormalities, because microscopic changes may be present. Multiple endoscopic biopsies (eight or more) should be taken, because the size of the specimens, crush artifacts, and fragmentation can make interpretation difficult.[78]

The duodenum and proximal jejunum (if possible) are biopsied routinely by endoscopy, whereas ileal biopsies may be obtained via colonoscopy. Full-thickness, longitudinal, elliptical surgical biopsies usually are taken from at least three sites, the duodenum, the jejunum, and the ileum.

222.3.7.1 Examination of Biopsies

Although histopathologic assessment of intestinal biopsies remains the gold standard for diagnosis of intestinal disease, it has marked limitations. Biopsy specimens can be normal by light microscopy, which suggests that many diseases have a functional rather than a morphologic abnormality (Box 222-11) or that sampling problems have occurred.[78] Agreement between histopathologists often is poor. In a recent study,

some histopathologists made a diagnosis of lymphoma after assessing tissues from healthy dogs.[79] Histopathologic scoring schemes and standardized criteria have been suggested as a means of improving agreement (Box 222-12), but marked variability still exists. Therefore the primary clinician should always interpret results cautiously and in light of the clinical presentation, and results should be questioned if the tissue diagnosis does not fit the clinical picture or if the response to apparently appropriate therapy is poor. In some cases, repeat biopsy (e.g., by exploratory laparotomy) may be required. Cytologic examination of endoscopic biopsy squash preparations or mucosal brushings may be a useful adjunct to histopathologic examination.[80] Alternate examinations are largely research tools, but they can provide significant information. Examinations available include electron microscopy; biochemical assay of brush border enzymes; immunocytochemical characterization of B cells, T cells, and their subsets (e.g., CD4 and CD8 cells)[22–24] and MHC expression[24,29]; cytokine expression[81]; and assessment of T-cell clonality.[82]

222.3.7.1.1

Box • 222-11 Causes of Chronic Diarrhea for which Small Intestinal Biopsy May Be Normal*

SIBO, ARD

Dietary indiscretion

Food intolerance

Type I hypersensitivity to food (if dog is starved before biopsy)

Toxigenic/secretory diarrheas

Motility disorders/irritable bowel syndrome

Brush border membrane disease (e.g., hypolactasia)

Patchy mucosal disease not sampled

Intestinal sclerosis (if biopsies are not full thickness)

Undiagnosed EPI or colonic or systemic disease

* Detection of histologic abnormalities depends on the size and quality of the biopsy, the quality of processing, and the expertise of the pathologist.

ARD, antibiotic-responsive diarrhea; EPI, exocrine pancreatic insufficiency; SIBO, small intestinal bacterial overgrowth.

- Edema
- Fibrosis
- Infective agents
- Neoplasia

222.3.7.2 Duodenal Juice

Duodenal juice can be collected during duodenoscopy through a sterile polyethylene tube passed down the biopsy channel or by needle aspiration through the intestinal wall at laparotomy. However, collection of sufficient sample without blood and tissue contamination can be difficult. The sample can be examined for *Giardia* trophozoites, although this has not proved reliable in diagnosis.[83] Alternatively, quantitative and qualitative aerobic and anaerobic cultures can be performed. This is the gold standard for diagnosis of SIBO, although there are major problems in interpretation. First, problems may arise from differences in the methods of collection (e.g., endoscopic aspiration versus needle aspiration) and from insufflation with air during endoscopy or dilution with endoscopic wash fluid, gastric juice, bile, or blood. Second, laboratory protocols for bacteriology may vary among laboratories, especially for obligate anaerobes. Third, large intraindividual variation exists in duodenal juice culture results,[16] with one report documenting a 7 log-unit difference between bacterial counts obtained on two separate occasions from an individual animal.[84] 1352
Fourth, because bacterial overgrowth may occur in pockets, a single upper SI culture may not be entirely 1353
representative. Despite these problems, a strict cutoff for the upper limit of normal bacterial counts is often applied; this is inappropriate, because healthy dogs can have numbers in excess of this limit without showing clinical signs. Finally, a recent study has suggested that it does not aid in decision making for cases of GI disease.[77] Therefore, given all these limitations, routine diagnostic use of duodenal juice bacterial culture is not recommended.

222.3.8 Acute Small Intestinal Disease

Potential causes of acute diarrhea are listed in Table 222-9, but whether a complete diagnosis is pursued and when therapy is instituted are clinical judgments. The diagnostic approach to acute diarrhea is discussed elsewhere.

Patients that are bright, alert, and not dehydrated may require no further investigation, because signs are often self-limiting. Further investigation of acute diarrhea is indicated under the following circumstances:

- The patient is dull or depressed, febrile, dehydrated, tachycardic or bradycardic or is having abdominal discomfort, melena, bloody mucoid stools, or frequent vomiting.
- Obvious physical abnormalities (e.g., intestinal masses, thickening, or plication) localize the problem to the SI, and diagnostic imaging, noninvasive biopsy, or surgery can define the cause.
- Systemic abnormalities are present, as defined by a minimum database and other clinicopathologic tests.

It is important that the patient be regularly re-evaluated to monitor the response to therapy and to detect any new abnormalities that may arise.

222.3.8.1 Treatment of Acute Diarrhea

The initial management of acute diarrhea associated with systemic illness is symptomatic and supportive, and is commenced on the basis of clinical findings, in particular the presence of dehydration, while the results of the initial data base and further tests are pending.

222.3.8.1.1

Fluid therapy

Oral fluid and electrolyte replacement therapy may be sufficient if acute diarrhea is associated with only mild or insignificant dehydration, and if vomiting is infrequent or absent,[85] although its efficacy should still be monitored. However, when diarrhea is accompanied by significant vomiting or dehydration, parenteral fluids should be administered at a rate that replaces deficits, supplies maintenance needs and compensates for ongoing losses. Patients with marked hypovolemia require more aggressive support.

Table • 222-9 Causes of Acute Diarrhea

CAUSES	EXAMPLES
Dietary	Hypersensitivity (allergy), intolerance, sudden diet change, food poisoning (poor quality, spoiled foods/bacterial)
Toxic	Food or other sources
Infectious	Parvovirus, coronavirus, paramyxovirus, adenovirus, may or may not be FeLV/FIV related; also *Salmonella, Campylobacter, Clostridium* spp. (?) and *Escherichia coli* (?)
Parasites	Helminths; *Coccidia, Giardia* spp.
Acute pancreatitis	
Anatomic	Intussusception
Metabolic	Hypoadrenocorticism

FeLV, feline leukemia virus; FIV, feline immunodeficiency virus.

The type of fluid and requirement for potassium supplementation is best judged by performing a minimum data base and blood gas analysis. Parenteral fluids are usually best given intravenously. The intraosseous route can be used if venous access is unavailable, but subcutaneous administration of fluids is likely to be inadequate.

222.3.8.1.2

Diet

Studies examining the role of diet in the treatment of acute diarrhea in dogs and cats are scarce.[86] Current recommendations are based on common sense and anecdotal evidence. Best practice generally is considered to be withholding food for 24 to 48 hours and then feeding a bland diet, given little and often, for 3 to 5 days. Thereafter the original diet is gradually reintroduced. In animals with no other significant clinical findings, this may be the only therapy required. Common choices of a bland, fat-restricted diet for dogs are boiled chicken or white fish or low-fat cottage cheese with boiled rice. Cats seem to have a lower tolerance to dietary starch and may benefit from a diet with a higher fat content. Little attention is paid to the overall nutritional adequacy of home-prepared bland diets when fed in the short term.

This dogma of *intestinal rest* has been challenged by studies that demonstrate that feeding human infants during diarrhea promotes recovery. The success of such *feeding through diarrhea* varies depending on the cause, with most benefit seen in secretory diarrhea. However, in dogs and cats, secretory diarrhea is less common, the increased volumes of diarrhea may be cosmetically unacceptable, and the frequently contemporaneous vomiting may preclude this approach. The inclusion of glutamine, a nutrient utilized preferentially by enterocytes, may also promote recovery and decrease bacterial translocation,[87,88] although experimental proof of improved intestinal integrity in animals is lacking.[89]

Theoretically, any intestinal disease may predispose the animal to the development of a food sensitivity, therefore feeding of a novel protein source during these periods may preclude the development of sensitivity to the staple diet. However, this concept of feeding of a *sacrificial protein* is supported only by circumstantial evidence.

222.3.8.1.3 Protectants and adsorbents

Bismuth-subsalicylate, kaolin-pectin, montmorillonite, activated charcoal and magnesium, and aluminum and barium-containing products are often administered in acute diarrhea to bind bacteria and their toxins and to coat and protect the intestinal mucosa, but they may also have an antisecretory effect. Therapy for acute diarrhea with protectants, absorbents or motility modifying agents (see below) should not exceed 5 days.

222.3.8.1.4 Motility-and secretion-modifying agents

Anticholinergics and opiates or opioids (loperamide, diphenoxylate) are frequently used for the symptomatic management of acute diarrhea, but anticholinergic agents can potentiate ileus and are not recommended. Opiate analgesics were thought to exert their effects by stimulating segmental motility, but they actually act mainly by decreasing intestinal secretion and promoting absorption and can be used in the short-term symptomatic management of acute diarrhea in dogs. They are contraindicated in cases involving obstruction or an infectious etiology.

222.3.8.1.5 Antimicrobial therapy

1353

1354

Antimicrobials are indicated only in animals with a confirmed bacterial or protozoal infection, those in which a breach of intestinal barrier integrity is suspected from evidence of GI bleeding, and hence in those at risk of sepsis. Leukopenia, neutrophilia, pyrexia, the presence of blood in the feces, and shock all are indications for prophylactic antibiotics in animals with diarrhea. Initial choices in these situations include ampicillin or a cephalosporin (effective against gram-positive and some gram-negative and anaerobic bacteria). If systemic translocation of enteric bacteria is suspected, antimicrobials effective against anaerobic organisms (e.g., metronidazole or clindamycin) and “difficult” gram-negative aerobes (e.g., an aminoglycoside or a fluoroquinolone) are indicated. Intravenous quinolones have been shown to reach therapeutic concentrations in the canine gut lumen and can be effective against enterococci, *E. coli,* and anaerobes.[90] Oxytetracycline, tylosin, and metronidazole are suitable for the treatment of SIBO.

A four-quadrant, intravenous antibacterial regimen may be required if septicemia is likely, and suitable combinations would be a cephalosporin (or amoxicillin) or a fluoroquinolone (or amikacin) with metronidazole or clindamycin. However, aminoglycosides should not be given until the patient is volume-expanded.

222.3.8.1.5.1 Probiotics

Traditionally, many practitioners have recommended feeding live yogurt as a way of repopulating the intestine with beneficial lactobacilli after an acute GI upset. There is evidence in other species that probiotics do exert a positive effect on intestinal permeability and mucosal immune responses, although the effects may be species specific and present only while the probiotic is continuously

administered.[91] Probiotics are now available for use in dogs and cats, and emerging data exist to support their use.[92]

222.3.8.2 Acute Diarrhea Induced by Diet, Drugs, or Toxins

Altered food intake, probably the most common cause of acute, self-limiting diarrhea in dogs, includes rapid diet change, dietary indiscretion, dietary intolerance, hypersensitivity, and food poisoning. Dietary hypersensitivity (food allergy) is probably rare. Ingestion of drugs (e.g., nonsteroidal anti-inflammatory drugs [NSAIDs] or antibacterials) or toxins (e.g., insecticides) also may cause vomiting and diarrhea. The history may allow an educated, presumptive diagnosis to be made. However, the exact cause often is never determined because the patient is not systemically unwell and responds to symptomatic therapy. The prognosis usually is excellent, and only if the diarrhea does not respond or the patient deteriorates is further investigation necessary.

222.3.8.3 Hemorrhagic Gastroenteritis

There are numerous potential causes of bloody vomiting and diarrhea, but *hemorrhagic gastroenteritis* (*HGE*) is the name given to a syndrome characterized by acute hemorrhagic diarrhea accompanied by marked hemoconcentration. The cause of the syndrome is unknown. It may represent an intestinal type 1 hypersensitivity reaction or could be a consequence of *C. perfringens* enterotoxin production.[93]

222.3.8.3.1 Clinical findings

Dogs present with acute hemorrhagic diarrhea, with small breed dogs most frequently affected. Pyrexia is unusual, but vomiting, depression, and abdominal discomfort are common. The onset may be peracute and can be associated with marked fluid shifts into the SI, leading to severe hypovolemic shock even before signs of dehydration (e.g., decreased skin turgor) appear.

222.3.8.3.2 Diagnosis

A presumptive diagnosis of HGE can be made on the basis of appropriate clinical findings associated with a packed cell volume (PCV) of 55% to 60% or more. Total protein is often normal or not as high relative to the PCV, probably because of intestinal plasma loss. Radiographs may demonstrate ileus. The absence of leukopenia and the presence of marked hemoconcentration help distinguish HGE from parvovirus. Positive fecal tests may support a diagnosis of clostridiosis, but direct evidence of SI infection is rarely obtained.[93]

222.3.8.3.3 Treatment

Intravenous fluids are essential in treating patients with HGE. Some patients become hypoproteinemic, and plasma or colloid support may be required. Parenteral antibiotics are often administered because of potential clostridial infection and the high risk of sepsis. Clinical improvement is usually noted within a few hours, though the diarrhea may take several days to resolve. Close patient monitoring is essential; patients that have not responded within 24 hours should be re-evaluated for parvovirus, intussusception, or foreign objects. Once the patient is in the recovery phase, standard dietary therapy for acute diarrhea

can be instigated. The prognosis for most animals with HGE is good, but if HGE is complicated by severe hypoproteinemia or sepsis, the prognosis is more guarded.

222.3.8.4 Infectious and Parasitic Causes of Acute Diarrhea

Diarrhea caused by infectious and parasitic agents is considered common in animals that are young, immunologically naïve or immunocompromised, housed in large numbers, or housed in unsanitary conditions. Parvovirus, *Giardia, Salmonella,* and *Campylobacter* spp., and some helminths can be significant causes of diarrhea. The importance of coronavirus, *C. perfringens,* and *E. coli* as causes of diarrhea has yet to be defined. The zoonotic potential of many of these infections has not been clearly elucidated, but basic hygienic precautions should always be adopted. Specific SI infections are discussed below, but the reader is referred elsewhere for detailed information on other viruses such as paramyxoviruses, adenoviruses, feline leukemia, and immunodeficiency viruses, which also cause diarrhea but affect many other organ systems apart from the GI tract.

222.4 VIRAL ENTERITIDES

Most viral enteritides of dogs and cats, especially the parvovirus infections, cause an acute and usually self-limiting diarrhea, although severe cases in young or immunocompromised patients may be fatal. Canine parvovirus infection is described here as the index case for viral enteritides.

222.4.1 Canine Parvovirus

Canine parvovirus type 2 (CPV-2) is a highly contagious cause of acute enteritis.[94] It emerged as a pathogen in the late 1970s, perhaps from a mutation of a feline vaccine as it is related to feline panleukopenia and mink enteritis viruses. CPV-2b has emerged as the most prevalent antigenic variant. There have been reports of cats being infected with CPV-2, but the severity of signs is much reduced.

Infected dogs shed massive quantities of virus particles in feces during the acute illness and then for about 8 to 10 days afterward. Parvovirus is extremely stable and can remain infectious in the environment for many months. Infection is acquired via the fecal-oral route and is more common in the summer months. The virus has an affinity for rapidly dividing cells and localizes to the intestine (crypt cells), bone marrow, and lymphoid tissues. It causes apoptotic cell death, leading to intestinal crypt necrosis and severe diarrhea, leukopenia, and lymphoid depletion.[95]

222.4.1.1 Clinical Findings

Clinical signs of diarrhea typically occur 4 to 7 days after infection. Anorexia, depression, fever, vomiting, diarrhea (often profuse and hemorrhagic), and dehydration are common. Hypothermia and disseminated intravascular coagulation (DIC) are associated with terminal bacterial sepsis or endotoxemia. Dogs of any age can be affected, but the incidence of clinical disease is highest in puppies between weaning and 6 months. Puppies younger than 6 weeks usually are protected by maternal antibody. In dogs older than 6 months, males are more likely to become infected than females. Overcrowding, intestinal parasitism, concurrent infection with distemper virus, coronavirus, *Giardia, Salmonella,* or *Campylobacter* spp. can increase the severity of illness.

1354
1355

Puppies infected *in utero* or shortly after birth may develop myocarditis and either die suddenly or develop cardiomyopathy if maternal antibody is absent. This situation rarely arises nowadays because widespread vaccination and infection have left few seronegative dams. Yet death still occurs, especially in young puppies, and particularly in susceptible breeds such as rottweilers, Dobermans, English springer spaniels, and American pit bull terriers.[96] Death is usually attributed to dehydration, electrolyte imbalances, hypercoagulability, endotoxic shock, or overwhelming bacterial sepsis related to mucosal barrier disruption and leukopenia. Infected dogs are immunosuppressed and susceptible to catheter infections.[97] Endotoxemia, TNF activity, coliform septicemia, and proliferation of enteric *C. perfringens* determine morbidity and mortality.[98]

222.4.1.2 Diagnosis

Parvovirus should be suspected in young dogs with sudden onset of vomiting and diarrhea, especially if they are also depressed, febrile, or leukopenic or if they have been in contact with infected dogs. Leukopenia (often 500 to 2000 white blood cells per microliter) may be detected in up to 85% of field cases and is very suggestive of parvovirus infection. It reflects neutropenia and lymphopenia. Neutropenia results from impaired bone marrow production with concurrent neutrophil loss through the damaged GI tract, and severe neutropenia crudely correlates with a poor prognosis.

In the absence of leukopenia, clinical signs are indistinguishable from those of other bacterial or viral enteritides, GI foreign bodies with peritonitis, or intussusception. Abdominal radiographs may reveal non-specific gas and fluid accumulation, and ileus. Biochemical abnormalities often include hypokalemia, hypoglycemia, prerenal azotemia, and increased bilirubin or liver enzymes.

Definitive diagnosis requires demonstration of CPV-2 virus (or viral antigens) in the feces. Fecal ELISA is regarded as an accurate and specific diagnostic test but is most sensitive in the first 7 to 10 days when virus excretion is greatest. Single anti-CPV antibody determination in serum (by hemagglutination inhibition) is not useful for diagnosis except in the presence of typical clinical signs in an unvaccinated animal. A rising IgG titer by paired serology provides only a retrospective diagnosis. Serum IgM analysis may provide evidence of recent infection.

222.4.1.3 Treatment

Treatment is supportive and is similar to regimens used in most animals with severe gastroenteritis. Intravenous fluid therapy usually is indicated and is continued until vomiting stops and oral intake resumes. A balanced electrolyte solution (e.g., lactated Ringer's solution) supplemented with potassium and 2.5% glucose is often used. Plasma or whole blood infusions are given to treat severe hypoproteinemia or anemia. Antibiotics are used to control potentially fatal sepsis (see above).

Traditionally, oral intake is withheld until vomiting has stopped for at least 24 hours; this may take 3 to 5 days in severe cases. Rather than avoid the oral route completely, it may be better to trickle feed small amounts of glutamine-containing solutions to reduce bacterial translocation.[87,88] Once vomiting has been controlled, small amounts of a bland diet are fed initially. Frequent or persistent vomiting can be managed with intermittent injections or constant-rate infusion of metoclopramide, once intestinal obstruction has been ruled out. Phenothiazines (e.g., chlorpromazine) can be used if metoclopramide is ineffective and the animal has been rehydrated.

Administration of corticosteroids is of unproven benefit and is probably best limited to dogs with severe endotoxic shock. Flunixin meglumine is best avoided because of its adverse effects on the GI tract and kidneys. Antiendotoxin therapy has been useful in some patients,[99] but the timing of antiendotoxins in relation to antibiotic therapy may be important. Because antibiotics may increase endotoxin liberation, it may be preferable to administer antiendotoxin serum before antibiotics. However, one study showed that the use of the antiendotoxin $rBPI_{21}$ had no beneficial effect on survival,[100] and in another study, use of antiendotoxin was correlated with decreased suvival.[101] Administration of recombinant human granulocyte colony-stimulating factor (G-CSF) to neutropenic parvoviral enteritis patients may raise neutrophil counts but is of no clinical benefit,[102] because the endogenous G-CSF concentration is already elevated.[103] In contrast, administration of feline interferon-omega was found to improve clinical signs and reduce mortality.[104]

222.4.1.4 Prognosis

Severe infection and leukopenia are associated with a high mortality rate, but most dogs with parvovirus recover if dehydration and sepsis are treated appropriately. Complications include hypoglycemia, hypoproteinemia, anemia, intussusception, and secondary bacterial or viral infections.

222.4.1.5 Prevention

Prevention is achieved by limiting exposure to the virus, adequate disinfection (1:32 dilution of sodium hypochlorite bleach), and vaccination.[94] Vaccination is an effective means of preventing and controlling CPV-2, but maternal antibody interference is a problem. Maternally derived antibodies (MDAs) can persist for up to 18 weeks and can interfere with vaccination, although most modern vaccines can overcome MDAs by 10 to 12 weeks of age. Modified live CPV-2 vaccines are most commonly used; killed vaccines provide less duration of immunity but may be recommended in pregnant dogs and puppies younger than 5 weeks. Vaccines may differ in efficacy; low-passage, high-titer vaccines are considered most effective, and only one injection at or after 12 weeks may be needed.[105] In susceptible breeds and dogs in high-risk areas, vaccination may begin at 6 to 8 weeks of age and be repeated every 3 to 4 weeks until 18 weeks of age. There is good correlation between the antibody titer and resistance to infection with canine parvovirus. Annual revaccination is currently recommended.

222.4.2 Feline Parvovirus (Feline Panleukopenia)

Feline panleukopenia is a highly contagious infection of cats that causes severe acute diarrhea and death, similar to canine parvovirus. Mortality in young kittens is high (50% to 90%), therefore the prognosis is guarded until the vomiting and diarrhea stop and the leukopenia resolves.

222.4.3 Canine Coronavirus

Canine coronavirus (CCV) can cause diarrhea of variable severity in dogs.[94] Transmission is by the fecal-oral route. The incubation period is 1 to 4 days, and infected dogs may shed virus intermittently for months after clinical recovery. However, the significance of coronavirus as a primary pathogen is unclear. Experimental inoculation is associated with only mild disease and CCV infection, and antibodies against CCV are present in

many healthy and diarrheic dogs. Infection is very prevalent, particularly in animal shelter and laboratory dogs. Most CCV infections are probably subclinical, although severe enteritis may occur in dense populations or with concurrent infections. In such situations, vaccination may be helpful. 1355 1356

222.4.4 Feline Enteric Coronavirus

Feline enteric coronavirus (FECV) is ubiquitous in the cat population. Mild to moderately severe diarrhea, which may be associated with weight loss, is seen in kittens infected with FECV. Inapparent infection is common in normal cats, many of which shed FECV in feces and are seropositive. FECV infection is important, because enteric coronaviruses may mutate to feline infectious peritonitis virus (FIPV).

222.4.5 Intestinal Feline Infectious Peritonitis

An unusual manifestation of feline infectious peritonitis (FIP) of isolated mural intestinal lesions has been reported.[106] Predominant clinical signs were diarrhea and vomiting, and all cats had a palpable mass in the colon or ileocecocolic junction. Affected intestine was markedly thickened and nodular, with multifocal pyogranulomas extending through the intestinal wall.

222.4.6 Feline Immunodeficiency Virus

Infection with feline immunodeficiency virus (FIV) is associated with a 10% to 20% incidence of chronic enteritis. Although secondary and opportunistic infections may be responsible for signs, sometimes no other etiologic agent can be identified.[107] Anorexia, chronic diarrhea, and emaciation are typical. Palpably thickened bowel loops reflect chronic enteritis with transmural granulomatous inflammation.

222.4.7 Feline Leukemia Virus

Among its many manifestations, feline leukemia virus (FeLV) infection can be associated with fatal peracute enterocolitis and lymphocytic ileitis.

222.4.8 Torovirus

A torovirus-like agent has been isolated from the feces of cats afflicted with a characteristic syndrome of chronic diarrhea and protruding nictitating membrane.[108] However, a clear association with clinical signs was not demonstrated.

222.5 BACTERIAL ENTERITIDES

Most GI infections by pathogenic bacteria are associated with acute diarrhea; however, because these bacteria sometimes can be isolated from healthy animals and from those with chronic diarrhea, confusion exists about the significance of these organisms. Enteroinvasive bacteria such as *Campylobacter* spp., *Salmonella* spp., *Shigella* spp., and *Yersinia enterocolitica* all can be pathogenic and yet may be isolated from healthy animals. The incidence of infection is greatest in young, kenneled animals and immunocompromised patients. Although these organisms may present a zoonotic risk, attempting to eradicate them with antibiotics may be unhelpful and unnecessary and may even induce a carrier state.

222.5.1 *Campylobacter* spp.

Campylobacter jejuni and *C. upsaliensis* have been associated with intestinal disease in dogs and cats, although experimental infection of dogs causes only transient signs.[109] Most infections are asymptomatic, with carriage rates in healthy dogs and cats of up to 50%; kenneled and young animals have the highest isolation rates. Clinically significant disease is usually restricted to young, parasitized, or immunocompromised animals. Clinical signs are watery, mucoid, or hemorrhagic diarrhea accompanied by vomiting, tenesmus, pyrexia, and anorexia. Concurrent infection with *Giardia* or *Salmonella* spp., parvovirus, or coronavirus causes more severe disease.

222.5.1.1 Diagnosis

Because the bacteria are fragile, the diagnosis is best made by isolating them from fresh feces. The presence of slender, seagull-shaped bacteria on a stained fecal smear yields a presumptive diagnosis.

222.5.1.2 Treatment

Animals with severe hemorrhagic mucoid diarrhea should be treated with erythromycin, or quinolone antibiotics such as enrofloxacin. Fluoroquinolones may be preferred, because erythromycin may cause vomiting, but the efficacy of the former has not been critically evaluated. Resistance to antibiotics has been reported, and post-treatment cultures should be performed to document eradication. It is important that the owner be instructed in hygienic precautions to prevent zoonotic infection.

222.5.1.3 Prognosis

The prognosis for recovery usually is good.

222.5.2 *Salmonella* spp

Salmonella organisms are gram-negative motile rods that can cause significant clinical signs in dogs and cats and that have a zoonotic potential. Asymptomatic carriage is common, and *Salmonella* bacteria have been isolated from the feces of up to 30% of healthy dogs and 18% of healthy cats. Clinically significant disease is unusual and occurs most frequently in young, parasitized, kenneled, or immunocompromised animals.

222.5.2.1 Clinical Findings

Three scenarios may follow infection: asymptomatic carriage, gastroenteritis, or bacteremia and endotoxemia. Significant infection causes acute diarrhea that ranges from mild to severe and bloody, as well as anorexia, pyrexia, abdominal pain, and vomiting. Bacterial translocation from the gut lumen may result in septicemia, endotoxemia, DIC, and death in susceptible animals.

Cats with *Salmonella* infection may show only vague signs (e.g., pyrexia, leukocytosis, and conjunctivitis) and no gastrointestinal signs. An acute febrile illness and diarrhea, known as songbird fever, has been reported in cats after ingestion of dead songbirds infected with *Salmonella typhimurium*.

222.5.2.2 Diagnosis

Diagnosis is based on the isolation of *Salmonella* organisms from feces or from blood in septicemic patients. Clinicopathologic features are nonspecific. Hyperkalemia and hyponatremia, suggestive of hypoadrenocorticism, may occur.

222.5.2.3 Treatment

Antibiotic treatment may promote bacterial resistance and a carrier state and is not recommended when *Salmonella* bacteria are isolated from healthy infected animals or stable animals with acute diarrhea. In animals with severe hemorrhagic diarrhea, marked depression, shock, persistent pyrexia, or sepsis, parenteral antibiotics should be given. The choice of antibiotic should be governed by sensitivity testing when possible, but fluoroquinolones appear to be effective against many *Salmonella* spp.[110] Therapy initially should be given for 10 days, but prolonged therapy may be required. The feces should be recultured on several occasions to ensure that the infection has been eliminated.

222.5.2.4 Prognosis

The prognosis for diarrhea associated with *Salmonella* infection in most cases is good. A guarded prognosis should be given in patients with septicemia. Negative prognostic indicators include peracute onset, marked pyrexia (temperature over 40°C), hypothermia, severe hemorrhagic diarrhea, degenerative left shift, and hypoglycemia. 1356 1357

222.5.3 *Clostridium* spp.

C. perfringens, C. difficile, and other clostridial species are part of the normal resident microflora of dogs and cats but may cause diarrhea as a consequence of enterotoxin production.[111,112]

C. difficile can produce two toxins (A and B) and is responsible for antibiotic-associated pseudomembranous colitis in humans. It has been incriminated as a cause of chronic diarrhea in dogs.

Enterotoxin-producing *C. perfringens* has been associated with diarrhea in hospital kennels and with acute and chronic GI signs. Examination of a Diff Quik-stained fecal smear for safety pin–shaped, *C. perfringens*–containing spores has been suggested as a simple screening test, because enterotoxin elaboration was believed to coincide with sporulation. However, this supposition has been disproved by the measurement of *C. perfringens* enterotoxin in feces in the absence of spore formation.[113] Furthermore, enterotoxin can be detected in the feces of healthy dogs, Although SI diarrhea may occur, most dogs show signs of LI diarrhea, and a causal relationship to diarrhea remains to be proven.

222.5.4 *Escherichia coli*

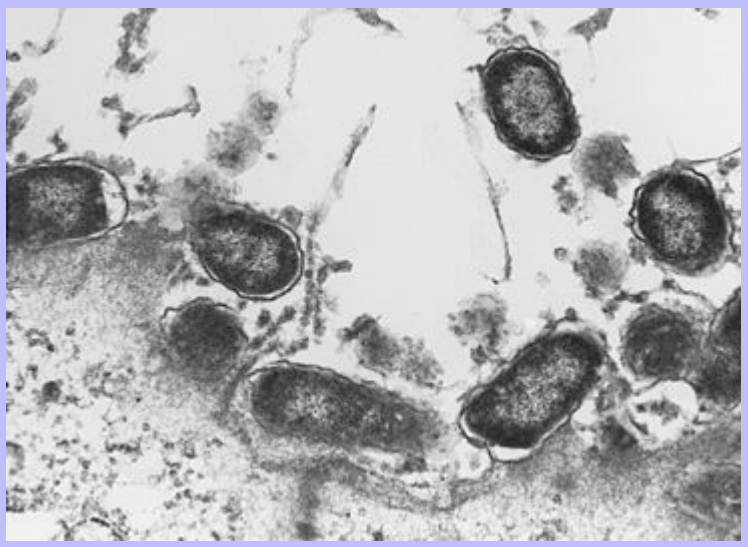
The role of enteropathogenic (EPEC) and enterotoxigenic (ETEC) *E. coli* as a cause of diarrhea in dogs and cats is unresolved. Although many strains are normal commensals, some are a significant cause of acute diarrhea, and other isolates may cause chronic diarrhea.[57] The attachment of ETEC organisms and subsequent release of heat-labile, heat-stable and Shiga-like toxins may cause acute diarrhea. EPEC bacteria attach to the

mucosa, cause effacement of microvilli, and produce profound malabsorption and diarrhea without causing marked changes on light microscopy (Figure 222-11).[114] Identification of pathogenic strains requires specialized assays, such as bioassays for toxins and genome probes for identification of pathogenicity markers, and isolation does not prove causation.[57]

222.5.5 Enteroadherent Organisms

Enteroadherent *E. coli* and other adherent organisms, including *Streptococcus* spp., have been reported to cause chronic diarrhea in dogs.

Figure 222-11 Electron micrograph showing attaching and effacing *Escherichia coli* organisms on the luminal surface of an enterocyte, causing widespread microvillus damage. (Courtesy R.J. Higgins and G.R. Pearson.)



222.5.6 *Yersinia pseudotuberculosis*

Yersinia pseudotuberculosis can be ingested when cats eat infected rodents or birds. The bacteria infect the GI tract, liver, and lymph nodes, causing marked weight loss, diarrhea, anorexia, lethargy, jaundice, and mesenteric lymphadenopathy. Treatment may be attempted with oxytetracycline or trimethoprim-sulfa, but the disease usually is progressive and fatal.

222.5.7 Tuberculosis

In dogs and cats, *Mycobacterium* spp. cause multisystemic, granulomatous infections that occasionally involve the GI tract. Cats may develop SI infection with *Mycobacterium bovis* from drinking infected cow's milk; the infection is associated with vomiting, diarrhea, weight loss, mesenteric lymphadenopathy, and peritonitis.

222.5.8 Miscellaneous Bacteria

Many GI bacteria may be opportunistic pathogens, and occasionally clinical signs are related directly to a specific organism. *Bacillus piliformis* is a rare disease that causes acute, fatal diarrhea in puppies and kittens (Tyzzer's disease). No effective treatment has been described. *Providencia alcalifaciens* was reported to cause primary bacterial enteritis in three dogs.[115]

222.6 RICKETTSIAL DIARRHEA (SALMON POISONING)

Neorickettsia helminthoeca and *Neorickettsia elokominica* are found in the metacercariae of the fluke *Nanophyetus salmonicola,* which is present in salmon in the western regions of the Cascade Mountains from northern California to central Washington. About a week after ingestion of infected salmon by dogs, the rickettsiae emerge from the mature fluke and cause a disease characterized by high fever, hemorrhagic gastroenteritis, vomiting, lethargy, anorexia, polydipsia, nasal-ocular discharge, and peripheral lymphadenopathy. Mortality is extremely high in untreated patients.

The diagnosis is based on a history of ingestion of raw fish in an endemic area, the detection of operculated fluke eggs in feces, and the presence of intracytoplasmic inclusion bodies in macrophages from lymph node aspirates. Oxytetracycline (7 mg/kg given intravenously three times a day) is the treatment of choice and should be continued for at least 5 days. The trematode vector is eradicated with praziquantel.

222.7 ALGAL INFECTIONS

Toxic algal blooms can lead to acute gastroenteritis and death in animals that drink contaminated water. Blue-green algae can synthesize an anticholinesterase that induces vomiting, diarrhea, ataxia, and rapid death in dogs. *Prototheca* spp. are achlorophyllous algae that cause protothecosis. Typically a cutaneous infection in cats, in dogs it can involve the intestine. LI disease is more common, but fatal disseminated disease affecting the SI has been reported.

222.8 FUNGAL INFECTIONS

Low numbers of fungi are found in the normal intestinal microflora and are generally not pathogenic. However, under the right circumstances, such as immunosuppression, they may invade the intestinal mucosa and even disseminate throughout the body. The incidence of these diseases varies worldwide; some are ubiquitous, some are localized to tropical and subtropical areas, and some are endemic in restricted areas. Intestinal infection with a variety of poorly septate molds and fungi is called *phycomycosis*. Of all cases, infection with *Pythium* spp. (pythiosis) is by far the most common. *Pythium insidiosum* may cause a primary intestinal infection.

1357 1358

222.8.1 Pythiosis

Pythiosis occurs sporadically throughout the world in tropical and subtropical climates. In the United States, pythiosis is most common in the states bordering the Gulf of Mexico. Animals may develop intestinal infection by ingestion of zoospore-contaminated water. Intestinal disease is seen most commonly from fall to spring after infection in late summer, when environmental conditions of warm, swampy water favor fungal growth.

222.8.1.1 History and Clinical Signs

Infection is more common in dogs than cats and typically occurs in young, large breed dogs under 3 years of age. Hunting dogs working in swamplike environments are the most likely to be exposed to infection. The organism can infect any part of the GI tract, but SI infection causes chronic, intractable, and sometimes bloody diarrhea. Vomiting, anorexia, depression, and progressive weight loss are usually noted. Infection is characterized by regions of transmural pyogranulomatous inflammation and ulceration. The bowel wall becomes greatly thickened, which may eventually result in partial or complete obstruction.

222.8.1.2 Diagnosis

On physical examination the most consistent findings in dogs with intestinal pythiosis are emaciation, with either one or more palpable abdominal masses or a thickened, irregular segment of bowel. Mild to moderate nonregenerative anemia and a mild neutrophilia with or without a left shift are typical. Definitive diagnosis can be made only by demonstration of branching, poorly septate or nonseptate hyphae in the tissues, because grossly, the mass or masses can resemble neoplasia at laparotomy. The organisms stain poorly with hematoxylin and eosin or periodic acid–Schiff (PAS) but are evident with Gomori methenamine silver stain. Recently an ELISA and a polymerase chain reaction (PCR) test have been developed.[116,117]

222.8.1.3 Treatment and Prognosis

The prognosis for phycomycosis is grave. Conventional treatment involves surgical excision followed by antifungal treatment. However, lack of ergosterol in the cell membrane makes azole derivatives largely ineffective. Euthanasia is often necessary, either because surgical excision is impossible or because of recurrence and wound dehiscence.

222.8.2 Zygomycosis

Other organisms have been isolated sporadically from cases of phycomycosis and are opportunistic pathogens in immunosuppressed patients. They are from the Zygomycetes class (zygomycosis), and include members of the Entomophthoraceae (e.g., *Basidiobolus* spp., *Conidiobolus* spp.) and Mucoraceae (e.g., *Absidia* spp., *Rhizopus* spp., *Mucor* spp., *Mortierella* spp.).

222.8.3 Histoplasmosis

H. capsulatum sometimes disseminates throughout the body, including the GI tract.

222.9 HELMINTHS

Helminthic infestation is common in dogs and cats. Some species are pathogenic in large numbers, and others are nonpathogenic.

222.9.1 Roundworm Ascarids

Toxocara canis and *Toxascaris leonina* are found in dogs, and *Toxocara cati* and *Toxascaris leonina* are found in cats. *T. canis* can be transmitted across the placenta and *T. canis* and *T. cati* through the milk. Infection is also caused by ingestion of the ova or of other hosts, such as rodents. The adult nematodes live in the SI. Migrating juvenile *T. canis* can cause hepatic, pulmonary, and occasionally ocular damage. *T. canis* presents a public health problem (i.e., visceral and ocular *larva migrans*).

222.9.1.1 Clinical Findings

Roundworms most often cause disease in young animals, and common signs are diarrhea, weight loss, or failure to thrive. A poor haircoat and a potbelly may be evident in puppies or kittens. Intestinal obstruction and perforation have been described in severe cases.

222.9.1.2 Diagnosis

Almost all puppies can be presumed to have *T. canis* infection. The diagnosis is made by fecal flotation (see Figure 222-7).

222.9.1.3 Treatment

A wide range of anthelmintics is effective against roundworms (Table 222-10). Treatment should be repeated at 2-to 3-week intervals in affected animals. Young animals should be routinely wormed at 2, 4, 6, 8, 12, and 16 weeks of age and then at least at 6-month intervals. It is important to ensure proper hygiene to stop reinfection or spread. *T. canis* can be controlled by administering fenbendazole to pregnant bitches at an oral dosage of 50 mg/kg given daily from day 40 to 2 days after whelping.

222.9.2 Hookworms

Ancylostoma caninum is the most important hookworm of dogs and is associated with blood loss and hemorrhagic enteritis. *Ancylostoma tubeforme* is the most common hookworm in cats but is less pathogenic. *Ancylostoma braziliense* occurs in dogs in the southern United States.

Uncinaria stenocephala is the hookworm of dogs in western Europe, although it also occurs in the northern United States and in Canada. Infection is most commonly reported in kenneled dogs, particularly greyhounds, and can be acquired prenatally, during lactation, by ingesting larvae, by migration of larvae through the skin, and by ingestion of a paratenic host.

222.9.2.1 Clinical Findings

Diarrhea, weakness, pallor, vomiting, dehydration, poor growth, and anemia are common in puppies with *A. caninum* infection. The infection can cause a rapid and fatal anemia or a more chronic iron deficiency anemia. *U. stenocephala* does not suck large quantities of blood and cause anemia, although severe infestations may be associated with diarrhea. Larval migration of *U. stenocephala* causes pedal pruritus.

222.9.2.2 Diagnosis

The diagnosis is made by demonstrating ova in feces (see Figure 222-7).

222.9.2.3 Treatment

Appropriate anthelmintics are detailed in Table 222-10. For *Ancylostoma* infection in anemic puppies, pyrantel pamoate has been suggested as the treatment of choice because it acts very rapidly and is comparatively safe. Anemic puppies may require blood transfusion and supportive care. Monthly administration of milbemycin or ivermectin plus pyrantel pamoate has been approved for the prevention or control of hookworm in dogs.

222.9.3 Tapeworms

Dipylidium caninum is the most common tapeworm infecting dogs and cats in the United States and Europe. Fleas are the intermediate host. *Echinococcus granulosus* is a tapeworm that uses dogs as definitive hosts, but humans and sheep are intermediate hosts. *E. granulosus* infection is not associated with clinical signs in dogs but is an important zoonosis. Various other *Taenia* spp. are also common in dogs and cats.

1358
1359

Table • 222-10 Common Anthelmintic Medications for Dogs

			SPECTRUM OF ACTIVITY	
DRUG	**DOSAGE**	**USUAL FORMULATION**	**NEMATODE**	**CESTODE**
Piperazine	83.2–300 mg/kg	Tablet	Yes	No
Pyrantel	5 mg/kg	Paste	Yes	No
Selamectin	6 mg/kg monthly	Topical Spot-on	Yes	No
Fenbendazole	20–100 mg/kg for 1–3 days	Granules, paste, suspension	Yes	*Taenia* sp.
Mebendazole	50 mg/kg for 2 days	Tablet	Yes	*Taenia, Echinococcus* spp.
Nitroscanate	50 mg/kg	Tablet	Yes (not *Trichuris* sp.)	*Taenia, Dipylidium caninum, (Echinococcus)* spp.
Pyrantel, febantel, praziquantel (combination)	1 tablet/10 kg	Tablet	Yes	*Taenia, Echinococcus* spp., *D. caninum*
Pyrantel, febantel (combination)	1 mL/kg	Suspension	Yes	*Taenia* sp., *D.caninum*
Dichlorophen	200 mg/kg	Tablet	No	*Taenia* sp., *D.caninum*
Praziquantel	5 mg/kg	Injection, tablet	No	*Taenia, Echinococcus* spp., *D. caninum*

222.9.3.1 Clinical Findings

Heavy infestations of *D. caninum* are only rarely associated with diarrhea, weight loss, and failure to thrive. There are usually no clinical signs except “rice grains” (proglottids) in the perineal area or feces.

222.9.3.2 Diagnosis

A diagnosis of *D. caninum* infection is made by demonstrating characteristic egg capsules, contained in proglottids, obtained from the perineal area or feces (see Figure 222-7).

222.9.3.3 Treatment

Treatment of *D. caninum* infection involves adequate flea control (the animal and the environment) and administration of an appropriate anthelmintic (see Table 222-10). *E. granulosus* and other *Taenia* spp. are best controlled by routine administration of praziquantel (see Table 222-10).

222.9.4 *Strongyloides* sp.

Strongyloides stercoralis is a small nematode that may cause hemorrhagic enteritis in young puppies. Infective larvae are ingested, transmitted transmammary or through penetration of the skin, and after migration through the lung develop in the SI.

222.9.4.1 Clinical Findings

Signs of hemorrhagic enteritis occur in young puppies.

222.9.4.2 Diagnosis

Fecal evaluation using the Baermann technique or demonstration of motile first-stage larvae in smears of fresh feces (see Figure 222-7) helps differentiate larvae from Filaroides and mature hookworms.

222.9.4.3 Treatment

Infection is treated with thiabendazole or possibly fenbendazole or ivermectin (see Table 222-10).

222.10 PROTOZOA

222.10.1 Coccidia

222.10.1.1 Isospora spp.

Isospora spp. are the most common coccidial parasites of dogs *(Isospora canis, Isospora ohioensis)* and cats *(Isospora felis, Isospora rivolta)*. Transmission occurs by ingestion of ova or paratenic hosts. Sporozoites are liberated in the SI and enter cells to begin development. The prepatent period ranges from 4 to 11 days, depending on the species. *Isospora* organisms are rarely associated with clinical signs. Puppies and kittens kept in unhygienic conditions or immunosuppressed animals may develop heavy infestations, which occasionally are associated with diarrhea that is often mucoid but sometimes bloody.

Isospora oocysts are found on direct examination of a fecal smear or by flotation. The infection is often self-limiting, but sulfadimethoxine (50 mg/kg given orally once daily for 10 days) or trimethoprim-sulfa (15

to 30 mg/kg given orally once daily for 5 days) can be used when clinical signs warrant treatment. The prognosis for recovery is good.

222.10.1.2 Cryptosporidium sp.

Cryptosporidium parvum, a significant pathogen in humans, is not a single species but is composed of genetically distinct genotypes. Transmission occurs by the fecal-oral route. Molecular studies have shown that dogs may transmit the cattle genotype to humans but that specific cat and dog genotypes also exist.[118] *C. parvum* has been associated with self-limiting diarrhea in dogs and cats and severe hemorrhagic diarrhea in immunocompromised animals.

Cryptosporidial oocysts are extremely small (approximately 1/10 the size of *Isospora* oocysts) and require identification by fecal flotation and oil immersion microscopy or by intestinal biopsy. 1359 1360

Paromomycin was reported to be effective against *Cryptosporidium* organisms in a cat. However, more recent studies have demonstrated that the drug's efficacy is poor and that it may cause acute renal failure. No other drugs are consistently efficacious, although nitazoxanide may prove to be effective. Fortunately, the disease is usually self-limiting in immunocompetent animals.

222.10.2 *Giardia* sp.

Giardia sp. can affect both dogs and cats. The prevalence of infection in canine studies ranges from less than 2% to 100% in kennels. Cats are less commonly infected than dogs. The parasite is usually transmitted via the fecal-oral route. Ingested oocysts excyst in the upper SI, and trophozoites attach to the intestinal mucosa from the duodenum to the ileum. After multiplication of trophozoites, oocysts are passed in the feces at 1 to 2 weeks after infection. Molecular epidemiologic studies indicate that giardiasis may be a zoonosis.[119]

222.10.2.1 Clinical Findings

Most infections are not associated with clinical signs. Clinical signs range from mild, self-limiting, acute diarrhea to severe or chronic small bowel diarrhea associated with intestinal protein loss and weight loss.

222.10.2.2 Diagnosis

Giardia infection can be diagnosed by demonstration of motile trophozoites in duodenal juice or on a fresh fecal smear or by demonstration of cysts by zinc sulfate fecal flotation. Shedding of cysts occurs intermittently, and three fecal analyses are 95% sensitive. *Giardia* antigen can also be detected by means of a fecal ELISA, and this is the preferred method of diagnosis compared to zinc sulfate flotation performed by inexperienced technicians.

222.10.2.3 Treatment

Metronidazole is the drug most commonly used to treat *Giardia* infection in small animals. The standard dosage recommended for dogs is 25 mg/kg given orally twice daily for 5 days; the standard dosage for cats is 10 to 25 mg/kg given orally twice daily for 5 days. The drug is effective at eliminating *Giardia* infection in two thirds of infected dogs but may cause side effects at these high doses.

Albendazole (25 mg/kg given orally twice daily for 2 days) and fenbendazole (50 mg/kg given orally twice daily for 3 days) also eliminate *Giardia* infection.[120] Fenbendazole is preferred, because albendazole has been associated with bone marrow toxicosis.[121] Febantel (in a combination product with praziquantel and pyrantel pamoate) is also effective in dogs.

Decontamination of the patient's coat by bathing and the patient's habitat by steam cleaning or cleaning with quaternary ammonium compounds is advised to prevent reinfection. A *Giardia* vaccine is available for use in high-risk areas, and it has been shown to be effective in clearing infection from dogs that failed to respond to standard drug therapy.[123]

222.10.2.4 Prognosis

The prognosis is usually good. Some patients may require several treatments to eliminate infection, because reinfection is a significant problem.

222.11 CHRONIC IDIOPATHIC ENTEROPATHIES

Chronic enteropathies have historically been defined by histologic description of the tissue, which provides little information as to the nature of the intestinal dysfunction or its etiology. Furthermore, tissue samples collected from many cases have no obvious morphologic changes. In the future, new methods of investigation may better characterize functional and immunologic abnormalities.

222.11.1 Management of Chronic Enteropathies

The management of idiopathic enteropathies is essentially symptomatic. If a specific diagnosis is made (e.g., lymphangiectasia, severe IBD, lymphoma), specific treatment modalities can be used (see below). However, in many circumstances the diagnosis is not obvious, often because of a lack of specific or marked histopathologic changes, and it usually is most appropriate to perform treatments sequentially. It is safest to commence with antiparasiticides, then a dietary trial, followed by an antibacterial trial, before finally attempting immunosuppression. Such an approach may identify occult parasitism, antibiotic-responsive diarrhea (ARD) and diet-responsive conditions. However, because different treatments also lack specific activities, caution should be exercised in using treatment trials for diagnosis without prior investigation.

222.11.1.1 Antiparasiticides

An appropriate trial of an antiparasiticide should eliminate the possibility of parasitic diseases, such as chronic giardiasis, that are difficult to diagnose. Fenbendazole (50 mg/kg given orally every 24 hours for 3 days) is the most appropriate drug for these circumstances, although alternatives exist (e.g., metronidazole or a febantel/pyrantel/praziquantel combination). Given the highly infectious nature of *Giardia* organisms, all in-contact animals may need to be treated concurrently or reinfection may occur, which might suggest apparent treatment failure.

222.11.1.2 Dietary management

Dietary management is a very important treatment modality in most chronic enteropathies and can be used in different ways. For diagnosis and treatment of adverse food reactions, an antigen-limited exclusion diet

is most appropriate (see below). Dietary management also can be important in the symptomatic management of many idiopathic enteropathies. The ideal diet is highly digestible, moderately fat restricted, lactose free, gluten free, not markedly hypertonic, nutritionally balanced, and palatable.

Inclusion of moderately fermentable fiber (e.g., psyllium, ispaghula) is known to promote colonic health, and soluble fiber also promotes small intestinal health.[124] However, because dietary fiber can delay intestinal transit, its inclusion may be contraindicated for some intestinal diseases. Feeding the daily requirement in divided meals (usually between two and four) reduces the load on a compromised intestine. Feeding more frequently is unnecessary, because the rate of gastric emptying imposes natural trickle feeding of the intestine.

Additional supplements include prebiotics such as fructo-oligosaccharides (FOS) and mannanoligosaccharides.[16,17,125,126] FOS has been shown to alter the constituents of the fecal flora, but the effect on the SI flora is limited.

222.11.1.3 Antibacterials

Antibacterials are indicated for specific conditions in which a bacterial pathogen has been documented (see above), in the treatment of ARD or secondary SIBO, and in other chronic enteropathies, such as IBD, in which modulation of the flora may be required. The drugs most commonly used in these circumstances are oxytetracycline, metronidazole, and tylosin. The beneficial effects of such drugs may go beyond their antibacterial activity, with potential effects on the mucosal immune system.

222.11.1.4 Immunosuppressive medication

Immunosuppressive or anti-inflammatory drugs are indicated when evidence of mucosal inflammation is present and no underlying cause is found. However, given that immunosuppression may lead to clinical deterioration in some cases, the diagnosis should be reviewed before institution of such therapy, especially if the diagnosis was made on the basis of endoscopic biopsy alone.

1360
1361

222.12 ADVERSE REACTIONS TO FOOD

An adverse reaction to food is a repeatable, unpleasant response to a dietary component that is a manifestation of an immunologic reaction to a dietary antigen (i.e., a true food allergy) or a nonimmunologic reaction (i.e., an intolerance). Although different pathogenetic mechanisms are responsible for the two groups, the clinical signs are similar, and the approach to treatment is the same, usually involving exclusion of the offending food component.

Food intolerance may be associated with a single ingredient of a prepared food (e.g., lactose, preservative) that may be present in immunologically unrelated foods. Conversely, confirmed allergy to a specific food may impart allergy to related foods. In humans, food intolerance is diagnosed more frequently than hypersensitivity, but its true prevalence in small animals is unknown. A recent study in cats demonstrated that 29% of cats had adverse food reactions, and a further 20% responded completely to diet and did not relapse.[127] However, the number of these reactions that were immunologically mediated was not documented.

222.12.1 Food Allergy (Hypersensitivity)

The prevalence of true food allergy is unknown because no reliable diagnostic tests are available. Furthermore, food allergy with GI signs may be more difficult to prove than cases in which dermatologic signs prevail. This is partly because other GI diseases may also respond (for nonallergenic reasons) to dietary manipulation (Box 222-13). The management of food allergy is simple: feed any food that does not contain the allergen, and the animal will be healthy. The difficulty for the clinician lies in the recognition of food allergy and the identification of foods that must be excluded.

222.12.1.1 Mechanisms

Currrent hypotheses of food allergy propose one or a combination of mechanisms that lead to breakdown of oral tolerance: an inadequate mucosal barrier, abnormal presentation of dietary antigens to the mucosal immune system, or immune system dysregulation (see earlier discussion). Such hypotheses could explain both genetic susceptibility to the development of allergy and the development of allergies after a primary GI insult that damages the mucosal barrier. For example, viral or parasitic enteritis can both damage the mucosal barrier and provide danger signals in the intestinal mucosa. Active immune responses, rather than tolerance, can then occur to bystander antigens (i.e., sensitization to dietary antigen). Dietary hypersensitivity may involve a variety of mechanisms, including type I (IgE mediated, immediate), type II (immune complex mediated), and type IV (delayed hypersensitivity) reactions.

222.12.1.1.1 Box • 222-13 Conditions that May Improve Clinically in Response to Dietary Modification

Food allergy

Food intolerance

Gastroesophageal reflux

Gastric emptying disorders

Portosystemic shunt

222.12.1.2 Clinical Signs

A contemporaneous association between ingestion of a particular food and the onset of signs is suggestive of an immediate (type I) IgE-mediated hypersensitivity, but mixed or delayed reactions are also possible. In such cases the inevitable delay between food ingestion and onset of signs obscures any causative link, particularly if repeated ingestion causes chronic disease.

Clinical signs of food allergy generally involve the skin and GI tract (Box 222-14). Most case studies have focused on dermatologic signs, with few reports of food-allergic GI disease.[128] Systemic signs (anorexia, lethargy) are rarely recorded, and urticaria-angioedema and even anaphylaxis seem rare. Concurrent skin and GI signs can occur but have been reported only rarely.[129] However, only 5% of human patients with gluten-sensitive skin lesions (dermatitis herpetiformis) have GI signs, yet intestinal histologic examination shows a subclinical enteropathy in 95% of these individuals.

222.12.1.2.1 Food-allergic skin disease

1361

1362

The major sign of food-allergic skin disease is pruritus, which is nonseasonal and has no characteristic distribution, although pedal pruritus, facial pruritus, and otitis externa may be noted. Excoriation, crusting, scaling, and lichenification arise through self-trauma and may predispose to secondary pyoderma. In cats, food allergy may also result in miliary dermatitis, eosinophilic granuloma complex, or symmetric alopecia.

Diarrhea

Small intestinal–like signs

Colitis-like signs

Abdominal pain, “colic”

Weight loss and/or stunting

Altered appetite

222.12.1.2.2 Food-allergic gastrointestinal disease

Signs of food-allergic gastrointestinal disease are not pathognomonic and include vomiting, diarrhea, abdominal pain, flatulence, borborygmi, and weight loss or failure to thrive.

222.12.1.3 Diagnosis

The cornerstone of the diagnosis of a food allergy is the response to dietary manipulation. Clinical signs should resolve on exclusion of the offending dietary component and return with rechallenge. Unfortunately, objective criteria by which to judge such a response are lacking, and other diseases also may respond to dietary manipulation (see Box 222-14). Furthermore, diagnosis requires confirmation with rechallenge studies, but many clients refuse to pursue this.

222.12.1.3.1 Indirect tests

Given the difficulties of diet trials, indirect tests for food allergy have been devised; unfortunately, none are reliable in veterinary medicine.

Antigen-specific serum antibodies to food components can be measured *in vitro* (by radioallergosorbent testing [RAST] or ELISA), and a number of laboratories now offer this commercially. In most situations IgG and/or IgE responses to different food components are assessed. Subjectively, clinicians who use such tests believe them to be of value, but critical appraisal suggests that they are unhelpful.[130] The use of such tests is flawed for many reasons. First, antibodies to food components can be found in normal individuals, therefore the presence of antibody in an affected individual may be incidental. Second, because vaccines may contain bovine serum albumin, individuals may develop antibodies to beef antigens. Third, some tests assess only IgG responses, therefore they may miss humoral responses of other antibody classes and cell-mediated responses. Fourth, because the affinity of antibodies formed to a particular antigen in different individuals may vary, not all may be detected in the immunoassay, and some may not react at all (if the *in vitro* antigen is not relevant). Fifth, the presence of antibodies does not necessarily prove primary food hypersensitivity, because the antibodies they may have arisen secondary to another underlying disease process (e.g., IBD).

It has been shown that dogs with chronic GI disease arising from a number of causes had greater levels of food-specific IgG than healthy or atopic dogs.[130] However, these findings did not correlate with the animals' response to exclusion diet trials. Thus any perceived benefit of dietary modification after food antigen testing may be coincidental. Given that most clinicians do not go on to prove a causal association by food provocation, such an coincidence is misinterpreted.

Skin testing has also proved unreliable in the diagnosis of food-allergic skin disease.

Gastroscopic food sensitivity testing (*GFST*), in which dietary antigens are instilled directly onto the gastric mucosa in an anesthetized patient, theoretically should give more specific results for cases presenting with GI signs. However, correlation between the results of GFST and the results of clinical challenge trials is poor. The method is tedious, technically demanding, and prone to artifacts and detects only immediate hypersensitivities. Using the colonic mucosa as the testing surface [colonoscopic allergen provocation (COLAP) testing] may be simpler but has not been widely adopted.[131,132]

222.12.1.3.2 Dietary trial (see below)

Dietary trial is the only reliable way to confirm the presence of dietary sensitivity, although such trials do not distinguish food intolerance from allergy.

222.12.2 Food Intolerance

Gluttony, scavenging, and food poisoning are common and may be considered examples of food intolerance. However, these tend to occur as isolated incidents causing acute GI signs. In contrast, true food intolerances are repeatable, but they may be either predictable or unpredictable. Predictable food intolerances occur in any animal after ingestion of a contaminated foodstuff or after consumption of a recognized toxin or excessive amounts of food. In contrast, unpredictable food intolerances (although repeatable in a susceptible individual) are the result of idiosyncratic reactions. Reasons for idiosyncrasies include differences (genetic or otherwise) in intestinal enzyme activities, intestinal permeability, postabsorption metabolism, and mast cell stability, as well as differences in the intestinal flora.

222.12.2.1 Mechanisms

Most of the suggested mechanisms of food intolerance are complex and often extrapolated from humans and consequently may not be valid for dogs and cats.

222.12.2.1.1 Food poisoning

Food poisoning incidents are most common in dogs that scavenge. Clinical signs are the result of toxicosis, usually caused by the presence of a toxin or by contamination with toxin-producing organisms. Furthermore, the term *food poisoning* also can be applied to infection by organisms that have multiplied in the food and subsequently cause acute GI signs.

222.12.2.1.2 Pharmacologic intolerances

These food intolerances result from the presence of pharmacologically active compounds (e.g., chocolate poisoning caused by excessive intake of methylxanthines). In humans, intolerances may result from naturally occurring compounds (e.g., vasoactive amines, cardiac glycosides, plant alkaloids, and fungal hallucinogens) or substances produced by intestinal bacterial metabolism. Similar reactions are likely to occur in animals, although reports are lacking.

222.12.2.1.3 Pseudoallergic mechanisms

These adverse reactions are histamine mediated, although they arise from nonimmunologic mechanisms. A high histamine concentration may be present naturally in some foods (e.g., tuna, mackerel, and some commercial dog foods) or because of histamine-producing bacteria (e.g., cheese or canned fish contaminated with *Proteus* or *Klebsiella* organisms). Some foods (e.g., shellfish, strawberries) and food additives (e.g., tartrazine) can cause histamine release from mast cells without IgE mediation. This mechanism is well documented in humans,[133] but its relevance to small animal food intolerances is unknown.

222.12.2.1.4 Metabolic reactions

Such reactions are poorly documented in small animals. Carbohydrate malabsorption and intolerance may be features of a number of intestinal diseases, whereas specific intolerance to lactose can be associated with lactase deficiency (see earlier). However, allergy to bovine milk proteins or previously subclinical intestinal disease may be the reason for clinical signs in animals that react adversely to milk ingestion.

222.12.2.2 Clinical Signs

The clinical signs of food intolerance, which are related to the GI tract, include vomiting, diarrhea, and abdominal discomfort. However, pruritus and even anaphylaxis are possible if histamine release is involved.

222.12.2.3 Diagnosis

The only reliable means of diagnosing food intolerance is by monitoring the responses to an exclusion diet and subsequent diet challenge. Again, such trials do not define the exact pathogenetic mechanism involved. The results of serologic food allergy testing are unhelpful and may even complicate the diagnosis.

222.12.2.4 Treatment

Treatment is simple once a diagnosis has been made: avoidance of the offending food prevents the occurrence of signs.

222.12.3 Dietary Trials for Adverse Food Reactions

Dietary trials are required to diagnose both food hypersensitivity and intolerance, but they do not distinguish between them. Objectivity in assessing the response to diet can be enhanced by measuring changes in intestinal permeability,[134] although not all adverse reactions may cause such changes. Although histopathologic changes could also be used to monitor response, the lack of pathognomonic findings for food sensitivity makes interpretation difficult.

222.12.3.1 Preliminary investigations

There are no pathognomonic signs for adverse food reactions, and other major differential diagnoses (which may also respond to dietary change) should be ruled out before an exclusion diet trial is begun (see Box 222-13). After a minimum database has been compiled, specific investigations of the skin and GI tract should be performed. Ectoparasites and secondary skin infections, as causes of pruritus, should be diagnosed and treated before a food trial is considered. Endoparasites should be excluded through examination of three fecal samples or by empirical fenbendazole treatment. Intestinal biopsy should be performed to look for morphologic diseases, although in many cases no histologic changes are apparent or there may be overlap with changes seen in idiopathic IBD (Box 222-15).

222.12.3.2 Exclusion

The principle of an exclusion (elimination) diet is to feed dietary components to which the animal has not previously (or recently) been exposed. This diet should be the sole source of nutrition for the duration of the trial. Complete owner compliance is essential, and it must be stressed that all treats and supplements must be withheld. Options for exclusion diets include home-prepared diets, single-source protein diets, and hydrolyzed protein diets. Home-cooked diets have been preferred to commercial diets because of reports of relapse when patients are switched to an equivalent commercial diet.[135,136] However, many clinicians recommend the use of a commercial diet initially, because it is easier for the owner and thus compliance is enhanced.

222.12.3.2.1

Box • 222-15 Histologic Gastrointestinal Biopsy Changes Sometimes Suspected to be Manifestations of Food Allergy but also Seen in Other Gastrointestinal Diseases

Intraepithelial lymphocyte infiltration

Villus atrophy (partial or subtotal)

Decreased enterocyte height

Lymphoplasmacytic gastritis

Lymphoplasmacytic enteritis

Eosinophilic gastroenteritis

A traditional *exclusion diet* is composed of single protein and carbohydrate sources. If a home-cooked diet is used, it is unlikely to be nutritionally balanced, but this is not important for the short duration of the trial. Lamb or chicken with rice have been the standard choices, but given the increased diversity of commercial pet foods, these components are not always appropriate. Thus more esoteric food sources have become a requirement. An alternative to home-prepared diets is use of a commercial exclusion diet, and a wide range is now available, containing different sources of protein (e.g., chicken, soy, fish, catfish, venison, or duck) and carbohydrate (e.g., rice, corn [maize], tapioca, or potato). It should be possible to find an appropriate diet in most cases, although manufacturers cannot always guarantee a constant supply of diets with more exotic components.

Recently, hydrolyzed protein diets, usually based on either chicken or soy protein, have become available. In principle, the hydrolysis process splits proteins into components of a molecular weight below that which would be expected to elicit an immune response.[137] To completely abolish all antigenicity, peptides probably need to be less than 1 kD, and at that size they have a bitter taste. At the size achieved in palatable hydrolyzed diets (7 to 10 kD), antigens should still be unable to cross-link IgE molecules on mast cells, and type I reactions would be abolished. However, the hydrolysis process itself might expose hidden antigenic epitopes. Hydrolyzed diets are also significantly more expensive to produce than standard exclusion diets, and both palatability and owner compliance may be problematic. Nevertheless, such diets are currently the easiest way to guarantee the feeding of novel antigens, and this approach may become the preferred method in the future. Preliminary studies have suggested a beneficial effect of such diets,[138,139] although it had not been proved that such diets have an advantage over traditional single-source protein exclusion diets.

222.12.3.3

Challenge

Once remission is achieved, the animal should be challenged with the original diet to demonstrate relapse and confirm the diagnosis. Some animals may not relapse,[127] perhaps because the mucosal barrier has been

restored and further reactions are prevented. However, some clients refuse challenge, particularly if relapse is likely to bring recurrence of diarrhea.

222.12.3.4 Rescue and provocation

After relapse on challenge, for clients who are willing, a series of provocation tests can be performed to identify the offending food or foods. Remission is regained by "rescue" with the exclusion diet, and single foodstuffs are then introduced sequentially as provocation tests. If there is no relapse, the food is identified as "safe," and the next food is tested; if there is a relapse, rescue is repeated and the food is identified as "unsafe."

222.12.3.5 Maintenance

When all the offending foods have been identified, or at least sufficient safe ones have been recognized to permit the choice of a regular diet, the animal is maintained on a safe commercial version. Studies in both cats and dogs have shown that, subsequent to the food trial, most animals can be maintained on one of the available antigen-limited diets.[135,136]

222.12.3.6 Protocol

A standardized protocol for food trials has not been established. The optimum duration for an exclusion diet trial is unknown, and 3 weeks has been chosen arbitrarily. However, cases of food-allergic skin disease may require up to 10 weeks to respond. Response is considered to be quicker in cases of food-allergic GI disease, such that it is rarely necessary to feed the exclusion diet for this length of time when it may become difficult to maintain owner compliance. Challenge trials and provocation tests are usually conducted for up to 14 days but are discontinued earlier if signs recur on 2 consecutive days.

1363

1364

222.12.3.7 Treatment

A number of gluten-free proprietary diets based on lamb, fish, or chicken are available; these are often suitable as maintenance diets, and they are preferred over home-prepared meals because they are nutritionally balanced. Hydrolyzed diets are an alternative. Assuming a correct diagnosis, dietary management should be all that is required, and the diagnosis should be re-evaluated if treatment failure occurs.

222.12.4 Gluten-Sensitive Enteropathy

SI disease induced by the presence of dietary wheat gluten has been clearly documented in Irish setters.[140,141] The condition resembles gluten-sensitivity (celiac disease) in humans, although intestinal damage and clinical signs are less marked. Celiac disease shows a clear genetic predisposition with a strong association with the MHC II haplotype HLA-DQω2. In Irish setters, it is a familial condition with an autosomal recessive mode of inheritance.[142] However, unlike human celiac disease, there is no relationship with major histocompatibility genes DQA and DQB,[142,143] and the pathogenesis is different. The disease may affect other dog breeds, but it has not been reported in cats. Gluten sensitivity has been suggested in soft-coated wheaten terriers[144,145] with protein-losing enteropathy and/or nephropathy.

222.12.4.1 Pathogenesis

Despite the apparent similarities with celiac disease, the pathogenesis of gluten-sensitive enteropathy (GSE) is different.[146] Clinical signs are caused by ingestion of the wheat protein gluten (or one of its digestion products), which is either directly toxic to the intestinal mucosa or induces an adverse immune reaction. Remission of clinical signs and histologic and biochemical changes occurs on a wheat/gluten-free diet, and signs relapse when gluten-containing diets are reintroduced.

In some studies, abnormal mucosal permeability that precedes the development of disease has been documented in affected Irish setters.[147] This implies that a breakdown in the mucosal barrier may play an important role in the pathogenesis by permitting abnormal entry of gluten peptide.[147] In contrast with human celiac disease, immunoglobulin responses to gluten or endomysial antigens are not noted.[146] However, involvement of the immune system is suggested by the fact that increased lamina propria CD4+ T-cell populations and decreased CD8+ populations have been described in affected dogs.[148]

The age of the animal at which gluten is introduced and the dose may affect expression of the disease, with some dogs becoming asymptomatic later in life.[149] The pathogenesis of Irish setter GSE, therefore, remains incompletely characterized, and mechanisms distinct from those underpinning human celiac disease are likely.

222.12.4.2 Clinical Signs

Affected Irish setters typically present with poor weight gain and chronic intermittent diarrhea in the months after weaning. Histologic changes in jejunal biopsies show partial villus atrophy and intraepithelial lymphocyte infiltration, with a variable lamina propria infiltrate. These changes resolve when a gluten-free diet is fed and relapse on wheat and gluten challenge.[141]

222.12.4.3 Treatment

Successful treatment depends on the exclusion of gluten from the diet, and the use of a proprietary gluten-free food (i.e., lacking wheat, barley, or rye) is recommended.

222.13 SMALL INTESTINAL BACTERIAL OVERGROWTH

Normally the bacterial population of the SI is controlled by a number of mechanisms (see above). Bacterial overgrowth is the uncontrolled proliferation of these bacteria[150] and, in humans, occurs secondary to a number of underlying disorders that interfere with the control mechanisms. Although the existence of SIBO in humans is not disputed, the subject is a source of controversy in small animal gastroenterology. In dogs, SIBO is best considered a clinical sign or a pathogenetic mechanism rather than a diagnosis. Historically, the term *idiopathic SIBO* was used to describe an antibiotic-responsive condition of large breed (especially German shepherd) dogs[44] for which no underlying cause could be recognized. However, given concerns as to whether a true overgrowth exists in these cases, the alternative name of *antibiotic-responsive diarrhea* has been suggested.[77,151] Although cats might feasibly suffer from secondary SIBO, an idiopathic antibiotic-responsive condition similar to that seen in German shepherds has not been documented in this species.[152]

222.13.1 Definition

Genuine bacterial overgrowth is defined by an increase in the absolute number of bacteria in the upper SI during the fasted state (i.e., the number of colony-forming units cultured per milliliter of duodenal juice [CFU/mL]). The upper limit for normal bacterial numbers was defined in humans, and that number has been extrapolated to dogs. Controversy exists as to its validity, however, because the original work used a small number of dogs and questionable bacteriologic techniques.[15] Subsequent studies with different collection methods and improved anaerobic culture techniques have demonstrated that a count equal to or greater than 10^7 CFU/mL total bacteria is commonly found in asymptomatic dogs.[15] Therefore, although a genuine bacterial overgrowth may exist in conditions equivalent to those in humans, defining the presence of SIBO based on the original numeric limit is flawed. In this chapter, cases with a documented underlying cause are defined as *secondary SIBO,* and the term *idiopathic ARD* is used for idiopathic antibiotic-responsive conditions without an obvious underlying cause.

222.13.2 Etiology and Pathogenesis

222.13.2.1 Secondary SIBO

SIBO can occur secondary to (1) diseases that result in excess substrate in the intestinal lumen (e.g., EPI, motility disorder, blind loop), (2) diseases that affect the clearance of bacteria (e.g., partial obstruction, abnormal motility), or (3) morphologic or functional derangement of the mucosa (Box 222-16). Increased numbers of bacteria in the upper SI cause malabsorption and diarrhea through several mechanisms. First, bacteria compete for nutrients; for example, by binding cobalamin and reducing its availability for absorption. Second, bacterial metabolism of nutrients can create products that provoke diarrhea (e.g., hydroxylated fatty acids and deconjugated bile salts), leading to diarrhea from fat malabsorption and stimulation of colonocyte secretion. Finally, the bacterial flora may damage the mucosal brush border, and alterations in enzyme activity, which reverse on antibiotic treatment, can be detected.[44,153]

222.13.2.2 Idiopathic ARD

A number of hypotheses exist as to the cause of idiopathic ARD. Historically, hypotheses were based on the belief that a genuine increase in SI bacterial numbers was present and therefore pathogenesis was related to the mechanisms described above. An underlying defect allowing overgrowth was not obvious, and suggested mechanisms such as abnormal intestinal motility or achlorhydria were not proved.

Given that recent studies have questioned whether a genuine increase in bacterial numbers occurs, recent hypotheses now focus on host-bacterial interactions. As was suggested for mouse models of enteric inflammation (see Table 222-1), ARD may develop secondary to defects in the mucosal barrier, aberrant mucosal immune responses, qualitative changes in the enteric bacterial flora, or a combination of these mechanisms. Defects in the mucosal barrier are supported by studies documenting abnormal permeability and the presence of brush border enzyme defects.[44,153] A possible underlying selective IgA deficiency in the German shepherd breed has been postulated.[154] German shepherds with intestinal disease have defective small intestinal IgA production, although mucosal IgA+ plasma cell numbers in affected dogs are either normal or increased. The cause of this IgA deficiency is not clear, but a complex defect is likely,

involving abnormalities either in the production and release of IgA from the plasma cell or in the pathway of translocation of IgA across the epithelium during secretion.

Dietary sensitivity (?)

Studies demonstrate that dogs with ARD have increased lamina propria CD4+ T cells and increased expression of certain cytokines.[81,155] It therefore is tempting to speculate that this represents immune dysregulation and perhaps a loss of tolerance toward endogenous bacterial antigens. Such a hypothesis is supported by the fact that antibacterials lead to resolution of clinical signs and decreased cytokine expression but not to a decline in bacterial numbers.[81] The fact that the most effective antibacterials are those with immune-modulating properties (e.g., oxytetracycline, metronidazole, tylosin) may support this hypothesis.

An alternative hypothesis is that an unidentified pathogen is involved; candidates include intestinal *Helicobacter* spp. or enteropathogenic *E. coli*. The predisposition of German shepherds to this syndrome could therefore be explained by genetic susceptibility to infection as a result of MHC II antigen expression.

222.13.3 Clinical Presentation

222.13.3.1 Idiopathic antibiotic-responsive diarrhea

Idiopathic ARD is most commonly recognized in young German shepherds, although cases have been reported in other dog breeds (but not in cats). Affected dogs show signs of chronic intermittent diarrhea accompanied by weight loss and/or stunting. Intermittent, watery diarrhea, often associated with excessive gas production (manifested as borborygmi and flatus), is seen most frequently. However, vomiting and signs of colitis are sometimes reported, and occasionally dogs are stunted yet do not have diarrhea. Activity levels are normal, and appetite is variable; most affected dogs have polyphagia, pica, or coprophagia, but few are anorectic. A positive response to antibiotics is expected, and the clinical condition may deteriorate if corticosteroids are given. The major differential diagnoses are EPI and IBD, both of which are common in German shepherds.

222.13.3.2 Secondary SIBO

SIBO may occur secondary to numerous primary conditions (see Box 222-16), and clinical signs usually relate to the underlying condition. However, signs of secondary SIBO also can been seen and are indistinguishable from those of idiopathic ARD, with diarrhea predominating. When SIBO develops secondary to a partial obstruction or focal dysmotility, bacterial numbers can exceed 10^9 CFU/mL.[150] Clinical signs may be noted intermittently, because recurrent diarrhea can temporarily flush out the overgrowth.

Using the historical numeric cutoff of 10^5 CFU/mL total bacteria, secondary SIBO was considered common in chronic enteropathies.[156] In reality, true secondary SIBO is uncommon, with the exception of SIBO secondary to EPI. An increase in SI bacterial numbers has been documented in experimentally induced EPI, although bacterial numbers decrease upon treatment of EPI with enzyme replacement. Therefore in many cases the SIBO itself is of no significance. However, a proportion of naturally occurring EPI cases respond suboptimally to pancreatic enzyme supplementation alone and may require concurrent antibiotic therapy. Given that the majority of dogs affected with EPI are German shepherds, it is not clear whether this is the result of secondary SIBO or of a concurrent idiopathic ARD.

222.13.4 Diagnosis

The diagnosis of SIBO and ARD is controversial. In all cases it is critical that a thorough investigation be conducted to eliminate causes of secondary SIBO before the patient is treated with antibacterials. In this regard, diagnostic imaging, especially ultrasonography, is useful for ruling out partial intestinal obstructions. Systemic disorders should be ruled out with a minimum database, and EPI is eliminated by serum TLI assay. Fecal examination for parasitic and bacterial diseases is also mandatory.

222.13.4.1 Idiopathic ARD

Although both direct and indirect tests were previously advocated for idiopathic SIBO, recent studies have suggested that they are all of limited value.[77] One recent study demonstrated that neither indirect biochemical markers (folate, cobalamin, unconjugated bile acids) nor quantitative bacterial culture could reliably identify cases of ARD. Therefore the only available diagnostic test for ARD is response to an antibacterial trial. However, such a diagnostic modality is appropriate only after thorough diagnostic investigations have eliminated all other causes of an antibacterial responsiveness.

222.13.4.2 Secondary SIBO

Although numerous tests are available to document secondary overgrowth (see below), in practice it is more important to identify the underlying cause.

222.13.4.3 Duodenal juice culture

Quantitative aerobic and anaerobic culture of duodenal juice previously formed the gold standard for diagnosis. For dogs, increases in either total or anaerobic bacteria above the upper cutoff (10^5 CFU/mL total bacteria or 10^4 CFU/mL anaerobic bacteria) were considered diagnostic. However, the validity of these cutoffs has been questioned. A count of 10^7 CFU/mL total duodenal bacteria has been documented commonly in healthy dogs, and numbers as high as 10^9 CFU/mL have been found occasionally in cats and asymptomatic dogs.[13–15] Some of the discrepancies may reflect difficulties and differences in the methodology, because numbers vary widely when individual animals are repeatedly sampled.[84] Use of an inappropriately low cutoff value leads to overdiagnosis of SIBO, which probably explains why it has been reported in 50% of dogs with chronic intestinal disease.[156] Culture of endoscopic biopsies has not been shown to be of greater diagnostic utility.[84]

The flora present in idiopathic antibiotic-responsive diarrhea may be comprised predominantly of either aerobic or anaerobic bacteria, but it tends to be a mixed population, with staphylococci, streptococci, coliforms, enterococci, and corynebacteria and anaerobes such as bacteroids, fusobacteria, and clostridia. These bacteria generally are commensals found normally in the oropharynx, small intestine, and large intestine. However, culture of fecal bacteria cannot be correlated with SI bacterial numbers and cannot be used to diagnose this condition.

222.13.4.4 Indirect tests for SIBO/ARD

Indirect tests include serum biochemical markers and breath hydrogen analysis.

222.13.4.4.1 Serum folate and cobalamin concentrations

Bacteria synthesize folate and bind cobalamin, preventing its absorption. Therefore SIBO would be predicted to be associated with an increased serum folate concentration or a decreased cobalamin concentration, or both. Although such results would be expected in cases of genuine SIBO (e.g., secondary SIBO), no studies have specifically assessed the usefulness of these tests in those diseases. Alterations of serum folate and cobalamin noted in EPI may reflect pancreatic dysfunction rather than secondary SIBO.

Furthermore, recent studies have demonstrated that these tests are of limited value in the diagnosis of idiopathic ARD.[77] This poor performance may be related to dietary factors, the presence of concurrent disease, or the use of drugs that alter serum vitamin concentrations. The other possibility (for idiopathic ARD) is that disease pathogenesis is not related to genuine increases in bacterial numbers. Although these tests are often the only tests available to practitioners, they are generally unhelpful in the diagnosis of idiopathic ARD.

222.13.4.4.2 Serum unconjugated bile acids

Bile acids are synthesized and conjugated in the liver and excreted into the intestine via the biliary tract. Some SI bacterial species can deconjugate bile acids, which then are absorbed passively by the SI. Studies in humans have suggested that increased serum unconjugated bile acid (SUBA) concentrations are an indirect indicator of SIBO. A preliminary study in dogs suggested that SUBA concentrations increased in SIBO.[76] However, these results have been contradicted by another recent study, which demonstrated that SUBA concentrations were neither sensitive nor specific for diagnosis of idiopathic ARD.[77] Further work may be required to clarify the diagnostic value of SUBA concentrations in dogs.

222.13.4.4.3 Other biochemical tests

Measurement of increased amounts of a bacterial product made either naturally or after oral administration of a test substance could be used to diagnose SIBO, but none of these are reliable.

222.13.4.5 Breath hydrogen excretion

Bacterial fermentation in the intestinal tract releases hydrogen which, after systemic absorption, is exhaled and can be measured in breath samples. Theoretically, SIBO can result in a high resting breath hydrogen concentration or an early (or double) hydrogen peak after ingestion of a test meal. However, increased breath hydrogen can also be seen with carbohydrate malabsorption or decreased orocecal transit time. Given these problems with interpretation and the fact that protocols have not been standardized, breath hydrogen testing has not been widely adopted.

222.13.4.6 Intestinal permeability

Intestinal permeability, as measured by ^{51}Cr-EDTA and differential sugar absorption, can be abnormal in SIBO and can improve after antibiotic treatment. However, such findings are not pathognomonic for either secondary SIBO or idiopathic ARD.

222.13.4.7 Lack of histologic changes on intestinal biopsy

Histopathologic examination of intestinal biopsies is most often normal or demonstrates only subtle abnormalities. However, such findings are not pathognomonic, because other conditions yield similar results. Despite the lack of histologic evidence of inflammation, disturbances in immune cell populations have been noted, most notably increases in IgA+ plasma cells and CD4+ cells. However, such techniques have not been applied for routine diagnostic purposes.

222.13.4.8 Empiric response to antibiotics

Currently, the best diagnostic test for idiopathic ARD is, logically, the response to empirical therapy. However, a response to antibacterials is not specific and indeed may be beneficial in IBD, infectious diarrhea, and even a range of nonenteric diseases such a portovascular anomalies. Furthermore, response to antibiotic therapy does not discriminate idiopathic ARD from secondary SIBO. Therefore an empirical response to antibiotics is valid only after thorough diagnostic investigations have eliminated other possible causes.

The suggested criteria for a diagnosis of idiopathic ARD are (1) a positive response to the antibiotic trial based on resolution of relevant clinical signs; (2) relapse of signs upon withdrawal of treatment; (3) remission on reintroduction of antibiotics; and (4) elimination of other etiologic causes based on the results of other diagnostic tests and histopathologic assessment.

222.13.5 Treatment

222.13.5.1 Secondary SIBO

Although antibacterial therapy improves clinical signs, appropriate treatment for the underlying condition is preferable. For EPI, pancreatic enzyme supplementation can reduce bacterial numbers because exogenous proteases have antibacterial properties.

222.13.5.2 Idiopathic ARD

No cure is available for idiopathic ARD, but signs can be controlled with antibacterials. A broad-spectrum antibiotic is indicated; suitable choices include oxytetracycline (10 to 20 mg/kg given orally every 8 hours), metronidazole (10 to 20 mg/kg given orally every 8 hours), and tylosin (20 mg/kg given orally every 8 or every 12 hours). Oxytetracycline (OTC) is cheap, and because systemic absorption is not required, it can be given with food. It cannot be used before permanent tooth eruption because it causes staining of tooth enamel. Some authors have criticized the use of OTC because it is associated with rapid development of plasmid-mediated antibiotic resistance.[151] However, given that long-term efficacy is maintained in most

cases, OTC may not be acting through its antibacterial properties, because it does not significantly reduce SI bacterial numbers.[81] Rather, it may provide a selective pressure on the intestinal flora, encouraging the establishment of less harmful bacteria, or it may exert immunomodulatory effects, which this antibiotic group has. Immunomodulatory activity has also been suggested for other antibacterials commonly used to treat ARD, namely metronidazole and tylosin.

Whichever antibacterial is chosen, a 4-to 6-week course is appropriate initially, although the antibiotic should be changed after 2 weeks if the response has been suboptimal. In some cases, premature cessation of treatment can lead to relapse, and prolonged therapy often is necessary. In some animals a delayed relapse occurs several months after cessation of antibiotics, and such cases require either repeated courses or indefinite therapy. Efficacy is often maintained despite a reduction in dosage frequency from three times to even once daily. Dogs may also "outgrow" the problem with age, either as a result of a decrease in caloric intake or because of developing maturity of the mucosal immune system. It has also been suggested that idiopathic ARD in German shepherds may predispose some of these dogs to IBD later in life, but currently no direct evidence supports this supposition.

1366
1367

222.13.5.3 Ancillary treatments

Dietary manipulation can be a useful adjunct to the treatment both of idiopathic ARD and of secondary SIBO. In general, a highly digestible, low-fat diet is desired to reduce the substrate available for bacterial use. Addition of FOS has been advocated to reduce SI bacterial numbers, although evidence of efficacy is conflicting. Administration of probiotics has not been thoroughly assessed in idiopathic ARD. Finally, if low cobalamin concentrations are documented, parenteral cobalamin therapy is warranted.

222.14 INFLAMMATORY BOWEL DISEASE

Inflammatory bowel disease is a collective term that describes a group of disorders characterized by persistent or recurrent GI signs and histologic evidence of intestinal inflammation on biopsy material. The disease bears little resemblance to IBD (Crohn's disease and ulcerative colitis) of humans, and indiscriminate use of the term "IBD" is no more useful than a dermatologist making a diagnosis of "chronic dermatitis." Although a number of recognized diseases are associated with chronic intestinal inflammation (Box 222-17), the cause of idiopathic IBD is, by definition, unknown. Variations in the histologic appearance of the inflammation suggest that idiopathic IBD is not a single disease entity (Figure 222-12), and the nomenclature reflects the predominant cell type present. Lymphocytic-plasmacytic enteritis (LPE) is the most common form reported; eosinophilic (gastro-) enteritis (EGE) is less common; and granulomatous enteritis is rare. Neutrophilic infiltration is a feature of human IBD but is infrequent in idiopathic IBD of dogs and cats.

222.14.1 Box • 222-17 Causes of Chronic Small Bowel Inflammation

Chronic infection

Giardia sp.

Histoplasma sp.

Toxoplasma sp.

Mycobacteria sp.

Protothecosis

Pythiosis

Pathogenic bacteria (*Campylobacter, Salmonella* spp., pathogenic *Escherichia coli*)

Food allergy

Small bowel inflammation associated with other primary gastrointestinal diseases

Lymphoma

Lymphangiectasia

Idiopathic causes

Lymphocytic-plasmacytic enteritis (LPE)

Eosinophilic gastroenterocolitis (EGE)

Granulomatous enteritis (same as regional enteritis?)

222.14.2 Clinical Presentation

Idiopathic IBD is a common cause of chronic vomiting and diarrhea in dogs and cats, but its true incidence is unknown. In reality it is often overdiagnosed because of difficulties in interpretation of histopathologic specimens and failure to eliminate adequately other causes of mucosal inflammation. No apparent gender predisposition occurs in dogs and cats, but in both species IBD is most common in middle-aged animals. GI signs, which may have been variably controlled by dietary manipulation, are sometimes seen from an earlier age. Although IBD can potentially occur in any dog or cat breed, certain predispositions are recognized, such as LPE in German shepherds and Siamese cats, lymphoproliferative enteropathy in basenjis, and protein-losing enteropathy/protein-losing nephropathy (PLE/PLN) in soft-coated wheaten terriers (see Table 222-6). Shar Peis often have a severe LPE with hypoproteinemia and extremely low serum cobalamin concentrations. In cats an association, called *triaditis,* has been reported for IBD, lymphocytic cholangitis, and chronic pancreatitis.[157]

Vomiting and diarrhea are the most common clinical signs, but an individual case may show some or all of the signs in Box 222-18. Sometimes an obvious precipitating event (e.g., stress, dietary change) is present in the history, but clinical signs may wax and wane. The nature of signs crudely correlates with the region of the GI tract affected: gastric signs are more common if gastric or upper SI inflammation is present; in cats, vomiting is often the predominant sign of small intestinal IBD; and LI-type diarrhea may be the result of colonic inflammation or may result from prolonged SI diarrhea. The presence of blood in the vomit or diarrhea is associated with more severe disease, especially eosinophilic inflammatory infiltrates. Severe disease is associated with weight loss and PLE, with consequent hypoproteinemia and ascites. Appetite is variable; polyphagia may be present in the face of significant weight loss, whereas anorexia occurs with severe inflammation. Milder inflammation may not affect appetite, although postprandial pain can be significant even without other signs. Systemic consequences of IBD can occur, although reports are sparse.[158]

222.14.3 Etiology and Pathogenesis

The underlying etiology of small animal IBD is unknown, and comparisons have been made with similar human conditions. In this regard, the breakdown of immunologic tolerance to luminal antigens (bacteria and dietary components) is thought to be critical,[49] perhaps resulting from disruption of the mucosal barrier, dysregulation of the immune system, or disturbances in the intestinal microflora (see above). Therefore antigens derived from the endogenous microflora are likely to be important in disease pathogenesis, and a potential role for diet-related factors is suggested by the clinical benefit of dietary therapy in some cases of canine IBD.

Genetic factors are likely to contribute to the pathogenesis of IBD,[159,160] and in humans the strongest associations are with genes of the human MHC (human leukocyte antigen [HLA]). Furthermore, some human patients with Crohn's disease have a mutation in the NOD2 gene on chromo-some 16.[161,162] This gene's product detects bacterial lipopolysaccharide and can activate the proinflammatory transcription factor NF-κB. Such a link may explain the development of aberrant immune responses to bacteria in certain individuals. Genetic factors are also likely in dogs, given the recognized breed predispositions, although studies are lacking.

Figure 222-12 Histologic appearance of **(A)** normal jejunum, showing long, slender villi and minimal numbers of cells in the lamina propria; **(B)** idiopathic lymphoplasmacytic enteritis in a Dachshund, showing stunted villi and a lymphoplasmacytic infiltrate; **(C)** lymphoplasmacytic intestinal inflammation associated with *Strongyloides* infection (a worm is actually visible in the section on the mucosal surface); and **(D)** eosinophilic enteritis in a German shepherd, showing massive infiltration of the crypt area with eosinophils. 222.14.4 Diagnosis

Intestinal biopsy is necessary for a definitive diagnosis of IBD, although the clinical signs and physical findings may be suggestive (see Box 222-18). The term *idiopathic IBD* is limited to cases in which histologic evidence of inflammation is found without an obvious underlying cause. All other etiologies, including infectious, diet-responsive, and antibacterial-responsive conditions, should be excluded. Therefore before intestinal biopsy is undertaken, laboratory evaluation and diagnostic imaging are performed. Such tests cannot provide a definitive diagnosis of IBD, but they can help eliminate the possibility of anatomic intestinal disease (e.g., tumor, intussusception), extraintestinal disease (e.g., pancreatitis), and known causes of intestinal inflammation. Furthermore, by determining whether focal or diffuse intestinal disease is present, the clinician can choose the most appropriate method of intestinal biopsy.

1368

1369

222.14.4.1 Box • 222-18 Clinical Signs Associated with Inflammatory Bowel Disease

- Vomiting of bile with or without hair in cats and grass in dogs
- Hematemesis
- Small intestinal–type diarrhea
  - Large volume
  - Watery
  - Melena
- Thickened bowel loops
- Large intestinal–type diarrhea
  - Hematochezia
  - Mucoid stool
  - Frequency and tenesmus
- Abdominal discomfort/pain
- Excessive borborygmi and flatus
- Weight loss
- Altered appetite

Polyphagia

Decreased appetite/anorexia

Eating grass

Hypoproteinemia/ascites

222.14.4.2 Hematology

Occasionally neutrophilia, with or without a left shift, is noted. Eosinophilia may suggest EGE, but it is neither pathognomonic nor invariably present. Anemia may reflect chronic inflammation or chronic blood loss.

222.14.4.3 Serum biochemistry

No pathognomonic changes are seen in IBD, but diseases of other organ systems should be recognized and excluded. Hypoalbuminemia and hypoglobulinemia are characteristic of PLE, whereas hypocholesterolemia may suggest malabsorption. Intestinal inflammation in dogs may cause a "reactive hepatopathy," with mild elevations in liver enzymes (alanine aminotransferase [ALT] and alkaline phosphatase [ALP]). In contrast, because of the shorter half-lives of liver enzymes in cats, increases are more likely to be the result of hepatocellular or cholestatic disease.

222.14.4.4 Fecal examination

Fecal examination is most important for eliminating other causes of mucosal inflammation, such as nematodes (e.g., *Trichuris, Uncinaria, Ancylostoma,* and *Strongyloides* spp.), *Giardia* infection, and bacterial infection (e.g., *Salmonella* or *Campylobacter* spp. or clostridia). Given that fecal parasitology may not always detect *Giardia* organisms, empirical treatment with fenbendazole is recommended in all cases.

Increased fecal $alpha_1$-PI concentrations would be expected in dogs with IBD, as well as significant intestinal protein loss even before hypoproteinemia develops (see above).

222.14.4.5 Folate and cobalamin

Serum concentrations of both these vitamins are affected by intestinal absorption, therefore proximal, distal, or diffuse inflammation can result in subnormal folate concentrations (proximal inflammation) or cobalamin concentrations (distal inflammation) or both (diffuse inflammation). Although such alterations are not pathognomonic for IBD, deficiencies may require therapeutic correction. Measurement of serum folate and cobalamin is now commercially available for cats, and cobalamin deficiency associated with IBD has been documented. Cobalamin deficiency has systemic metabolic consequences,[45] and anecdotal evidence suggests that deficient cats with IBD require parenteral supplementation to respond optimally to immunosuppression.

222.14.4.6 Diagnostic imaging

Imaging studies document whether focal or diffuse disease is present and whether other abdominal organs are affected. Such information, in conjunction with specific clinical signs, allows the clinician to choose the most appropriate method of biopsy. Plain radiographs may be useful for detecting anatomic intestinal disease; contrast studies rarely add further information. Ultrasonographic examination is superior to radiography for documenting focal anatomic intestinal disease and is particularly useful in cats with IBD.[163] Ultrasonography permits evaluation of intestinal wall thickness[63,163] and can document mesenteric lymphadenopathy. Ultrasound-guided fine needle aspiration (FNA) can provide samples for cytologic analysis, which may aid in diagnosis.

222.14.4.7 Intestinal biopsy

Intestinal biopsy is necessary to document intestinal inflammation. Endoscopy is the easiest method of biopsy, but it has limitations, because samples are superficial and in most cases can be collected only from the proximal SI (see Box 222-8). In some cases exploratory laparotomy and full-thickness biopsy are necessary, although the procedures are more invasive and can be problematic if severe hypoproteinemia is present. These techniques may be more suitable for cats, given the tendency in this species for multiorgan involvement.

Histopathologic assessment of biopsy material remains the gold standard for IBD diagnosis, and the pattern of histopathologic change depends on the type of IBD present (see below). However, the limitations of histopathologic interpretation of intestinal biopsies are recognized. The quality of specimens can vary,[78] agreement between pathologists is poor, and differentiation between normal specimens and those showing IBD and even lymphoma can be difficult.[79] Grading schemes for the histopathologic diagnosis of IBD have been suggested,[158] but these have not yet been widely adopted.

222.14.4.8 IBD activity index

In humans, activity indices are used to quantify the severity of IBD; this helps practitioners to assess the response to treatment and to make a prognosis by allowing comparisons between published studies in the literature. Recently an activity index was suggested for canine IBD,[164] and this may aid disease classification in the future.

222.14.4.9 Other diagnostic investigations

Given the limitations of histopathology, other modalities are required. One approach would be the use of immunohistochemistry or flow cytometry to analyze immune cell subsets. However, such techniques are labor intensive and poorly standardized and are unlikely to be generally available in the foreseeable future.

222.14.5 Treatment

Whatever the type of IBD, treatment usually involves a combination of dietary modification and antibacterial and immunosuppressive therapy. Unfortunately, objective information on efficacy is lacking, and most recommendations are based on individual experience. The authors usually recommend a staged approach to

therapy whenever possible; initial treatment involves antiparasiticides to eliminate the possibility of occult endoparasite infestation. Thereafter, sequential treatment trials with an exclusion diet and antibacterials are pursued; immunosuppressive medication is used only as a last resort. However, in some cases, clinical signs or mucosal inflammation is so severe that early intervention with immunosuppressive medication is essential. If clinical signs are intermittent, the owners should keep a diary to provide objective information as to whether treatments produce genuine improvement.

1369

1370

222.14.5.1 Dietary modification

The diets recommended for patients with IBD are antigen limited, based on a highly digestible, single-source protein preparation. An exclusion diet trial should be undertaken to eliminate the possibility of an adverse food reaction, and most clients are happy to try this, given concerns over the side effects of immunosuppressive drugs. An easily digestible diet decreases the intestinal antigenic load and thus reduces mucosal inflammation. Such diets may also help resolve any secondary sensitivities to dietary components that may have arisen from disruption of the mucosal barrier. After the inflammation has resolved, the usual diet often can be reintroduced without fear of an acquired sensitivity.

Well-cooked rice is the preferred carbohydrate source because of its high digestibility, but potato, corn starch, and tapioca are also gluten free. Fat restriction reduces clinical signs associated with fat malabsorption. Modification of the n3 to n6 fatty acid ratio may also modulate the inflammatory response and may have some benefit both in treatment and in maintenance of remission, as in human IBD.[165,166] However, no direct studies have been done to prove a benefit in canine IBD. Supplementation with oral folate and parenteral cobalamin is indicated if serum concentrations are subnormal.

222.14.5.2 Antibacterial therapy

Treatment with antimicrobials can be justified in IBD, partly to treat secondary SIBO and partly because of the importance of bacterial antigens in the pathogenesis of IBD.[50] Ciprofloxacin and metronidazole are often used in human IBD,[167] and metronidazole is the preferred drug for small animals. The efficacy of metronidazole may not be related just to its antibacterial activity, because it may exert immunomodulatory effects on cell-mediated immunity. Furthermore, other antibacterials (e.g., tylosin) may also have immunomodulatory effects and have efficacy in canine IBD.

222.14.5.3 Immunosuppressive drugs

The most important treatment modality in idiopathic IBD is immunosuppression, although this should be used only as a last resort. In human IBD, glucocorticoids and thiopurines (e.g., azathioprine, 6-mercaptopurine) are used most widely.[168] In dogs, glucocorticoids are used most frequently, and prednisone and prednisolone are the drugs of choice. Dexamethasone should be avoided, because it may have deleterious effects on enterocytes. In severe IBD, prednisolone can be administered parenterally, because oral absorption may be poor. The initial dosage of 1 to 2 mg/kg given orally every 12 hours is given for 2 to 4 weeks and then tapered slowly over the subsequent weeks to months. In some cases therapy can be either completely withdrawn or at least reduced to a low maintenance dose given every 48 hours.

Signs of iatrogenic hyperadrenocorticism are common when the highest glucocorticoid dose is administered. However, signs are transient and resolve as the dosage is reduced. If clinical signs of IBD consistently recur when the dosage is reduced, other drugs can be added to provide a steroid-sparing effect

(see below). Budesonide, an enteric-coated, locally active steroid that is destroyed 90% first-pass through the liver, has been successful in maintaining remission in human IBD with minimal hypothalamic-pituitary-adrenal suppression. A preliminary study showed apparent efficacy in dogs and cats,[169] but limited information is available on the use of this drug.[170]

In dogs, azathioprine (2 mg/kg given orally every 24 hours) is commonly used in combination with prednisone/prednisolone when the initial response to therapy is poor or when glucocorticoid side effects are marked. However, azathioprine may have a delayed onset of activity (up to 3 weeks) and, given its myelosuppressive potential, regular monitoring of the hemogram is necessary. Azathioprine is not recommended for cats; chlorambucil (2 to 6 mg/m^2 given orally every 24 hours until remission, followed by drug tapering) is a suitable alternative. Other immunosuppressive drugs are methotrexate, cyclophosphamide, and cyclosporine. Methotrexate is effective in the treatment of human Crohn's disease,[171] but it is not widely used in companion animals; it often causes diarrhea in dogs. Cyclophosphamide has few advantages over azathioprine and is rarely used. However, cyclosporine may show promise for the future, given its T lymphocyte–specific effects and efficacy in canine anal furunculosis. Unfortunately, it is expensive, and studies in human IBD have shown variable efficacy and toxicity.[172,173]

222.14.5.4 Novel therapies for IBD

Novel therapies are increasingly used for human IBD in an attempt to target more accurately the underlying pathogenetic mechanisms. These therapies include new immunosuppressive drugs, monoclonal antibody therapy, cytokines and transcription factors, and dietary manipulation (Table 222-11).[174] In the future, such therapies may be adopted for small animal IBD.

Mycophenolate mofetil recently has been used to treat human IBD, although its efficacy is variable.[175] Drugs that target TNF-α (e.g., thalidomide and oxpentifylline) may be suitable for the treatment of canine IBD because of the importance of this cytokine in disease pathogenesis. Human open-label trials have demonstrated a beneficial effect for thalidomide in refractory Crohn's disease.[176] Oxpentifylline has shown efficacy in studies *in vitro*, but clinical results have been less rewarding.[177] Anti–TNF-α monoclonal antibody therapy, which has also undergone trials in human IBD, has the additional beneficial effect of inducing apoptosis in inflammatory cells.[178] Species-specific monoclonal antibodies will be needed for canine and feline IBD.

Finally, modulation of the enteric flora with probiotics or prebiotics may have benefits in targeting the pathogenesis of IBD. A *probiotic* is an orally administered living organism that exerts health benefits beyond those of basic nutrition. In addition to having direct antagonistic properties against pathogenic bacteria,[91] they modulate mucosal immune responses by stimulating either innate (e.g., phagocytic activity) or specific (e.g., secretory IgA) immune responses.[179] However, care should be taken to select the most appropriate organisms, which are likely to vary between host species.

Prebiotics are selective substrates used by a limited number of “beneficial” species, which therefore cause alterations in the luminal microflora. The most frequently used prebiotics are nondigestible carbohydrates, such as lactulose, inulin, and FOS. Both probiotics and prebiotics can reduce intestinal inflammation in mouse models of IBD.[180] Preliminary placebo-controlled trials with probiotics and prebiotics in human

IBD patients have shown promising results,[181] although similar trials in canine and feline IBD are still awaited.

222.14.6 Lymphocytic-Plasmacytic Enteritis

Lymphocytic-plasmacytic enteritis (LPE) is the most common form of idiopathic IBD. It is characterized by a mucosal infiltrate of lymphocytes and plasma cells (see Figure 222-12). However, there are numerous other causes of lymphocytic-plasmacytic infiltration of the SI (see Box 222-17 and Figure 222-12), including enteric pathogens, bacteria, and *Toxoplasma* organisms. All such underlying causes must be excluded before a diagnosis of idiopathic LPE is confirmed.

Table • 222-11 Novel Therapies for Human Inflammatory Bowel Disease

THERAPY	MECHANISM OF ACTION
Drug Therapy	
Tacrolimus	Immunosuppressant macrolide
Mycophenolate	Inhibits lymphocyte proliferation; reduces IFN-gamma production
Leukotriene antagonists (zileuton, verapamil)	Inhibit arachidonic acid cascade
Prostaglandin (PG) targeting agents	Mucosal protection from PG analogs; anti-inflammatory effects from PG antagonists
Thromboxane synthesis inhibitors	Anti-inflammatory effects
Ridogrel	
Picotamide	
Oxpentifylline	Inhibits TNF-alpha expression
Thalidomide	Inhibits TNF-alpha and IL-12 expression; reduces leukocyte migration; impairs angiogenesis
Bone Marrow and Stem Cell Transplantation	
Bone marrow grafts	Unknown; immunomodulation (?)
Dietary Manipulation	
Protein hydrolysate diets	"Hypoallergenic"
Fish oil therapy	Diverts eicosanoid metabolism to LTB_5 and PGE_3
Short chain fatty acid therapy	
Butyrate	Provides nutrition for enterocytes
Probiotics and prebiotics	Antagonize pathogenic bacteria; immunomodulatory effects
Cytokine Manipulation	
Systemic IL-10	Down-modulatory cytokine
Anti–IL-2 monoclonal antibody (MAb)	Counteracts proinflammatory effects
Anti–IL-2R (CD25) MAb	Inhibits IL-2 effects
Anti–IL-12 MAb	Counteracts proinflammatory effects
Anti–IL-11 MAb	Downregulates TNF-alpha and IL-1beta
Recombinant IFN-alpha	Anti-inflammatory; antiviral (?)
Anti–IFN-gamma MAb	Immunomodulatory effect on Th1 cells
Anti–TNF-alpha MAb	Counteracts proinflammatory effects; induces inflammatory cell apoptosis
Endothelial Cell Adhesion Molecules and Their Manipulation	
ICAM-1 (antisense oligonucleotide)	Reduces immune cell trafficking

222.14.6.1 Pathogenesis

Idiopathic LPE is believed to reflect immune dysregulation, and the spectrum of severity ranges from mild to severe infiltration. Alterations in immune cell populations in canine LPE have been documented,

including increases in lamina propria T cells (especially CD4+ cells), IgG+ plasma cells, macrophages, and granulocytes.[154]

Increased concentrations of acute-phase proteins (e.g., C-reactive protein), which normalize after treatment, have been documented in canine LPE.[164] Marked alterations in cytokine patterns also were recently documented in canine LPE, with increased expression of Th1 (IL-2, IL-12, and IFN-gamma), Th2 (IL-5), proinflammatory (TNF-alpha), and immunoregulatory (TGF-beta) cytokines.[81] These studies confirm that the mucosal immune response is upregulated in canine IBD.

1371 1372

222.14.6.2 Clinical Signs

Clinical signs of LPE include diarrhea and weight loss, but these are not pathognomonic. Chronic vomiting may be the predominant sign, especially in cats. LPE is prevalent in German shepherds, Shar Peis, and purebred cats, and in dogs it often causes a PLE. Severe LPE (immunoproliferative disease) is recognized in basenjis. Protein-losing enteropathy with or without concurrent protein-losing nephropathy has also been described in soft-coated wheaten terriers.[144] LPE typically affects older animals; it is uncommon (but not impossible) in individuals less than 2 years of age.

222.14.6.3 Diagnosis

The approach to diagnosis of LPE is the same as for any chronic enteropathy, although definitive diagnosis ultimately depends on documentation of characteristic histopathologic changes in the absence of an underlying cause. Such changes include the presence of increased numbers of lymphocytes and plasma cells in association with architectural disturbances. Complete or partial villus atrophy may be present, and villus fusion and crypt abscessation may be noted in severe cases. The distinction between severe LPE and alimentary lymphoma is sometimes difficult, and discrepancies may arise between endoscopic biopsies and postmortem examination of the same patient. It is hypothesized that such discrepancies arise because the two conditions may be present concurrently in the SI, because prolonged intestinal inflammation may ultimately result in transformation to lymphoma, or because low-grade lymphoma is initially misdiagnosed.

Another major concern is the criteria by which a diagnosis of LPE is made. In this regard, major discrepancies exist in interpretation of intestinal biopsies by different histopathologists.[79] Interpretation of the degree of inflammation is subjective; inflammation may be patchy, and the presence of edema (due to hypoproteinemia) may make cell density difficult to assess. Furthermore, discrepancies exist between gross endoscopic and histologic findings, and proximal endoscopic biopsies may not be representative. Attempts have been made to standardize interpretation by using grading schemes; those that assess morphologic abnormalities in conjunction with changes in cellularity are most appropriate.[158]

222.14.6.4 Treatment and Prognosis

The treatment of LPE is that outlined for idiopathic IBD above. First-line treatment usually involves dietary manipulation and metronidazole. The prognosis for severe LPE is guarded. Some patients respond dramatically and can ultimately be weaned off all medication; other cases, however, require persistent, low-dose maintenance immunosuppressive therapy.

222.14.7 Basenji Enteropathy

A severe, hereditary form of LPE has been well characterized in basenjis,[182] although the mode of inheritance is unclear.[183] It has been likened to immunoproliferative small intestinal disease (IPSID) in humans, because both conditions involve intense intestinal inflammation. However, IPSID is characterized by an associated gammopathy (alpha heavy chain disease) and a predisposition to lymphoma. Affected basenjis often have hyperglobulinemia but not alpha heavy chain disease and may be predisposed to lymphoma. The intestinal lesions in basenjis are characterized by increases in CD4+ and CD8+ T cells.[182]

222.14.7.1 Clinical Signs

Signs of chronic intractable diarrhea and emaciation are most common. Lymphocytic-plasmacytic gastritis, with hypergastrinemia and mucosal hyperplasia, may be seen in addition to the enteropathy. PLE often occurs, with consequent hypoalbuminemia, although edema and ascites are not common. Clinical signs are usually progressive, and spontaneous intestinal perforation may occur.

222.14.7.2 Diagnosis

The approach to diagnosis is the same as before, and ultimately depends on histopathological examination of biopsy specimens.

222.14.7.3 Treatment

Treatment generally is unsuccessful, with dogs dying within months of diagnosis. However, early, aggressive combination treatment with prednisolone, antibiotics, and dietary modification may achieve remission in some cases.

222.14.8 Familial Protein-Losing Enteropathy and Protein-Losing Nephropathy in Soft-Coated Wheaten Terriers

Recently a clinical syndrome unique to soft-coated wheaten terriers was characterized.[144,184] Affected dogs present with signs of PLE or PLN or both. A genetic basis is likely, and although the mode of inheritance is not yet clear, pedigree analysis of 188 dogs has demonstrated a common male ancestor.[185] The disease is probably immune mediated, given the presence of inflammatory cell infiltration. A potential role for food hypersensitivity has been suggested, because affected dogs have demonstrated adverse reactions during provocative food trials and alterations in antigen-specific fecal IgE concentrations.[145,184,186]

222.14.8.1 Clinical Signs

Signs of PLE tend to develop at a younger age than PLN. Clinical signs of the PLE include vomiting, diarrhea, weight loss, and pleural and peritoneal effusions. Occasionally, thromboembolic disease may occur.[187]

222.14.8.2 Diagnosis

Preliminary laboratory investigations, as in most dogs with PLE, demonstrate panhypoproteinemia and hypocholesterolemia. In contrast, hypoalbuminemia, hypercholesterolemia, proteinuria, and ultimately azotemia are seen with PLN.[185] Histopathologic examination of intestinal biopsy material reveals evidence of intestinal inflammation, villus blunting, and epithelial erosions, as well as dilated lymphatics and lipogranulomatous lymphangitis.

222.14.8.3 Treatment and Prognosis

The treatment for PLE is similar to that described for general IBD, but the prognosis is usually poor.

222.14.9 Eosinophilic Enteritis

Eosinophilic enteritis (EE) is reported to be the second most common form of IBD. It frequently also involves the stomach and/or colon in eosinophilic gastroenteritis (EGE) and/or colitis. Segmental EE has also been reported.[188] Histologically, variable mucosal architectural disturbances (e.g., villus atrophy) are present in conjunction with a mixed infiltrate of inflammatory cells in which eosinophils predominate (see Figure 222-12). However, as with LPE, diagnostic criteria vary among pathologists; some define EE based purely on subjective increases in mucosal eosinophil numbers, whereas others apply stricter criteria, requiring that eosinophils predominate in the lamina propria. Another criterion is the presence of eosinophils between epithelial cells of the villus and crypt, which suggests transepithelial migration. Nevertheless, the number of mucosal eosinophils can vary markedly in normal dogs,[22] and therefore this condition may be overdiagnosed. As with other forms of IBD, a diagnosis of EE should be made only after other causes of eosinophilic infiltration have been eliminated.

1372 1373

222.14.9.1 Clinical Signs

EE may be seen in dogs and cats of any breed and age, although it is most common in younger adult animals. Boxers and Dobermans may be predisposed, and an increased incidence in German shepherds has been suggested. EGE may also be associated with systemic eosinophilic disorders in both cats and dogs. The clinical signs reported, which depend on the area of GI tract involved, include vomiting, SI diarrhea, and LI diarrhea. Mucosal erosion/ulceration may occur more frequently in EE than in other forms of IBD, therefore hematemesis, melena, or hematochezia may be seen. Severe EGE has been associated with PLE and hypoproteinemia and, rarely, spontaneous perforation of the GI tract.[189]

222.14.9.2 Pathogenesis

An eosinophilic mucosal infiltrate may be related to dietary sensitivity, endoparasitism, or idiopathic EGE. The eosinophil infiltration is likely to be the result of local and systemic production of cytokines and chemokines, such as IL-5, and members of the eotaxin family.[190] These mediators may be produced by the Th2 subset of CD4+ T cells.

222.14.9.3 Diagnosis

The diagnosis of EGE is made by histopathologic assessment of intestinal biopsies after exclusion of parasites and food allergy. Peripheral eosinophilia is neither invariably present nor pathognomonic for EGE, because it may also be seen in parasitism, hypoadrenocorticism, allergic cutaneous or respiratory disease, and mast cell neoplasia.

222.14.9.4 Treatment

Given that eosinophilic mucosal infiltrates may also be related to endoparasitic diseases, empirical treatment with fenbendazole is always advisable. Subsequent to this, an exclusion diet trial should be instigated to eliminate the possibility of dietary sensitivity before immunosuppressive therapy is considered. The prognosis in idiopathic EGE is guarded, even with a good initial response to treatment, because recurrence is common.

222.14.10 Other Forms of Inflammatory Bowel Disease

222.14.10.1 Granulomatous Enteritis

Granulomatous enteritis is a rare form of IBD characterized by mucosal infiltration with macrophages, resulting in the formation of granulomas. The distribution of inflammation can be patchy. This condition is probably the same as “regional enteritis,” in which ileal granulomas have been reported. Granulomatous enteritis has some histologic features in common with human Crohn's disease, but obstruction, abscessation, and fistula formation are not noted. Conventional therapy is not usually effective, and the prognosis is guarded, although a combination of surgical resection and anti-inflammatory treatment was reported to be successful in one case.[191] In cats, a pyogranulomatous transmural inflammation has been associated with FIPV infection.

222.14.10.2 Proliferative Enteritis

Proliferative enteritis is characterized by segmental mucosal hypertrophy of the intestine. Although many species can be affected, the condition is most common in pigs. A similar but rare condition has been reported in dogs.[192] There have been suggestions of an underlying infectious etiology, and *Lawsonia intracellularis* has been implicated, although this has not yet been proved. Other infectious agents with a proposed link are *Campylobacter* spp. and *Chlamydia* organisms.

222.15 LYMPHANGIECTASIA

222.15.1 Definition and Cause

Intestinal lymphangiectasia is characterized by marked dilatation and dysfunction of intestinal lymphatics. Abnormal lymphatics leak protein-rich lymph into the intestinal lumen, ultimately causing PLE and hypoproteinemia. Lymphangiectasia may be a primary disorder or can develop secondary to lymphatic obstruction.

Primary lymphangiectasia usually is limited to the intestine, although it may be part of a more widespread lymphatic abnormality involving, for example, chylothorax.[193] It is considered congenital, although clinical signs are not usually present from birth. The development of associated lipogranulomatous lymphangitis, superimposed on the congenital abnormalities, is one reason for a progressive disorder. The disease is most commonly seen in small terrier breeds (e.g., Yorkshire, Maltese) and the Norwegian lundehund (Figure 222-13), suggesting a genetic predisposition.

Secondary lymphangiectasia is caused by intestinal lymphatic obstruction. Underlying causes include (1) infiltration or obstruction of lymphatics by an inflammatory, fibrosing, or neoplastic process; (2) possibly obstruction of the thoracic duct; and (3) right heart failure due to congestive heart failure or cardiac tamponade. Lipogranulomatous lymphangitis is sometimes reported in association with lymphangiectasia, but it is not clear which is the primary event; lymphangitis could cause lymphatic obstruction, or leakage of lymph could cause granuloma formation.

222.15.2 History and Clinical Signs

The clinical manifestations of lymphangiectasia are largely attributable to the effects of the enteric loss of lymph. Other intestinal functions remain intact, and hypoproteinemia may be present without diarrhea.[194] Diarrhea, steatorrhea, profound weight loss, and polyphagia are more typical, and vomiting, lethargy, and anorexia are reported occasionally. Signs may have an insidious onset and an intermittent pattern. Ascites or subcutaneous edema may develop if hypoproteinemia is marked. The ascitic fluid usually is a pure transudate, but if right heart failure causes secondary lymphangiectasia, a modified transudate develops through portal hypertension. Lymphangiectasia has been associated with granulomatous hepatopathy[195] and in lundehunds with chronic gastritis and gastric carcinoma.[196]

Figure 222-13 Normal lundehund (*left*) and one affected with lymphangiectasia, showing abdominal distension caused by hypoproteinemic ascites. (Courtesy D.A. Williams.)

1373

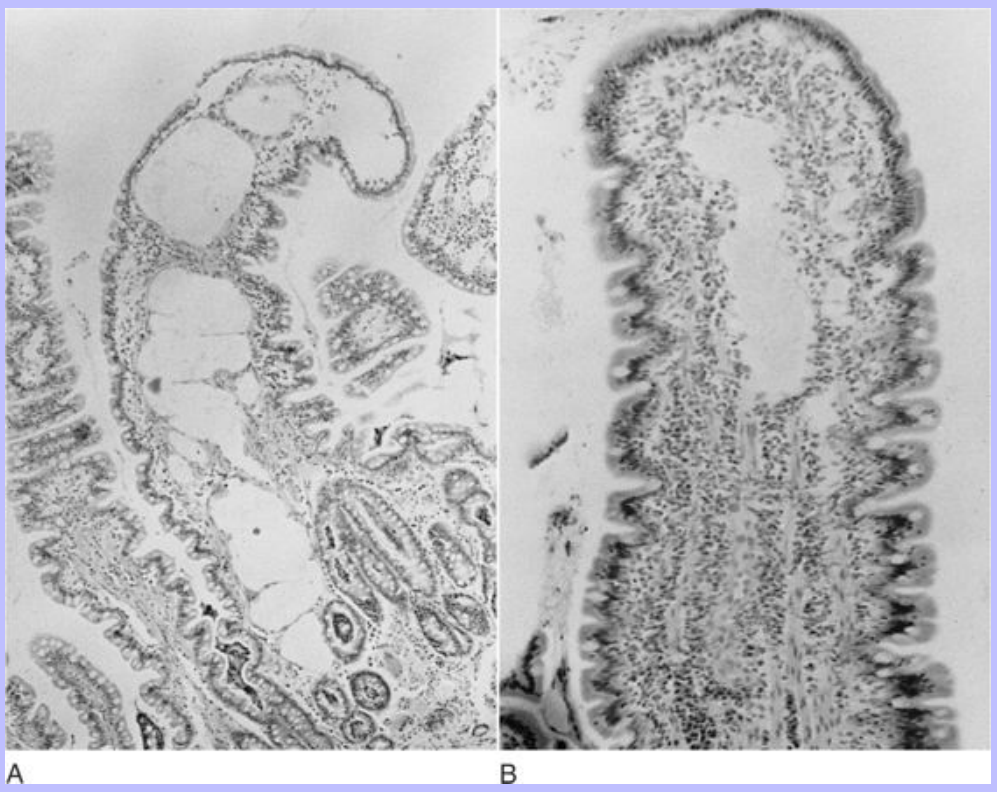
222.15.3 Diagnosis

Given that lymph is rich in lipoproteins and lymphocytes, laboratory analysis often shows panhypoproteinemia, hypo-cholesterolemia, and lymphopenia. Hypocalcemia and hypomagnesemia have been reported.[55,197] The hypocalcemia is the result not only of hypoalbuminemia, but also of the development of ionized hypocalcemia. Therefore other mechanisms, including vitamin D and calcium malabsorption, may be involved. PLE can be documented by measuring[51] Cr-albumin leakage or fecal concentrations of $alpha_1$-PI. In affected lundehunds, increased permeability has been documented by both methods, and the increases in the fecal $alpha_1$-PI concentration were seen before changes in serum proteins.[198]

Gross findings at endoscopy include the presence of white lipid droplets or prominent mucosal blebs, which are likely the result of villus tip distension with chyle. Endoscopic biopsies may be supportive of the diagnosis, but full-thickness biopsies may be required to make a definitive diagnosis. At exploratory laparotomy, most dogs show gross abnormalities, including thickened small intestine, dilated lymphatics (in the mesentery and intestinal serosa), and occasionally adhesions.[199] Mesenteric lymph nodes may also be enlarged, and yellow-white nodular masses (1 to 3 mm in diameter) are often observed in and around the mesenteric and serosal lymphatics. The nodules are lipogranulomas, consisting of accumulations of lipid-laden macrophages, and result from perilymphatic extravasation of chyle or are associated with a lymphangitis.

Characteristic histopathologic changes include “ballooning dilatation” of lymphatics, not only in the mucosa but also in the submucosa. This true lymphangiectasia must be distinguished both from normal postprandial dilatation of lacteals and from the secondary lacteal dilatation occasionally noted in other enteropathies (e.g., IBD) (Figure 222-14). Genuine cases are less common than currently believed, and failure to recognize an underlying inflammatory cause may explain the success of steroid treatment in some cases. Assessment of the degree of inflammatory cell infiltrate in the lamina propria is subjective, and if edema is present, the LP cell density may be underestimated.

Figure 222-14 Histologic appearance of a jejunal biopsy from **(A)** a Jack Russell terrier with a protein-losing enteropathy, in which markedly dilated lacteals consistent with a diagnosis of lymphangiectasia are present, and **(B)** a retriever with moderate lymphoplasmacytic enteritis and mild secondary ectasia of the lacteals.



222.15.4 Treatment

Secondary lymphangiectasia is managed by specific treatment of underlying disease, such as pericardiocentesis or pericardectomy for cardiac tamponade. The aim of treatment of primary lymphangiectasia is to decrease the enteric loss of plasma protein, resolve associated intestinal or lymphatic inflammation, and control any edema or effusions. Dietary manipulation and glucocorticoids are the most important treatment modalities.

The ideal diet for cases of lymphangiectasia is markedly fat restricted, calorie dense, and highly digestible. Weight reduction diets, although low in fat, are inappropriate, because patients require a high level of nutrition. Previously, administration of medium chain triglycerides (MCT) was recommended, because these lipids were thought to be absorbed directly into the portal blood. However, this theory was recently

contradicted.[200] Supplementation with fat-soluble vitamins is advised, and there are anecdotal reports of improvement with glutamine supplementation.

Glucocorticoid therapy (prednisolone, 1 to 2 mg/kg given orally divided daily and then tapered) may be beneficial in some cases, especially if associated lymphangitis, lipogranulomas, and a lymphocytic-plasmacytic infiltrate are present in the lamina propria. Unfortunately, not all cases respond to such therapy. The use of antimicrobials such as tylosin or metronidazole has not shown any obvious success. Diuretics are indicated in the management of effusions, and combinations of diuretics are preferred (e.g., furosemide and spironolactone); administration of plasma or colloid may also help if hypoproteinemia is marked. The response to treatment is unpredictable, but cessation of clinical signs may be achieved temporarily, with remissions of months to several years. However, the overall long-term prognosis is poor, and patients eventually succumb to severe malnutrition, incapacitating effusions, and intractable diarrhea.

1374
1375

222.16 MISCELLANEOUS CAUSES OF PROTEIN-LOSING ENTEROPATHY

Common causes of PLE include lymphoma and IBD. However, there have also been recent reports of PLE associated with intestinal crypt lesions[201,202] without evidence of lymphangiectasia or inflammation in most cases. The underlying etiology of such lesions is not known. Response to therapy with antibacterials and immunosuppressive medication is variable; some dogs deteriorate suddenly and can die from thromboembolic disease.

222.17 INTESTINAL NEOPLASIA

Lymphomas, adenocarcinomas, and mast cell tumors are the most common GI tumors in cats, whereas adenocarcinomas and leiomyomas are more common in dogs. Intestinal fibrosarcomas, hemangiosarcomas, carcinoids, and plasma cell tumors are rare. Clinical signs usually include weight loss, although a spectrum of signs may be seen, including diarrhea, anorexia, melena, vomiting, abdominal discomfort, abdominal effusion, and anemia. Other consequences of intestinal neoplasia include intussusception, intestinal perforation, and a variety of paraneoplastic effects.

222.17.1 Intestinal Lymphoma

Lymphoma is characterized by mucosal, submucosal, and/or epithelial infiltration of neoplastic lymphocytes,[203,204] which can invade the intestine in either a diffuse or a focal manner (Figure 222-15). Focal forms may cause obstruction; diffuse infiltration is more common and usually results in malabsorption. Most affected cats test negative for the feline leukemia virus (FeLV) at the time of diagnosis. Progression from LPE to lymphoma has been reported.

222.17.1.1 Clinical findings

Middle-aged or older dogs and cats are most commonly affected. Weight loss, chronic diarrhea, and progressive inappetence are common features, although vomiting and melena may also be noted. Diffusely thickened intestines, intestinal mass lesions, mesenteric lymphadenopathy (see Figure 222-15), or abdominal pain may be noted on abdominal palpation. Concurrent hepatosplenomegaly and generalized lymphadenopathy are suggestive of multicentric lymphoma or an alimentary form involving the liver. Clinical signs of hypoproteinemia may develop if diffuse lymphoma results in severe PLE.

222.17.1.2 Diagnosis

Hematologic examination may demonstrate anemia, characterized as either normocytic-normochromic nonregenerative or microcytic and hypochromic. Neutrophilia may also be evident. Routine biochemistry tests may reveal panhypoproteinemia in dogs and cats with diffuse lymphoma, although B-cell neoplasms may present with hyperglobulinemia as a result of monoclonal gammopathy. Alterations in serum folate or cobalamin concentrations may be the result of malabsorption or of SIBO secondary to intestinal obstruction. Ultrasonography may demonstrate diffuse or focal intestinal wall thickening, loss of intestinal wall layering, and mesenteric lymphadenopathy; it also facilitates fine needle aspiration of focal lesions. Samples for cytologic evaluation can be collected at endoscopy by cytology brush or squash preparation, but in many cases intestinal biopsy is required. Full-thickness biopsy material is preferable to endoscopic pinch biopsies, which may miss the lesion or simply demonstrate adjacent LPE. However, exploratory laparotomy is a risky procedure, because many patients are severely debilitated and hypoproteinemic.

Although histopathologic assessment of biopsy material is the gold standard for diagnosis of alimentary lymphoma, differentiation from LPE can be difficult. Immunohistochemistry may aid in the diagnosis if all lymphocytes are of a single lineage. In the future, immunohistochemistry,[204] flow cytometry,[205] and assessment of T-cell clonality by PCR may prove to be more accurate methods of diagnosis.[82]

222.17.1.3 Treatment and prognosis

Dogs with diffuse alimentary lymphosarcoma (LSA) usually respond poorly to therapy, and there is a risk of intestinal perforation. In contrast, the prognosis in cats is more favorable; some attain prolonged remission.[206,207] Response to combination chemotherapy has been reported, either with standard multidrug protocols or with an “oral only” regimen (e.g., prednisolone and chlorambucil).[206] The latter treatment is well tolerated and may be particularly applicable to cases in which the differentiation between lymphoma and LPE is uncertain.

222.17.2 Intestinal Adenocarcinoma

Intestinal adenocarcinoma is most common in middle-aged to older dogs and cats, and Siamese cats may be over-represented. In dogs these tumors have a predilection for the duodenum, whereas the jejunum and ileum are more commonly affected in cats (see Figure 222-8).

222.17.2.1 Clinical findings and diagnosis

Adenocarcinomas are locally infiltrative, and clinical signs usually relate to partial obstruction or peritonitis when perforation has occurred. Abdominal palpation may reveal focal thickening of the intestine. Melena and signs of anemia may be present if significant ulceration has occurred. Hematologic examination may demonstrate anemia, which usually is strongly regenerative and either normocytic-normochromic or hypochromic and microcytic. Occasionally the anemia is Coombs' positive. Diagnostic imaging may delineate a mass lesion, although definitive diagnosis requires percutaneous aspiration or surgical biopsy.

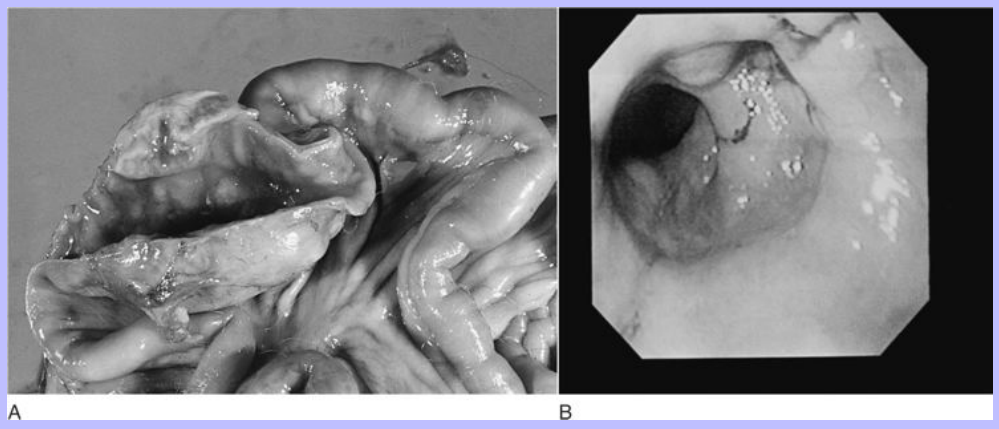
222.17.2.2 Treatment and prognosis

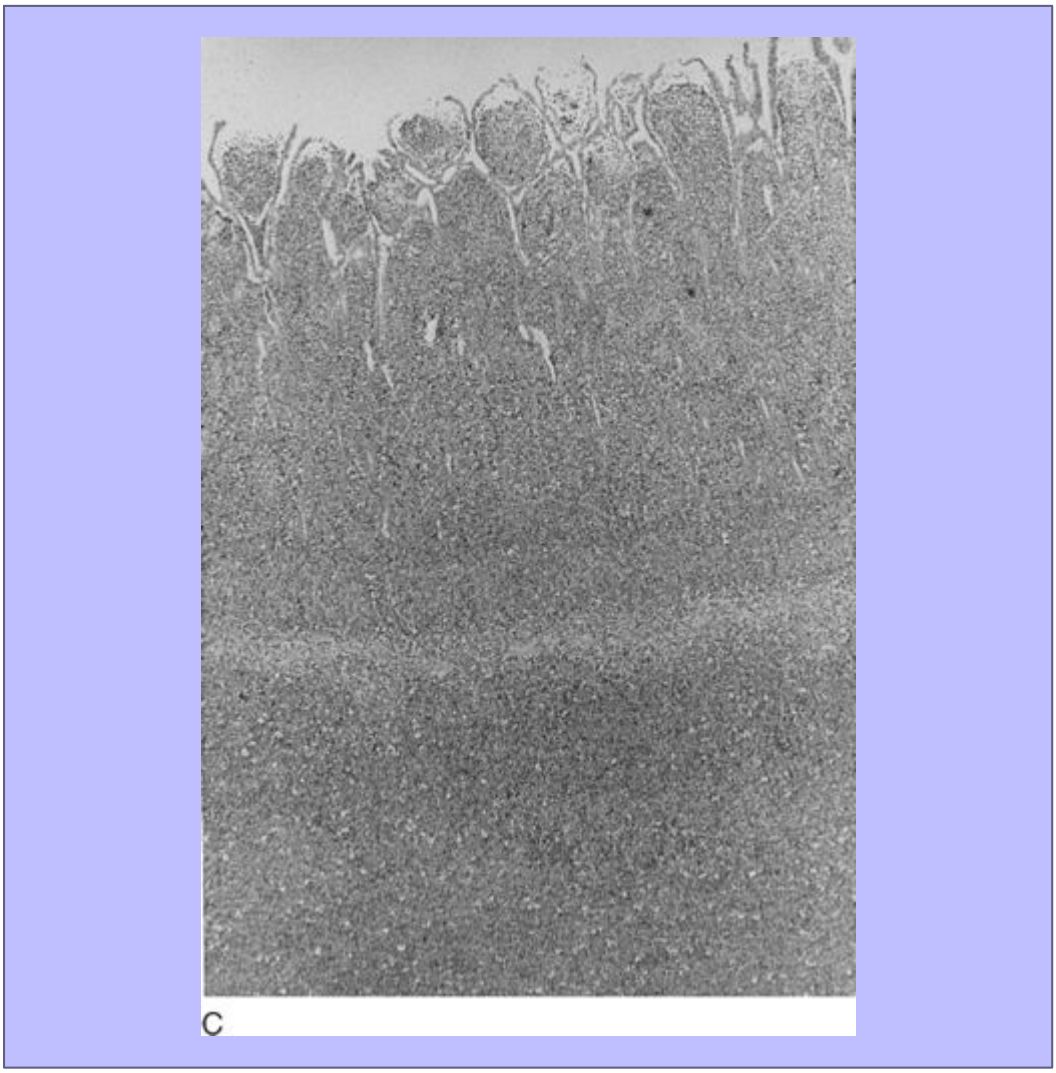
Surgical resection is the treatment of choice. However, the prognosis is usually grave, because tumors almost invariably have spread at the time of diagnosis. Metastatic spread commonly involves local lymph nodes and the liver, and metastasis to the testes was recently reported.[208] Remission times from surgery of up to 2 years have been reported, but survival time is usually less than 6 months. Chemotherapy has not been demonstrated to be effective.

222.17.3 Smooth Muscle Tumors of the Small Intestine

Smooth muscle tumors of the intestine (including leiomyoma and leiomyosarcoma) are uncommon in dogs and rare in cats.[209] Differentiation of smooth muscle tumors from other types of stromal neoplasia can be difficult and may require immunohistochemical procedures.[210] Presenting clinical signs can vary but may include vomiting, diarrhea, anorexia, polyuria, polydipsia, melena, acute collapse, and weight loss. Although some of these signs are the result of local tumor effects (i.e., obstruction, hemorrhage), paraneoplastic effects 1375
are reported, especially hypoglycemia,[211,212] which is thought 1376
to be the result of production of an insulin-like growth factor II-like peptide.[213] Other paraneoplastic syndromes associated with leiomyosarcomas include nephrogenic diabetes insipidus[214] and erythrocytosis.[215]

Figure 222-15 Intestinal lymphosarcoma. **A,** Nodular mass in the jejunum of a 10-year-old Pekinese cut open to demonstrate the mucosal wall thickening caused by focal lymphoma. **B,** Endoscopic image of the duodenum of a 6-year-old retriever, showing bulging of the mucosa caused by diffuse infiltration of lymphoma. **C,** Histologic appearance of lymphoma, showing loss of the normal epithelium and infiltration of all layers with malignant lymphocytes. (Courtesy G.R. Pearson.)





Laboratory findings may reflect the consequences of direct or paraneoplastic effects, but they also may be unremarkable. Diagnostic imaging may aid the identification of a mass lesion, and upper GI endoscopy may confirm the presence of a lesion if it is within reach and disrupting the mucosa. However, pinch biopsies are too superficial, and exploratory laparotomy is the technique of choice both for diagnosis and for treatment. Leiomyosarcomas are slow to grow and metastasize. If surgical resection is complete and if the dog survives the initial postoperative period, the prognosis is good, with median survival times of 21 months reported.[209] Even if metastasis is evident at the time of surgery, the prognosis is reasonable, with prolonged survival reported in some cases. The prognosis for leiomyomas is excellent after surgical excision.

222.17.4 Amine Precursor Uptake and Decarboxylation Tumors

Other functional amine precursor uptake and decarboxylation tumors (APUDomas), such as vasoactive intestinal peptide tumors (VIPomas), pancreatic polypeptide tumors (PPomas), and functional carcinoids, have yet to be adequately described in dogs and cats.

1376

1377

222.17.5 Other Neoplasms

Fibrosarcomas, mast cell tumors, and nonfunctional carcinoid tumors tend to be focally invasive and usually present with clinical signs similar to those of intestinal adenocarcinomas. The diagnosis is based on histologic and occasion-ally immunohistochemical confirmation of the tumor type. Hemangiosarcoma rarely arises in the SI, and signs relate to hemorrhage. Adenomatous polyps affecting the SI have been reported in middle-aged cats,[216] with clinical signs that include vomiting, hematemesis, or diarrhea. However, in some cases chronic, low-grade blood loss may occur, and animals instead present with microcytic anemia.

222.18 ADYNAMIC ILEUS AND INTESTINAL PSEUDO-OBSTRUCTION

Adynamic ileus is a common sequel to parvoviral enteritis, abdominal surgery, pancreatitis, peritonitis, endotoxemia, hypokalemia, and dysautonomia (see Box 222-10).[217] The term *intestinal pseudo-obstruction* describes a condition in which patients show clinical evidence consistent with an obstruction, but no mechanical cause can be found.[218–220] The condition has been associated with both visceral neuropathies and myopathies in humans, and such causes may occur in small animals. Most canine cases are associated with idiopathic sclerosing enteropathy, with fibrosis and a mononuclear cell infiltrate of the tunica muscularis. A case of feline intestinal pseudo-obstruction occurred secondary to intestinal lymphoma.

After the possibility of a mechanical obstruction has been eliminated, management of both adynamic ileus and intestinal pseudo-obstruction is aimed at identifying any underlying cause and providing specific treatment. Symptomatic therapy to stimulate intestinal motility is also indicated.[221] Suitable prokinetic agents include the 5-HT_4 receptor agonist cisapride, the D_2 dopaminergic antagonist metoclopramide, and motilin-like drugs such as erythromycin. In dogs and cats cisapride appears to be the most effective agent, but it is no longer marketed in many countries. Antibacterials may also be appropriate, given the probability of secondary SIBO, and immunosuppressive medication may be appropriate if an underlying IBD is suspected. Feeding is beneficial in humans, and nutritional support can be continued indefinitely, although vomiting, constipation, and diarrhea usually continue. Unfortunately, most cases reported in the veterinary literature responded poorly to therapy, and the prognosis is grave.

222.19 INTESTINAL OBSTRUCTION

Intestinal obstruction can be classified as acute or chronic, partial or complete, and simple or strangulated. Obstruction can be the result of extraluminal, intramural, or intraluminal mass lesions.[222] The most common extraluminal cause of obstruction is intussusception. Younger animals are more likely to develop intussusception after a case of gastroenteritis or after having intestinal surgery, although an increased risk in postparturient queens has also been reported.[223] Intestinal neoplasia is the more frequent cause of intussusception in middle-aged and older animals. Intramural causes include intestinal neoplasia (most common), hematomas, granulomas (e.g., focal FIP), IBD, stricture, and phycomycosis. Most intraluminal obstructions are caused by

foreign objects, such as stones, fruit pits, and toys in dogs and linear foreign objects in cats.[224] *Intestinal volvulus* describes a condition in which the intestines rotate around the mesenteric axis, compromising the cranial mesenteric artery, and complete vascular obstruction may lead to strangulation. Reports are sporadic, but a predisposition in German shepherds has been reported.[225]

The prognosis depends on the cause of the obstruction and the severity of associated abnormalities. The outcome is likely to be favorable with simple foreign bodies, but it is grave for animals with volvulus or metastatic intestinal neoplasia. The patient may be at risk of developing short bowel syndrome if a significant length of intestine must be removed (see below).

222.20 SHORT BOWEL SYNDROME

Short bowel syndrome refers to a syndrome that occurs when large lengths of the SI (more than two thirds) are absent because of resection or, rarely, a congenital anomaly.[226,227] Clinical signs (e.g., diarrhea) result because the animal has an insufficient functional mass of SI for assimilation of nutrients and electrolytes. The degree of malabsorption depends on the length of intestine resected; in dogs, experimental studies suggest that removal of up to 85% of the intestine can be tolerated. The site of resection is also important; resection of the jejunum causes malabsorption of food, water, and electrolytes; resection of the ileum causes malabsorption of cobalamin and bile acids. Massive resection of the SI also precipitates changes in GI hormonal regulation, leading to hypergastrinemia and subsequently increased acid secretion. In some cases, the syndrome may occur only transiently after resection, because adaptive hyperplasia in the remaining intestine may lead to subsequent improvement.

222.20.1 Clinical Signs

The signs of intestinal malabsorption, i.e., intractable diarrhea and weight loss.

222.20.2 Diagnosis

The diagnosis usually is based on a history of intestinal resection with consequent diarrhea and weight loss. If a congenital lesion is suspected, contrast radiography can demonstrate the shortened SI length.

222.20.3 Treatment

After massive resection, aggressive parenteral fluid therapy and total parenteral nutrition should be instigated. Oral feeding is restricted but not withheld completely, because the presence of food, bile, and pancreatic secretions in the gut are important stimuli for intestinal adaptation. An isotonic, oligomeric, fat-restricted liquid diet can be fed initially, with a gradual transition first to a polymeric liquid diet and then to an easily assimilable, fat-and fiber-restricted diet. Malabsorption of fat-and water-soluble vitamins and of minerals (zinc, copper, and calcium) may also occur, and dietary or parenteral supplementation may be required. Parenteral cobalamin supplementation is essential if the ileum has been resected. Acid blockers (e.g., H_2-receptor antagonists) may be used in the postoperative period to counteract possible hypergastrinemia. Antimicrobial agents may be necessary if the ileocecocolic valve has been resected or if secondary SIBO is suspected. If the response to diet and antibiotics is poor, antisecretory agents (loperamide, diphenoxylate, or octreotide) may be required. Bile salt–binding resin (e.g., cholestyramine) may help reduce colonic secretion caused by bile salts malabsorbed after ileal resection.

Complications of short bowel syndrome in humans include gallstones, oxalate uroliths, and lactic acidosis. In refractory cases, experimental surgical modifications of the gut to try to slow intestinal transit and increase absorptive surface area have been described. Intestinal transplantation may be feasible in the future.

222.20.4 Prognosis

The prognosis depends on the amount of intestine left and the response to therapy. Some animals undergo remarkable adaptive hyperplasia and may return to a normal diet, whereas others never respond adequately. 1377 1378

222.21 IRRITABLE BOWEL SYNDROME

Irritable bowel syndrome (IBS) is characterized by recurrent, usually acute, episodes of abdominal pain, borborygmi, and diarrhea. In the absence of morphologic changes, a functional disorder is considered the cause of this enigmatic problem. Disordered intestinal motility may be of primary importance, and a number of mechanisms have been proposed for IBS in humans (Box 222-19).[228] However, it is not known whether any are responsible in dogs and cats. A variety of treatments, including antispasmodics (anticholinergics and also smooth muscle relaxants, such as mebeverine), anxiolytics (e.g., diazepam, chlordiazepoxide) and dietary modification (low-fat diet, increased fiber) have been tried with no consistent results. IBS probably will remain a frustrating condition to diagnose and treat successfully until its etiology is better understood.

223 CHAPTER • 223 Diseases of the Large Intestine

Robert J. Washabau

David E. Holt

The large intestine of the dog and cat has evolved to serve two major functions: (1) extraction of water and electrolytes from the fluid contents of the lumen and (2) control of defecation. The large intestine accomplishes these functions by regulating fluid transport, bacterial fermentation, motility, immune surveillance, and blood flow. Sodium and water absorption serve to dehydrate the feces prior to defecation; mucus glycoproteins serve to trap bacterial pathogens and prevent bacterial translocation; epithelial cells, lymphocytes, plasma cells, macrophages, and dendritic cells serve to regulate the bacterial flora and the immune response to microbes; and motility serves to facilitate storage or defecation of feces. Perturbations in any of these functions may result in the problems of diarrhea, constipation, or the systemic inflammatory response syndrome (SIRS).

223.1 STRUCTURE

223.1.1 Macroscopic Anatomy

The large intestine consists of the cecum, colon, rectum, and anal canal (Figure 223-1). In dogs and cats, the ileum communicates directly with the colon, and what is referred to as the *cecum* in the dog and cat is actually a diverticulum of the proximal colon. The colon is further compartmentalized into ascending, transverse, and descending portions, each segment having slightly different functions and properties. The right colic or hepatic flexure separates the ascending and transverse colon, and the left colic or splenic flexure separates the transverse and descending colon. In dogs and cats, the large intestine contributes 20% to 25% of the total (small and large) intestinal length.[1,2]

The cranial and caudal mesenteric arteries provide the arterial blood supply to the colon, and venous return from the colon is transmitted to the main portal vein via the cranial and caudal mesenteric veins. Lymph is circulated from the colon to the right, middle, and left colic lymph nodes, and eventually into the cisterna chyli and thoracic duct. Parasympathetic innervation arises from the vagus nerve in the proximal colon, and from the pelvic nerves in the distal colon. Sympathetic innervation arises from the paravertebral ganglia and follows the lumbar splanchnic nerves and mesenteric arteries to the colonic mucosa and muscularis. Parasympathetic preganglionic fibers and sympathetic postganglionic fibers synapse on cell bodies and neurons of the enteric nervous system, respectively.

223.1.2 Microscopic Anatomy

As with the small intestine, the cross-sectional structure of the large intestine consists of four distinct layers (i.e., mucosa, submucosa, muscularis, serosa) (Figure 223-2). The large intestine differs from the SI in the following important ways: villi are absent in the large intestine, the microvilli of the large intestine epithelial cells are much less abundant, goblet cells are more prominent in the large intestine, endocrine cells are less prominent in the large intestine, and crypt-to-epithelial migration is a much slower process in the large intestine.

The mucosa of the large intestine is a flat absorptive surface area differing from the small intestine in that villi are not present. However, numerous straight tubular glands (400 to 600 μm) are present in parallel cylinders,

and they extend from the muscularis mucosa to the mucosal surface.[3] The glands are lined by a continuous sheet of columnar epithelial cells, which are separated from the mesenchymal tissue of the lamina propria by a well-defined basement membrane. The epithelium in the lower half of the crypts is composed of proliferating undifferentiated columnar cells, mucus-secreting goblet cells, and at least three types of endocrine cells.[4]

Cellular proliferation is predominantly in the lower part of the crypts in both dogs and cats. The epithelium of the upper half of the crypts consists of differentiating columnar cells, goblet cells, and a few endocrine cells. The flat absorptive surface is lined by many columnar cells and a moderate number of goblet cells (10 to 25 goblet cells per 100 epithelial cells),[3,5] most of which are largely depleted of their mucous granules. Intraepithelial lymphocytes (IELs) are relatively sparsely distributed throughout the epithelium (one to seven lymphocytes per 100 epithelial cells),[3,5] and as in the small intestine, the predominant T cell subset is the cytotoxic-suppressor (CD8+) type.[6,7] The cellular elements of the lamina propria of the large intestine resemble closely those found in the small intestine and include lymphocytes, many plasma cells, mast cells, macrophages, eosinophils, enteric neurons, and fibroblasts.

Figure 223-1 **A,** Radiographic anatomy of the feline colon—lateral projection, barium enema. **B,** Radiographic anatomy of the feline colon—ventrodorsal projection, barium enema.

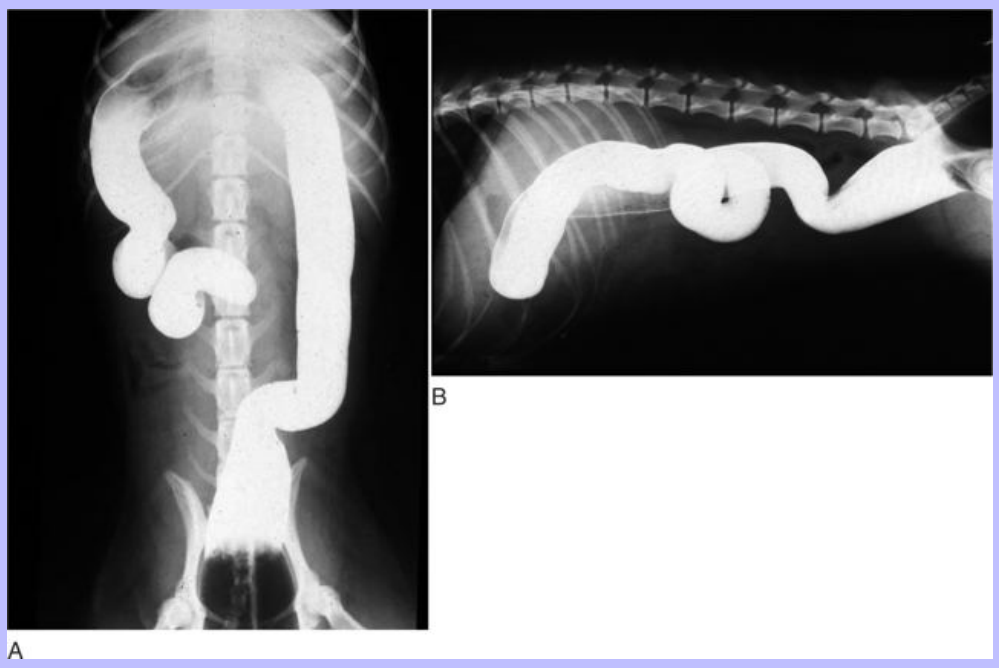

Figure 223-2 Microscopic anatomy of the canine colon.

The innermost layer of the mucosa is separated from the submucosa by the muscularis mucosae, a layer of smooth muscle cells roughly 8 to 10 cells (or 70 to 80 μm) thick. The submucosa of the colon resembles the submucosa of the other tubular digestive organs. It contains many blood and lymph vessels, dense connective tissue sparsely infiltrated by cells (fibroblasts, lymphocytes, plasma cells, mast cells, macrophages, and eosinophils), and the unmyelinated nerve fibers and ganglion cells that form the submucosal plexus.

The muscularis is composed of an inner circular muscular layer forming a tight spiral circumferentially along the course of the colon and an incomplete outer longitudinal muscle layer. The ganglion cells of the myenteric plexus of Auerbach are found between the circular and longitudinal muscle layers. Unmyelinated postganglionic fibers are also found in the circular muscle layer and communicate with the submucosal (Meissner's) plexus. The interstitial cells of Cajal, which are located on the submucosal surface of the circular smooth muscle, play a dual role as pacemaker cells and as mediators of neuromuscular transmission in the colon.[8–10]

The serosa is composed of mesothelial cells and covers only the portions of the large bowel found within the peritoneal cavity (cecum and colon). Several classification systems for colonic mucosal architecture and cellularity have been proposed. One such classification system[11] is outlined in Table 223-1. It should be emphasized that important *age*,[12] *site*,[1,3] *diet*,[13–16] and *procedure*-related[3] differences exist in the cellularity and architecture of the colonic mucosa, and these differences must be taken into account when interpreting colonic histology. For example, the protein and fiber content of the diet have significant effects on colonic mucosal morphology (e.g., crypt depth, cellularity).[14–16] The pathologist should always take these factors into account when interpreting colonic biopsy specimens. The method of biopsy also influences the architecture and cellularity of the mucosa. Compared with full-thickness biopsies, gland length is 25% to 30% shorter and goblet cell numbers are 70% to 75% less in endoscopic biopsies from the same animals. The shallow depth of the endoscopic biopsy apparently causes glandular collapse, and enema or cathartic preparative solutions are believed to cause discharge of mucous goblets.[3,11]

Table • 223-1 Guidelines for Histologic Interpretation of the Canine and Feline Colonic Mucosa

PARAMETER	NORMAL	FREQUENT ABNORMAL FINDINGS
Overall mucosal appearance	Crypts straight, dominated by goblet cells throughout, separated from muscularis mucosae by no more than four layers of leukocytes (or 15 to 20 µm)	Crypts irregularly distributed, tortuous, lifted from muscularis mucosae by more than four-cell thicknesses
	Lamina propria sparse so that crypts are closely applied to adjacent crypts	Crypts obviously separated from adjacent crypts by edema, fibrosis, or leukocytes
	Proprial cell population is sparse and leukocytes almost all lymphocytes and plasma cells; neutrophils absent and eosinophils sparse except at base of crypts	Increase in lymphocyte and/or plasma cell numbers; presence of eosinophils in superficial half of lamina propria. Neutrophils anywhere are abnormal
	Mitotic figures are found in basilar 50% to 60% of each crypt, averaging 2 to 3 per crypt	Basal third of crypts excessively basophilic, mitotic figures in superficial third of crypt
	Overall crypt length 10 or 20 cm proximal to the anus averages 384 to 406 µm	Overall mucosal thickness substantially<or >400 µm (only valid if section is well oriented and includes muscularis mucosae)
Epithelium	Columnar epithelium, basal oval nucleus; a few surface enterocytes may be cuboidal and more basophilic than the neighboring cells	Surface epithelium focally missing with pyknosis or flattening of adjacent enterocytes (versus artifactual loss in which adjacent cells are normal); surface or cryptal epithelium cuboidal or squamous, abnormally basophilic, with suprabasilar nucleus
	Intraepithelial lymphocytes are few (1 to 2 per 100 enterocytes)	Obvious increase in intraepithelial lymphocytes
	Goblet cells diffusely distributed, least numerous at crypt base and on luminal surface; mucin expulsion easily induced by pre-biopsy manipulations (so clinician should evaluate mucin loss into dilated crypt lumens with caution)	Loss of mucin from goblet cells, thus crypts seem depleted of goblet cells and may be dilated with intraluminal mucin
Lamina propria	Inconspicuous except in zone between base of crypt and muscularis mucosae that normally contains mixture of lymphocytes, plasma cells, and eosinophils	Increase in distance between crypts and between crypt base and muscularis mucosae; increases in lymphocytes, plasma cells, eosinophils, and collagen are frequent but not mutually exclusive
	Edema is a frequent biopsy artifact, impossible to distinguish from serious inflammation; similarly, physiologic congestion or hyperemia cannot be distinguished from inflammatory hyperemia	Edema must be regarded with skepticism unless accompanied by other evidence of inflammation or other changes in vascular permeability (e.g., hemorrhage, thrombosis)
Submucosa	Few lymphocytes or plasma cells; no neutrophils or eosinophils	Any type of leukocyte around dilated submucosal vessels (rarely observed except in eosinophilic colitis or invasive bacterial infection); if lymphocytes cross muscularis mucosae into submucosa, clinician should consider lymphoma
	Loosely interwoven collagen	Fibrosis

223.2 FUNCTION

223.2.1 Electrolyte Transport

The large intestine regulates the electrolyte and water composition of the feces. Distinct differences exist in the mechanisms of electrolyte transport between the ascending and descending colon,[17,18] but in general the canine and feline colon absorbs water, sodium, and chloride while secreting potassium and bicarbonate.

1380

1381

Table • 223-2 Anatomic and Physiologic Differences—Large versus Small Intestine

	LARGE INTESTINE	SMALL INTESTINE
Villous projections (villi)	Absent	Present
Brush border microvilli	Sparse	Prominent
Goblet cells	Abundant	Sparse
Endocrine cells	Three cell types	>20 cell types
Crypt-to-epithelial migration	Slow	Rapid
Amino acid +glucose absorption	Absent	Present
Lipid absorption	Absent	Present
Vitamin absorption	Absent	Present
Glucose-stimulated Na absorption	Absent	Present
Electrogenic Na absorption	Present	Absent
Mineralocorticoid-stimulated Na absorption	Significant	Negligible
SCFA production and absorption	Prominent	Minimal

The mechanisms of absorption and secretion in the large intestine are in many ways similar to those of the small intestine (Chapter 222), but several important differences exist (Table 223-2). Active nutrient (glucose, amino acid, monoglyceride) transport is prominent in the small intestine, but no evidence indicates active glucose or amino acid absorption in the colon except during the early neonatal period. Sodium transport also differs in the colon. Glucose-and amino acid–stimulated sodium transport is a well-established property of the small intestine, so much so that oral glucose-electrolyte solutions have been used to reduce the morbidity of cholera and other infectious diarrheal diseases of the small intestine. In contrast, glucose-coupled sodium transport does not take place in the colon and glucose-electrolyte solutions are of no benefit in diarrheal diseases of the large intestine. Sodium transport in the colon instead relies upon electrogenic transport.[18,19] The large intestine also differs in its response to mineralocorticoids. Aldosterone markedly increases sodium transport in the colon, but it has only a modest effect in the small intestine. Net sodium absorption ceases in the colon only when the luminal sodium concentration is reduced below 30 to 50 mEq/L, whereas net sodium absorption in the jejunum occurs only at luminal sodium concentrations above 130 mEq/L.[19]

Chloride absorption in the colon has both passive and active properties. Passive chloride absorption primarily represents a potential-dependent process secondary to the electrical potential generated by electrogenic sodium absorption.

Bicarbonate secretion is an important feature of colonic electrolyte function and helps to neutralize acids produced by bacterial fermentation. Chloride-bicarbonate ($Cl\text{-}HCO_3$) exchange is the primary cellular mechanism responsible for bicarbonate secretion.

The descending colon possesses both potassium absorptive and potassium secretory processes that are regulated by luminally and hormonally mediated mechanisms, and the overall net potassium movement represents the balance of these oppositely directed transport mechanisms.[18,19] Therefore the colon has the potential to serve as an important regulatory system for the maintenance of overall potassium balance. Although renal potassium transport is critical in the overall control of potassium balance, the colon also contributes to the maintenance of potassium balance by modifying both potassium secretion and absorption, especially when kidney function is impaired.

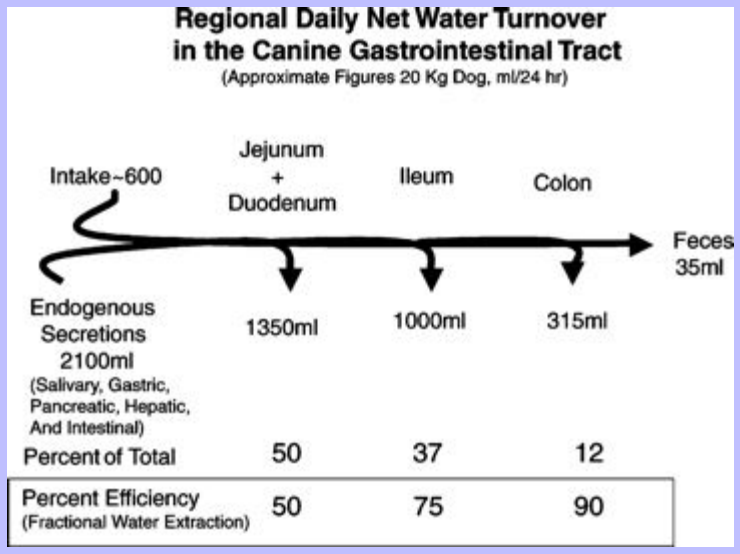
223.2.2 Water Absorption

In health, approximately 2.7 L of fluid (oral intake, saliva, gastric fluid, bile, pancreatic fluid, and intestinal secretions) is presented each day to the small intestine of a 20 kg dog. About 1.35 L is absorbed in the jejunum, 1.0 L in the ileum, and 315 mL in the colon, leaving 35 mL in feces.[20] Thus the jejunum absorbs 50%, the ileum 75%, and the colon 90% of fluid volume presented to it (Figure 223-3). This fluid absorptive capacity of the colon is largely determined by basal electrolyte (primarily sodium) transport and by the ability of several agonists (aldosterone and glucocorticoids) to augment electrogenic and electroneutral sodium absorption. As long as ileocecal flow is less than the colonic absorptive capacity, significant alterations in small intestinal fluid movement may be present, but colonic absorption will prevent the development of diarrhea. On the other hand, when small intestinal absorption and ileocecal flow are normal, a relatively small decrease in colonic absorption (inflammatory bowel disease [IBD]) will produce significant increases in fecal water output.

223.2.3 Mucus Secretion

A lubricant layer of mucus forms a crucial physiologic barrier between the colonic mucosa and the luminal environment. Mucus is a constantly changing mix of secretions and exfoliated epithelial cells, the chief determinants of which are high molecular weight glycoproteins or mucins.[21] Gastrointestinal (GI) mucins are secreted from goblet cells as they ascend from their origin in the crypts up to the colonic epithelium. Mucin secretion is dependent upon the close integration of the cystic fibrosis transmembrane regulator (CFTR), chloride secretion, and granule exocytosis. In addition to their physiologic role as a mucosal barrier, mucins may also have a pathologic role in the metastases of epithelial tumors and enhanced susceptibility to infection.[21]

Figure 223-3 Regional daily water turnover in the canine gastrointestinal (GI) tract. (Adapted from Burrows CF: Chronic diarrhea in the dog. Vet Clin North Am Small Anim Pract 13:521, 1983, with permission.)



1381

1382

223.2.4 Bacterial Fermentation

The colon contains the largest concentration of bacteria in the GI tract, up to 10^{11} organisms per gram of feces. The colonic microflora play an important role in the nutrition of the animal primarily via the production of short chain fatty acids (SCFAs).[22] Major fiber fermentation substrates include cellulose, hemicellulose, and pectin, substrates that typically are not digested by pancreatic or intestinal amylases. Acetate, propionate, and butyrate account for more than 85% of formed SCFAs, and they accumulate in concentrations up to 150 mmol/L in the colon of dogs.[23] SCFAs are rapidly absorbed by the colonic mucosa, are readily metabolized by colonic epithelial cells, and have various physiologic effects. Among their physiologic effects, SCFAs promote differentiation and proliferation of colonocytes,[24] stimulate absorption of water and electrolytes,[25] provide 7% to 10% of an animal's overall energy requirements,[23] and influence or modify motility of the GI tract.[26]

The colonic flora is influenced by many factors, including host species, breed, developmental stage, dietary history, environmental conditions, geographic locale, colonic motility patterns, disease, and medication history.

In general, anaerobic bacteria (*Bacteroides* spp., *Bifidobacterium* spp., *Clostridium* spp., and *Lactobacillus* spp.) predominate in the canine colon, accounting for up to 90% of the colonic microflora. Most are facultative or aerotolerant anaerobes, not true obligate anaerobes.[27] Enterobacteria and streptococci are the predominant aerobic bacteria found in the canine colon. In the cat, approximately equal numbers of anaerobic and aerobic bacteria are found in the colonic lumen.[28]

The colonic flora changes significantly with developmental stages. The aging canine colon becomes more readily populated by *Clostridium perfringens* and other obligate anaerobes, and less populated by aerobes and aerotolerant anaerobes.[27,29] This change takes place in the ascending and descending colon, but it is most significant in the descending colon where anaerobic conditions tend to predominate. Senescent changes in bacterial populations of the colon conform to the principles of successional ecology.[30] Over time, changes in pH, redox potential, bacterial competition, and nutrient availability facilitate the proliferation of anaerobic bacteria permitting them to eventually displace the aerotolerant forms.

An animal's breeding and genetic background may also influence the colonic flora. For example, far fewer *Bifidobacterium* spp. are recovered from the feces of beagle dogs than are recovered from other dog breeds.[29,31] This represents a problem for studies of colonic bacteriology because many of the reference studies have been generated from beagle dogs.

Diet has a major impact on numbers and types of bacteria recovered from the colon. *Bacteroides* spp. appear to be particularly susceptible to changes in the diet.[31–33] The protein, carbohydrate, and fiber content of the diet all appear to influence the ability of bacteria to grow within the colon. Thus dietary history should always be considered when interpreting results of fecal or colonic bacterial cultures.

Geographic locale and environmental conditions can also influence colonic bacteriology in the dog. *Bifidobacterium* spp. are readily isolated from dogs from Japan, but they are inconsistently found in American dogs.[29,31] Housing conditions appear to be another confounding factor. Open housing environments[27] appear to facilitate colonization of a greater proportion of facultative anaerobic bacteria compared with closed facility conditions.[34]

Motility patterns of the colon influence the bacterial ecology of the colon. The antiperistaltic activity of the ascending and transverse colon particularly facilitates the mixing of fecal material with endogenous bacteria. Abnormalities in the motility patterns of this part of the colon lead to changes and proliferation of obligate anaerobes similar to that found in the descending colon.[35]

Disease and medical therapies, particularly antibiotics, alter the microbial characteristics of the colon. These changes are poorly understood in dogs and cats, but they very likely contribute to clinical symptomatology.

223.2.5 Immune Surveillance

The colon contains a diverse array of immune cells, including T and B lymphocytes, plasma cells, macrophages, dendritic cells, antigen-presenting cells, mast cells, eosinophils, and neutrophils.[3,5–7,36–39] Immune cells are found in the epithelium, lamina propria, and submucosa of the colon. As in the small intestine, appropriate interactions between these different cell types are essential in generating either immune responsiveness or tolerance to the large array of luminal antigens.[40,41] Much less is known about colonic immunity, but some generalizations may be made. In the colon, CD8+ T cells are found primarily in the epithelium; very few CD8+ T cells are found in the lamina propria or submucosa. Most IELs are CD3+ and CD8+, a phenotype consistent with suppressor-cytotoxic functions. Lamina propria T cells, on the other hand, are predominantly of the CD4+ helper phenotype. Immunoglobin A (IgA)-containing plasma cells are more prominent than IgG-or IgM-containing plasma cells in the lamina propria. Thus in the normal colonic mucosa, a balance would appear to be maintained between helper and suppressor T cell populations, which allows specific antigen responsiveness while avoiding hyper-reactivity.[5,6,42] A more detailed discussion of GI

immunity may be found in Chapter 222, Diseases of the Small Intestine. Many similarities exist in the immune systems at both sites, but important differences exist in the immune response of the small and large intestine (discussed in Inflammation).

223.2.6 Motility

The colon has evolved to serve two important functions: (1) extraction of water and electrolytes from the luminal contents in the ascending and transverse colon and (2) control of defecation in the descending colon. This specialization of function has been attributed to regional differences in colonic motility patterns.[35,43–46] Electrical slow wave frequency and rhythmic phasic contractions (RPCs) are slower in the proximal portion of the colon, thus facilitating extraction of water from the fecal mass by diffusion and active transport. Retrograde giant contractions (RGCs) and antiperistalsis further facilitate the mixing of contents in the proximal colon. In contrast to that of the proximal colon, motility of the distal colon is characterized primarily by migrating spike bursts and powerful giant migrating contractions (GMCs) that propagate the fecal mass toward the rectum.[46]

Colonic smooth muscle generates at least four different types of contractions to perform the complex motility functions of mixing and propulsion: (1) tone, (2) RPCs, (3) RGCs, and (4) GMCs. The time course, frequency, and force generated by each of these contractions are significantly different from each other.[43–46] The precise role of tone in circular muscle cells is not known, but the resulting decrease in the diameter of the colon may enhance the efficiency of the phasic contractions in mixing and propulsion. Tone is normally of small to moderate force and can last for prolonged periods of time (several minutes to hours). RPCs produce mixing and net slow distal propulsion of luminal contents in the postprandial and fasting state. Phasic contractions occur rhythmically at a few cycles per minute, last for about 3 to 5 seconds, and generate a moderate force (75 to 100 g). RGCs occur infrequently, last for about 20 seconds, generate a very strong force (> 150 g), and are propagated from their point of origin into the ascending colon. RGCs facilitate mixing in the ascending colon. The GMCs are of a similar magnitude and frequency to the RGCs, but they generate mass movements from their point of origin to the anorectal junction. It has been suggested that different signal transduction pathways are used by smooth muscle cells to trigger different contractions.[47,48] It is remarkable that the same smooth muscle cells can generate so many different types of contractions using a limited number of second messengers.

1383

223.3 DIAGNOSTIC EVALUATION

223.3.1 History and Physical Examination

Inflammation is the most important pathophysiologic condition of the colon. Colitis is responsible for the major clinical signs of hematochezia, mucus in the feces, dyschezia, abdominal discomfort, tenesmus, urgency, and increased frequency of defecation. The colon is an important target organ for IBD in the dog, whereas the upper GI tract (stomach and small intestine) is more frequently involved in feline IBD. Clinical signs are useful in localizing the anatomic site of the diarrhea to the small or large bowel (Table 223-3), although some animals will have diffuse involvement of the small and large intestines.

The history should include specific questions about diet, parasite control, environment, travel history, concurrent medical disease, and drug history. Dietary sensitivity reactions[49] and parasitism are major causes of colitis in many pet populations. Dietary history should include information regarding type of diet, incidence

of dietary indiscretion, supplements, snacks, and treats. Information concerning previous fecal examinations and anthelmintic use may provide useful clues to the cause of the diarrhea. Environmental history should identify other pets in the household, the composition of their diets, and any behavioral interactions or hierarchies that might influence the development of clinical signs. The travel history may yield important information about exposure to histoplasmosis, pythiosis, and heterobilharziasis, all of which have regional distributions. Concurrent medical disease (e.g., Addison's disease, IBD, pancreatitis) will also help place the current episode of colitis in context. The drug history should include information about the use of alternative and complementary medicines that could contribute to clinical symptomatology.

The physical examination may be normal in many cases of colitis. The most consistent physical examination findings are pain and irregularities of the colonic mucosa on digital rectal examination. The perineum should be examined carefully to exclude perineal diseases such as perineal hernia and perianal fistula. Physical examination may reveal other important findings, including *fever* (IBD, cecal or colonic perforation, fungal infection), *abdominal pain* (IBD, colonic neoplasia, cecal or colonic perforation), *abdominal mass* (colonic neoplasia, granulomatous colitis, intussusception), *small intestinal thickening* (concurrent SI IBD, SI lymphoma), *mesenteric lymphadenopathy* (SI IBD, SI lymphoma), *hepatosplenomegaly* (lymphoma, disseminated fungal infection), and *uveitis* (protothecosis, lymphoma). A scoring system has been developed to relate clinical signs with histologic findings in canine IBD.[50]

Table • 223-3 Clinical Signs Associated with Diarrhea—Large Bowel versus Small Bowel

SIGNS	SMALL BOWEL	LARGE BOWEL
Weight loss	May be present	Uncommon
Vomiting	May be present	Uncommon
Flatulence	Present with malassimilation	Unusual
Defecation frequency	Normal to mild increase	Marked increased frequency
Fecal volume	Increased	Normal to mild increase
Urgency	Absent	Usually present
Tenesmus	Absent	Usually present
Mucous in feces	Usually absent	Frequently present
Hematochezia	Absent	Often present
Melena	Sometimes present	Absent
Steatorrhea	Present with malassimilation	Absent

Constipation is the second most important pathophysiologic condition of the colon. Clinical signs include reduced, absent, or painful defecation for a period of time ranging from days to weeks or months. Physical examination findings will depend on the severity and pathogenesis of constipation. Dehydration, weight loss, abdominal pain, and mild to moderate mesenteric lymphadenopathy are common findings in cats with idiopathic constipation. Physical examination might also reveal *abdominal mass* (cecal or colonic neoplasia, granulomatous colitis), *abdominal pain* (foreign bodies, colonic perforation), *autonomic neuropathy* (dysautonomia), *hindlimb paresis* (lumbar spinal cord pathology), *pelvic fracture* (pelvic outflow obstruction), and *perineal hernia* (cause or complication of constipation).

223.3.2 Laboratory Data

For both inflammation and constipation, the scope of the medical investigation will be shaped by prior history, suspected cause, chronicity, and signs of systemic illness[51,52] (Figure 223-4).

Complete blood count (CBC), serum chemistry, and urinalysis should be considered in animals with signs of colonic disease, particularly those with signs of systemic disease. These tests may provide evidence of *anemia* (chronic disease, GI blood loss), *leukocytosis* (IBD, neoplasia, cecal or colonic perforation), *eosinophilia* (parasitism, Addison's disease, mast cell disease, hypereosinophilic syndrome), *thrombocytopenia* (concurrent immune thrombocytopenia), *hypoproteinemia* (protein-losing enteropathy [PLE]), *hyperglobulinemia* (FIP, IBD, infection, neoplasia), *hypercalcemia* (neoplasia, fungal disease), *hypoglycemia* (leiomyosarcoma), and *hyponatremia* and *hyperkalemia* (Addison's or pseudo-Addison's disease). This minimum data base is also useful to screen animals prior to anesthesia and colonoscopy. If fungal, *Oomycetes*, or algal infections are possible causes in the pet's geographic area, special serologic tests are available for the diagnosis of some of these diseases (Table 223-4). Feline leukemia virus (FeLV) and Feline immunodeficiency virus (FIV) testing are warranted in cats with unexplained, chronic diarrhea.

223.3.3 Fecal Parasitic Evaluation

Direct fecal smears and fecal flotation studies should be performed to evaluate for helminth, protozoa, and some bacterial infections (see Table 223-4). Direct fecal smears may be useful in detecting *Giardia*, *Tritrichomonas*, and *Campylobacter* organisms. Zinc sulfate flotation is the most accurate and practical fecal flotation test available, and it may be more sensitive for the detection of *Giardia* and *Tritrichomonas* infections. Some animals may have intermittent shedding of helminth ova, *Giardia* trophozoites and cysts, or both; therefore suspected infections should always be treated with anthelmintics or antiprotozoal agents before animals are subjected to colonoscopy.

223.3.4 Fecal Bacterial Culture

Fecal cultures should be considered in animals with suspected bacterial infections of the intestine and colon. Risk factors for bacterial colitis include young age, crowded or poor hygienic environmental conditions, co-infection with helminth or protozoal parasites, viral immunosuppression,[53] boarding or kenneling conditions, and multiple-pet households. Bacterial pathogens associated with colitis or enterocolitis lesions in dogs and cats have included *Brachyspira pilosicoli*, *Campylobacter* spp., *Clostridium perfringens* and *C. difficile*, certain *Escherichia coli* (enterotoxigenic, enteroinvasive, enteropathogenic, enterohemorrhagic, enteroadherent), *Salmonella* spp., and perhaps *Yersinia enterocolitica* (see Table 223-4). Culture results should always be interpreted in light of clinical signs, other findings such as coinfections, and substantiating laboratory data such as serologies or polymerase chain reaction (PCR) results. Fecal cultures should not be performed for the purpose of diagnosing small intestinal bacterial overgrowth (Chapter 222).

1383 1385

Figure 223-4 **A,** Diagnostic approach to large intestinal diarrhea. **B,** Diagnostic approach to constipation. *PCR,* Polymerase chain reaction; *RT-PCR,* reverse transcriptase polymerase chain reaction.

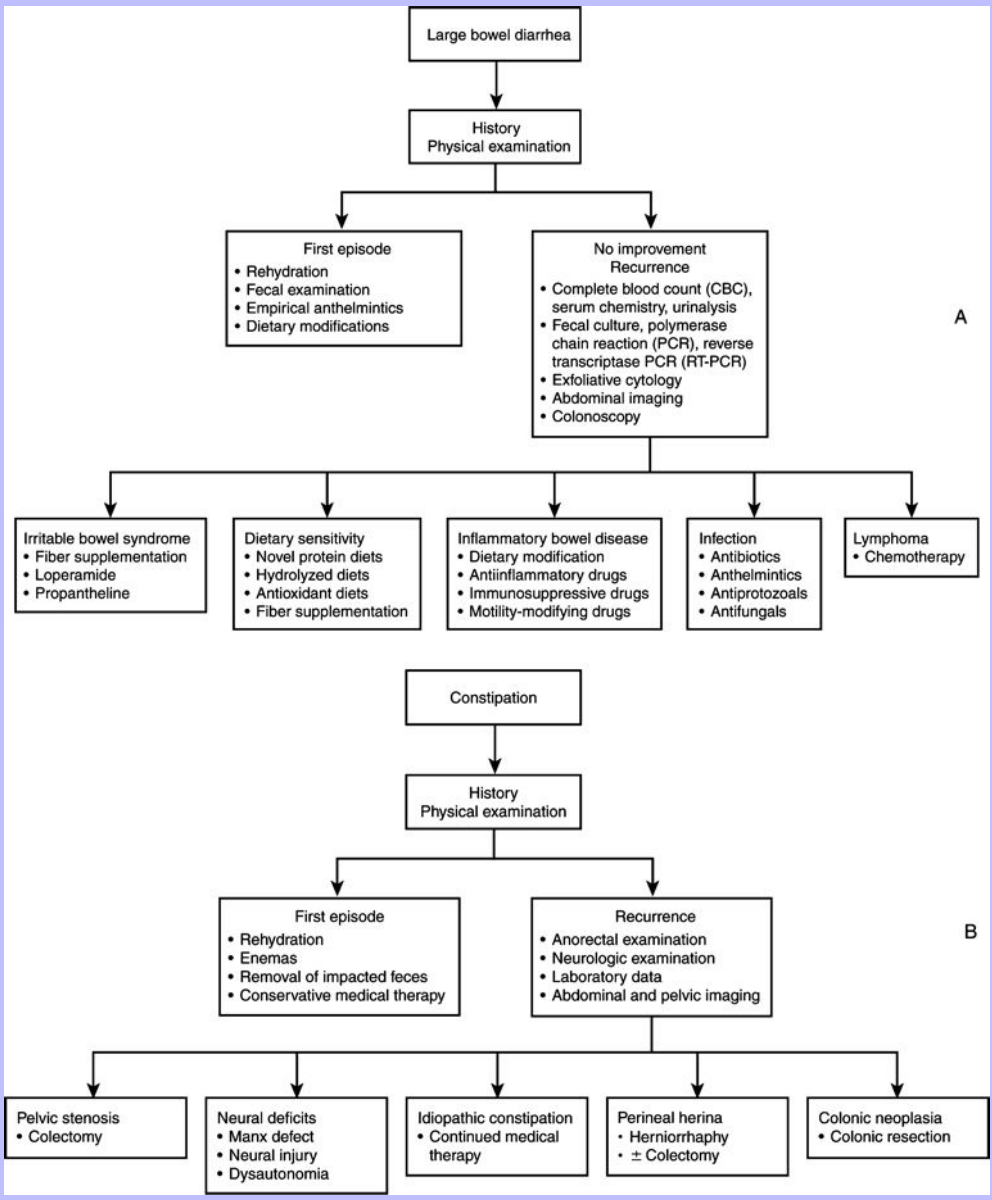

Table • 223-4 Definitive, Suspected, and Unproved Pathogens of the Large Intestine of Dogs and Cats

CLASSIFICATION/ORGANISM	TISSUE TROPHISM	EVIDENCE OF PATHOGENICITY	DIAGNOSIS	REFERENCES
Helminths				
Trichuris vulpis	Cecum, colon	Good evidence	Fecal flotation	63,64
Trichuris serrata, *T. campanula*	Cecum, colon	Moderate evidence	Fecal flotation	63,64
Ancylostoma caninum	Intestine, colon	Good evidence	Fecal flotation	63,71,116,117
Heterobilharzia americana	Colon	Good evidence	Fecal flotation, histology	66,67,68
Protozoa				
Balantidium coli	Colon	Poor evidence	Fecal flotation	69,70
Entamoeba histolytica	Colon	Weak evidence	Fecal flotation	71,72,73
Giardia spp.	Intestine, colon	Moderate to good evidence	Fecal flotation, ELISA, IFA, duodenal/colonic aspiration	74–87
Isospora ohioenesis—dogs	Intestine, cecum, colon	Weak evidence	Fecal flotation	88,89
Tritrichomonas foetus—cats	Ileum, cecum, colon	Moderate to good evidence	Fecal flotation, culture, PCR	90–95
Fungi				
Histoplasma capsulatum	Intestine, colon	Good evidence	Exfoliative cytology, histology	96–100
Oomycetes				
Pythium insidiosum	Stomach, intestine, colon	Good evidence	Histology, immunohistochemistry, ELISA, PCR	101–107
Algae				
Prototheca zopfii/wickerhamii	Eyes, skin, colon, CNS	Good evidence	Exfoliative cytology, histology	108,109
Bacteria				
Brachyspira pilosicoli	Ileum, colon	Moderate evidence	Culture, PCR, histology	110–114
Campylobacter coli, *C. jejuni*, *C. upsaliensis*, *C. helveticus*	Intestine, colon	Moderate to good evidence	Culture, PCR	115–124
Clostridium perfringens	Colon	Moderate to good evidence	Gram staining, culture, ELISA, PCR	126–133
Clostridium difficile	Colon	Weak to moderate evidence	Culture, Toxin A ELISA, genotyping	131–136
E. coli (ET, EI, EP, EH, EA)	Intestine, colon	Good evidence	Culture, serotyping, PCR	137–144
Salmonella spp.	Intestine, colon	Good evidence	Culture, serotyping, PCR	145–147
Yersinia enterocolitica	Colon	Poor evidence	Culture	148,149

ELISA, Enzyme-linked immunosorbent assay; IFA, indirect fluorescent antibody; PCR, polymerase chain reaction.

223.3.5 Molecular Diagnosis

A number of PCR and reverse transcriptase (RT)-PCR assays have been developed for gene amplification products and messenger RNAs of infectious organisms. Assays are now available for the molecular diagnosis of *Tritrichomonas foetus*, *Pythium insidiosum*, *Campylobacter jejuni*, *Clostridium perfringens*, *C. difficile*, *E. coli*, *Salmonella* spp., and *Brachyspira pilosicoli*, and many more are likely forthcoming. Molecular detection has become the standard for infectious disease diagnosis in many instances.[54]

1385
1386

223.3.6 Exfoliative Cytology

Exfoliative rectal or endoscopic cytology may be useful in identifying causative agents (e.g., fungal elements, neoplastic cells) and inflammatory cells (e.g., lymphocytes, eosinophils). Rectal smears may be obtained with cotton-tipped applicator or conjunctival spatula during anorectal examination or with a cytology brush at the time of endoscopy. A good correlation (specificity: 97%; sensitivity: 93%) has been shown between exfoliative cytology and subsequent endoscopic or surgical biopsy in one study.[55] Additional studies will be needed to verify the diagnostic value of this test.

223.3.7 Imaging

Survey abdominal radiographs may occasionally document colonic foreign objects, mesenteric or sublumbar lymphadenopathy, intussusception, and extraluminal compression; however, survey radiographs are generally nonspecific in the diagnosis of colonic disease. Contrast studies (i.e., barium enema) are performed infrequently because of their poor sensitivity and requirement for general anesthesia. Ultrasonographic imaging has proved more useful in documenting mass lesions, lymphadenopathy, intussusceptions, and bowel thickening. Abdominal ultrasound may also be used to facilitate percutaneous aspiration of luminal masses, mucosal thickenings, and lymph nodes.[56,57] Computed tomography (CT) colonography, also known as *virtual colonoscopy*, has been successfully implemented in human medicine and has been studied experimentally in the dog.[58]

223.3.8 Colonoscopy

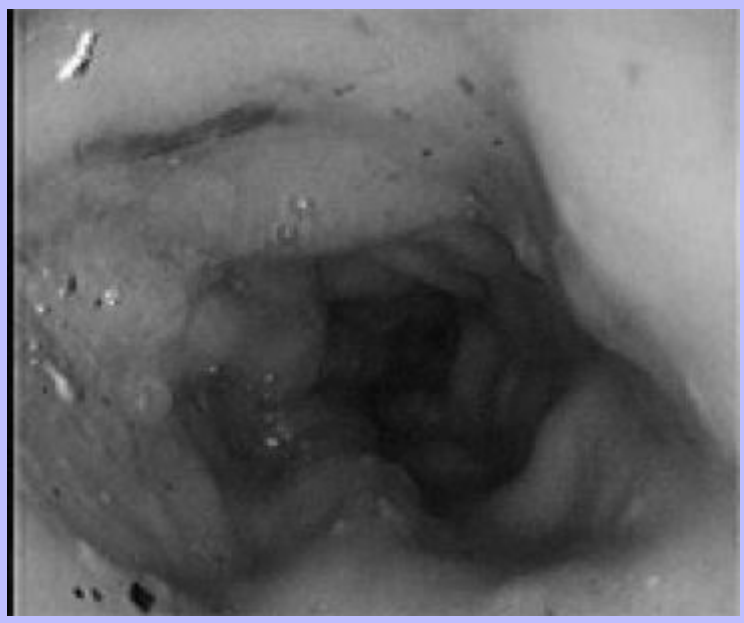
Colonoscopy is indicated for the diagnosis of colitis-type diarrhea unresponsive to dietary modification and medical therapy, suspected colorectal neoplasia, chronic constipation, unexplained stricture, and evaluation of prior surgical or medical treatment.[59] Colonoscopy is performed after other noninvasive diagnostic tests (e.g., fecal parasitologic examination, fecal bacteriologic examination, exfoliative cytology, abdominal ultrasonography, survey ± barium contrast radiography) have failed to diagnose the disease.

Rigid or flexible endoscopy may be performed, but flexible endoscopy provides better visualization and examination of the entire colon. The normal colonic mucosa is pink in color, smooth in texture, and glistening in appearance (Figure 223-5). Unlike the esophageal, gastric, and duodenal mucosa, submucosal blood vessels are readily apparent. The mucosa should not hemorrhage when abraded by the endoscope; active hemorrhage usually implies an underlying disorder such as inflammation or infection. The colonoscopic procedure should include examination of the more proximal structures (e.g., ascending colon, cecum, ileocecal sphincter, distal ileum) whenever possible. The proximal colon is an important site of inflammation, parasitism, ileocolic intussusception, cecal inversion, and neoplasia.

Fecal materials must be completely evacuated before the colonic mucosa can be properly examined. Incomplete bowel preparation is the major reason for an unsuccessful colonoscopic examination. Patient permitting, food should be withheld for 36 to 48 hours so that fecal material does not accumulate in the colon. The patient should also be given warm-water enemas, GI lavage solutions, or both. Lavage solutions are preferable to warm-water enemas,[60–62] but both may be given to facilitate successful colonoscopy. Polyethylene glycol solutions are isosmotic, administered orally, and induce a diarrhea that rapidly removes fecal material from the bowel. Large volumes may be administered without inducing significant changes in

water or electrolyte balance.[60] Electrolyte solutions should be given at a dose of 25 mL/kg at 24 and 12 hours prior to colonoscopy. Warm-water enemas should be performed gently, without irritating substances, at 24, 6, and 2 hours before colonoscopy. The combination of a 36 to 48 hour food-fast, GI lavage solution, and enemas will usually result in a colon that is free of fecal fluids and solids. Endoscopic examination of the colon is described in detail (see Chapter 101).[59]

Figure 223-5 Normal endoscopic appearance of the canine large intestine.



Diseased tissue, nondiseased tissue, and the transition zone between diseased and nondiseased tissue should be biopsied during colonoscopic procedures. This standard helps to verify the extent of the disease, ensures that disease in the submucosa has not been missed, and provides representative tissue samples to the pathologist to diagnose the disease. In some cases of severe IBD or colonic neoplasia, advanced tissue necrosis may prevent the diagnosis of the disease process in the central part of the lesion. In the absence of gross mucosal abnormalities, three to five biopsy specimens should be obtained from each of the midascending, midtransverse, and mid-descending colonic regions.

223.4 INFECTION

The colon may be colonized by several types of infectious organisms. The most important of these are the helminths (*Trichuris* spp., *Ancylostoma* spp., *Heterobilharzia* spp.), protozoa (*Giardia* spp., *Tritrichomonas* spp.), fungi (*Histoplasma* spp.), Oomycetes (*Pythium* spp.), algae (*Prototheca* spp.), and bacteria (*Brachyspira* spp., *Campylobacter* spp., *Clostridium* spp., enteropathogeneic and enterotoxigenic *E. coli*, and *Salmonella* spp.). The routine medical investigation of any dog or cat affected with chronic large bowel diarrhea should include direct and indirect fecal examinations for helminth and protozoa, bacterial culture of feces, and serologies (see Table 223-4). Some organisms appear to be of low pathogenicity, but it should be emphasized that even commensal organisms may become pathogens given the appropriate circumstance.

223.4.1 Helminths

223.4.1.1 Trichuris

223.4.1.1.1 Cause

Trichuris vulpis is perhaps one of the most common causes of chronic large bowel diarrhea in dogs.[63] 1386
Cats are occasionally infected with *T. serrata* and *T. campanula*. Clinical signs in *Trichuris*-infected 1387
dogs and cats may vary from asymptomatic infections to mild intermittent episodes of mucousy feces to acute-onset bloody diarrhea with tenesmus and dyschezia.

223.4.1.1.2 Pathophysiology

The fecal-oral route of transmission is the canonical route of infection. After ingestion of infective *Trichuris* ova, eggs hatch in the small intestine and larvae migrate to the cecum and colon where they attach to the mucosa. The pathogenicity of any infection is generally related to the magnitude of the host immune response. Factors contributing to the pathogenicity and clinical signs include the number of mature worms present, the location of the worms, the degree of inflammation, the severity of anemia or hypoproteinemia, nutritional status of the host, and the presence of other GI parasites and micro-organisms.[64]

223.4.1.1.3 Clinical examination

Affected animals generally have mild clinical signs of typhlitis and colitis, although some dogs develop a clinical scenario of signs and laboratory findings (e.g., hyponatremia, hypochloremia, hyperkalemia) consistent with hypoadrenocorticism. When tested, *Trichuris*-infected dogs are normoreactive to ACTH stimulation and are instead referred to as *pseudo-Addisonian*.[65] Eosinophilia, anemia, and hypoalbuminemia are possible, but these are more common laboratory findings with other GI helminth infections (e.g., hookworms).

223.4.1.1.4 Diagnosis

Trichuris ova can be identified on routine fecal flotation procedures; however, they may be missed because of intermittent shedding. Empiric treatment for occult *Trichuris* infection should always be performed before moving on to a more detailed, costly, and unnecessary medical investigation.

223.4.1.1.5 Treatment

Many safe and effective therapeutic agents are available for *Trichuris* spp. Fenbendazole, febantel with praziquantel, milbemycin, and ivermectin with pyrantel pamoate all have established efficacy against whipworms. Treatment should be repeated in 3 weeks and again in 3 months, and pet owners should be advised to decontaminate the environment.

223.4.1.1.6 Prognosis

The prognosis for recovery and cure is excellent.

223.4.1.2 Ancylostoma caninum.

Hookworms are primary pathogens of the small intestine (Chapter 222), but they occasionally infect the cecum and colon with overwhelming infestations. Diagnosis is achieved by demonstrating hookworm ova in the feces, and treatments are similar to those used for whipworm infections (Chapter 222).

223.4.1.3 Heterobilharzia americana

223.4.1.3.1 Cause

H. americana is considered the primary agent of schistosomiasis in dogs. It is an uncommon infection in dogs and is encountered almost exclusively in the southern Atlantic and Gulf Coast states in the United States. In addition to the dog, nutria, raccoons, rabbits, and mice serve as important reservoir hosts. Although uncommon, heterobilharziasis is an important consideration in the differential diagnosis of acute and chronic large bowel diarrhea in endemic areas.[66,67]

223.4.1.3.2 Pathophysiology

The life cycle of *H. americana* is complex and involves an intermediate (snail) and definitive (dog) host and various life stages. Dogs are infected when motile cercaria from snails penetrate their skin. The schistosomulae migrate from the skin to the liver of the definitive host, where they develop into mature male and female worms. Adult schistsomes lay eggs in the terminal mesenteric venules, and egg migration through the bowel wall elicits an intense granulomatous response. It is usually the host response that gives rise to the clinical symptomatology.

223.4.1.3.3 Clinical examination

Clinical signs vary from none to acute signs of vomiting, weight loss, bloody diarrhea, and progressive emaciation. Affected animals may have biochemical evidence of hypoalbuminemia, hyperglobulinemia, hypercalcemia, and liver enzyme elevation.[68]

223.4.1.3.4 Diagnosis

Diagnosis is confirmed by demonstration of ova on direct fecal examination or tissue biopsy. Serologic tests have not yet been successfully implemented in companion animals.

223.4.1.3.5 Treatment

Fenbendazole in combination with praziquantel appears to be effective in the treatment of *H. americana*.

223.4.1.3.6 Prognosis

The prognosis for acute infections is generally favorable, although severe liver involvement may portend chronic liver disease and cirrhosis.

223.4.2 Protozoa

223.4.2.1 Balantidium coli

B. coli is primarily a pathogen of sheep. Only one case report of natural infection in the dog has ever been published.[69] In another report, a total of 375 fecal samples of 56 mammalian species belonging to 17 families of 4 orders were examined for the detection of *Balantidium coli. B. coli* organisms were detected in several animal species, but not in dogs or cats.[70]

223.4.2.2 Entamoeba histolytica

Two isolated case reports of colitis in dogs[71] and one in cats[72] are associated with recovery of *E. histolytica* from the feces. *E. histolytica* can be recovered from the feces of healthy dogs and cats, but it appears to be of low pathogenicity in dogs and cats.[73]

223.4.2.3 Giardia

223.4.2.3.1 Cause

Giardia spp. are protozoal parasites that primarily infect the small intestine of dogs and cats. The cecum and colon are only occasionally colonized by *Giardia*. All mammalian isolates are currently classified as *Giardia lamblia*, although some nomenclature systems use the name *G. duodenalis* or *G. intestinalis*.[74] Recent DNA sequence technology suggests that one or two distinct *Giardia* genotypes can be isolated exclusively from dogs,[75,76] and a distinct genetic group can be isolated from cats.[77] It is not clear whether differences in pathogenicity exist between these genotypes. *Giardia* species have a worldwide distribution. Because *Giardia* is maintained in nature primarily by fecal-oral transmission, more cases are associated with crowded and unsanitary conditions. A recent study showed a prevalence in the dog of 7.2%.[78]

223.4.2.3.2 Pathophysiology

Giardia spp. are found on the surface of enterocytes, where the trophozoites attach to the brush border of the epithelium. Specific histologic changes have not been reported, but persistence of infection may promote apoptosis and inhibition of re-epithelialization.

223.4.2.3.3 Clinical examination

Although infected animals may remain asymptomatic, clinical signs such as acute or chronic diarrhea, weight loss, or even acute or chronic vomiting may develop. Although *Giardia* cysts and trophozoites have been found in the feces of dogs with both small bowel and large bowel diarrhea, *Giardia* infection is primarily a problem of the small intestine (Chapter 222).

223.4.2.3.4 Diagnosis

Giardia infections can be diagnosed by demonstrating motile trophozoites on fresh fecal smears or cysts by zinc sulfate sedimentation.[79,80] Commercial enzyme-linked immunosorbent assay (ELISA) kits have also been used to detect *Giardia* antigen in fresh fecal samples. ELISA assays may be slightly more sensitive and specific than a single zinc sulfate concentrating technique in diagnosing *Giardia* infections in dogs.[78,80] A direct immunofluorescent antibody test has been used in the diagnosis of *Giardia* infections in humans, but it has not yet been validated in the dog. Duodenal aspirates during GI endoscopy appear to be ineffective in diagnosing *Giardia* infection.[81]

223.4.2.3.5 Treatment

Metronidazole, ipronidazole, fenbendazole, albendazole, and a praziquantel, pyrantel pamoate, febantel combination have all been used in the treatment of *Giardia* infections with varying levels of success.[82–85] A *Giardia* vaccine has been shown to be effective in prevention and therapy in dogs,[86,87] but efficacy has not yet been established in cats.[74]

223.4.2.3.6 Prognosis

The prognosis for long-term health and recovery is generally very favorable.

223.4.2.4 Isospora canis, I. ohioensis, I. felis, I. neorivolta.

The *Isospora* species are the most common coccidial parasites of dogs (*I. canis* and *I. ohioensis*) and cats (*I. felis* and *I. neorivolta*). The coccidia are primarily parasites of the small intestine (Chapter 222), but *I. ohioensis* may induce cecal and colonic pathology in puppies and young dogs.[88,89] Sulfadimethoxine (50 mg/kg orally, once a day for 10 days) or sulfatrimethoprim (15 to 30 mg/kg orally, once a day for 5 days) may be used where clinical signs warrant treatment.

223.4.2.5 Tritrichomonas foetus

223.4.2.5.1 Cause

Tritrichomonas foetus is a flagellated protozoan parasite that is an important venereal pathogen in cattle. *T. foetus* has also been identified as an intestinal pathogen in domestic cats from which intraluminal infection of the colon leads to chronic large bowel diarrhea.[90] Infected cats are usually young and frequently reside in densely populated housing such as catteries or animal shelters. Cats often have a

history of infection with *Giardia* spp.; these infections are subsequently identified as *trichomoniasis* after failure to eradicate the organisms with standard antiprotozoal treatment (e.g., metronidazole or fenbendazole).

223.4.2.5.2 Pathophysiology

After experimental inoculation in cats, *T. foetus* organisms have been shown to colonize the ileum, cecum, and colon, reside in close contact with the epithelium, and are associated with transient diarrhea that is exacerbated by coexisting cryptosporidiosis.[91]

223.4.2.5.3 Clinical examination

Infected animals have clinical signs that are consistent with chronic colitis-type diarrhea.

223.4.2.5.4 Diagnosis

Diagnosis of trichomonosis in cats is made by direct observation of trichomonads in samples of freshly voided feces that are suspended in physiologic saline (0.9% NaCl) solution and examined microscopically at ×200 to ×400 magnification.[92] *T. foetus* can also be grown from feces via incubation at 37°C in Diamond's medium.[93] The sensitivity of direct examination of a fecal smear for diagnosis of *T. foetus* in naturally infected cats is unknown but is suspected to be poor. A commercially available culture system that is sensitive and specific for culture of *T. foetus* will improve the diagnostic outcome. These kits are most useful when inoculated with less than or equal to 0.1 g of fresh feces at 25° C. More recently, a single-nested tube PCR technique has been developed that is ideally suited for diagnostic testing of feline fecal samples that are found negative by direct microscopy and by definitive identification of microscopically observable or cultivated organisms.[94]

223.4.2.5.5 Treatment

At this time the origin of the infection in most cats is unknown, and no effective antimicrobial treatment exists for *T. foetus* infection. Metronidazole and fenbendazole may improve clinical signs but generally do not resolve infection. Nitazoxanide eliminates shedding of *T. foetus* and *Cryptosporidium* oocysts, but diarrhea and oocyst shedding recur with discontinuation of treatment. A series of cats that were treated with paromomycin for *T. foetus* infection subsequently developed kidney failure.[95] Consequently, paromomycin should probably not be used in cats.

223.4.2.5.6 Prognosis

The prognosis for eradication of the organism is not encouraging at this time.

223.4.3 Fungi

223.4.3.1 Histoplasma capsulatum

223.4.3.1.1 Cause

Histoplasmosis is a systemic fungal disease of dogs and cats caused by *H. capsulatum*. In the environment, *H. histoplasma* organisms are mycelial, saprophytic soil fungi. In infected tissue or when cultured at 30 to 37° C, the organism is a yeast. The fungus is endemic throughout most of the temperate and subtropic regions of the world. Most cases of histoplasmosis in the United States occur in the central states, with the geographic distribution following the Mississippi, Ohio, and Missouri Rivers.[96,97]

223.4.3.1.2 Pathophysiology

Infection is probably via inhalation or ingestion of infective conidia from the environment. The respiratory system is thought to be the primary route of infection in cats and dogs, although the GI tract may also be an important route in the dog. After inhalation or ingestion, conidia transform from the mycelial phase and are phagocytized by macrophages, where they grow as facultative intracellular organisms. Hematogenous and lymphatic dissemination results in multisystemic disease. Organisms can be disseminated to any organ system, but the lungs, GI tract, lymph nodes, liver, spleen, bone marrow, eyes, and adrenal glands are the most common organs of dissemination in the dogs; lungs, liver, lymph nodes, eyes, and bone marrow are most commonly affected in cats. Cell-mediated immunity induces a granulomatous inflammatory response in most infections.[98]

223.4.3.1.3 Clinical examination

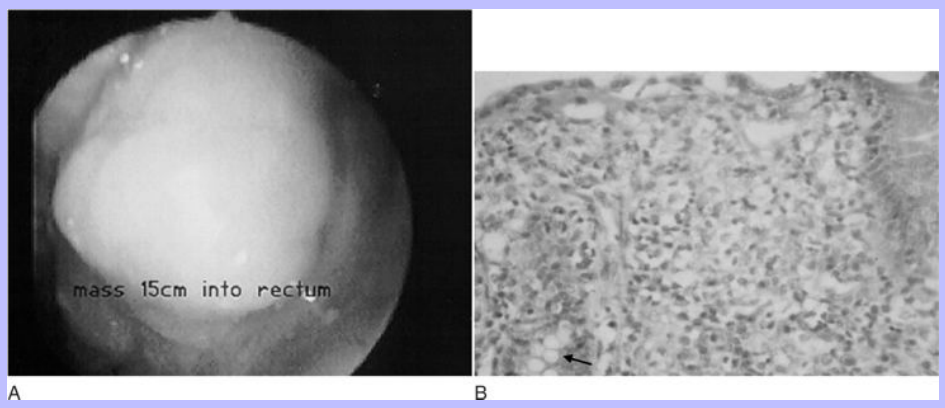
Dogs with GI histoplasmosis typically have mild fever, anorexia, lethargy, weight loss, vomiting, diarrhea, hematochezia, and tenesmus. Cachexia is a common physical examination finding. Other historical and physical examination findings (dyspnea, cough, ascites, lameness, oropharyngeal ulcerations, chorioretinitis, neuropathy) will depend upon organ and tissue involvement. The full clinical spectrum of histoplasmosis infection is outlined in Chapter 174.

223.4.3.1.4 Diagnosis

Endoscopic examination usually reveals severe granulomatous inflammation of the large intestine (Figure 223-6, *A*). Organism identification is required for definitive diagnosis. The most common means of organism identification is cytology. Cytology from affected tissue reveals pyogranulomatous inflammation, often with numerous small, round to oval intracellular yeast cells (2 to 4 μm in diameter) characterized by a basophilic center and a light halo (Figure 223-6, *B*). Exfoliative cytology during colonoscopy is particularly useful in diagnosing the disease.[55] Histopathology is helpful if cytology is nondiagnostic or inconclusive. Multiple endoscopic colonic biopsies are usually sufficient to diagnose the disease. The yeast form does not stain well with routine hematoxylin-eosin (H&E) stains, so special stains such as PAS and Gomori's methenamine silver stain are often used to demonstrate organisms.

Fungal culture from affected tissue can be used for diagnosis but is rarely needed in clinical cases. Currently available serologies have poor specificity and sensitivity.[98]

Figure 223-6 **A,** Endoscopic appearance of granulomatous colitis in a dog infected with *Histoplasma* spp. **B,** Histologic appearance of granulomatous colitis in a dog infected with *Histoplasma* spp. Arrow indicates numerous small, round to oval intracellular yeast cells (2 to 4 µm in diameter) (Hematoxylin-eosin [H&E] stain).



223.4.3.1.5 Treatment

Itraconazole (5 mg/kg orally, twice a day for 2 to 4 months) is considered the treatment of choice for feline histoplasmosis. In one study, itraconazole therapy cured histoplasmosis infections in all eight study cats.[99] Ketoconazole and amphotericin B have been described as the treatments of choice for canine histoplasmosis. With colonic involvement, additional GI therapy may be useful in affected dogs (e.g., dietary modification, treatment for small intestinal bacterial overgrowth, direct antidiarrheal therapy). Corticosteroids may have been used successfully in the treatment of airway obstruction secondary to hilar lymphadenopathy in chronically infected dogs.[100]

223.4.3.1.6 Prognosis

There may be important species differences in prognosis, although the paucity of reports, especially of prospective clinical trials, makes it difficult to generalize. It would seem that the prognosis is guarded in dogs but fair to good in cats.

223.4.4 Oomycetes

223.4.4.1 Pythium insidiosum

223.4.4.1.1 Cause

P. insidiosum is an aquatic oomycete that causes severe GI pathology in a range of hosts in the tropic and subtropic climates.[101] Based on ribosomal RNA gene sequence data, members of the Class Oomycetes are phylogenetically distinct from the Kingdom Fungi and are more closely related to algae than to fungi.[102] The Oomycetes differ from fungi in two important properties (i.e., cell wall and cell membrane composition). Chitin is an essential component of the fungal cell wall, but it is generally lacking in the oomycete cell wall. Oomycetes also differ from fungi in that ergosterol is not a principal sterol in the oomycete cell membrane. This difference may explain why ergosterol-targeting drugs like itraconazole are less effective in the medical treatment of pythiosis.[102]

223.4.4.1.2 Pathophysiology

The infective state of *P. insidiosum* is thought to be the motile zoospore, which is released into stagnant water in warm environments and likely causes infection either by encysting in the skin or by being ingested into the GI tract. Ingested zoospores encyst and adhere to the gastric, jejunal, and colonic epithelium with a polarity oriented toward the submucosa for rapid tissue penetration after germ tube eruption. *Pythium* induces a chronic pyogranulomatous response in the GI tract and mesenteric lymph nodes. The gastric outflow tract and ileocolonic junction are the most frequently affected portions of the GI tract, and it is not uncommon to find two or more segmental lesions in the same patient.[103] Inflammation in affected regions is typically centered on the submucosa, with variable mucosal ulceration and occasional extension of disease through serosal surfaces, resulting in adhesion formation and peritonitis.

223.4.4.1.3 Clinical examination

Weight loss, vomiting, diarrhea, and hematochezia are the most important clinical signs. Physical examination often reveals emaciated body condition and a palpable abdominal mass. Signs of systemic illness such as lethargy and depression are not typically present unless intestinal obstruction, infarction, or perforation occurs.

223.4.4.1.4 Diagnosis

Ileocolonic wall thickening, obliteration of the normal layered appearance, and regional lymphadenopathy are common ultrasonographic features of canine intestinal pythiosis.[104] Of course, these findings cannot be readily differentiated from those associated with intestinal malignancy. Definitive diagnosis requires histologic demonstration or immunohistochemical staining of the organism, positive ELISA or PCR assays, or a combination of these techniques. The histologic findings associated with pythiosis generally are characterized by eosinophilic granulomatous to pyogranulomatous inflammation with fibrosis. Affected tissue typically contains multiple foci of necrosis surrounded and

infiltrated by neutrophils, eosinophils, and macrophages. Discrete granulomas composed of epithelioid macrophages, plasma cells, multinucleate giant cells, and neutrophils and eosinophils may also be observed. *Pythium* zoospores may be cultured directly from affected tissue in antibiotic-containing (e.g., streptomycin, ampicillin) media. More recently, sensitive and specific ELISA and PCR assays have been developed for the accurate diagnosis of pythiosis in dogs.[105–107]

1389

1390

223.4.4.1.5 Treatment

Aggressive surgical resection remains the treatment of choice for pythiosis in dogs. Because it provides the best opportunity for long-term cure, complete resection of infected tissue should be pursued whenever possible. Segmental lesions of the GI tract should be resected with 3 to 4 cm margins whenever possible. Medical therapy for the oomycetes has not been very promising. This may relate to the absence of ergosterol (cell membrane target of most currently available antifungal drugs) in the oomycete cell membrane. Clinical and serologic cures have been obtained in a small number of dogs after therapy with amphotericin B lipid complex (2 to 3 mg/kg every other day, administered to a cumulative dose of 24 to 27 mg/kg) or itraconazole (5 mg/kg every 12 hours for 6 to 9 months).

223.4.4.1.6 Prognosis

Unfortunately, most dogs with GI pythiosis are not presented to the veterinarian until late in the course of the disease, when complete excision is not possible. The anatomic site of the lesion (e.g., pylorus, ileocolic sphincter) may also prevent complete excision. Consequently, the prognosis is usually grave in most animals.[102]

223.4.5 Algae

223.4.5.1 Prototheca zopfii and P. wickerhamii

223.4.5.1.1 Cause

Three species have been recognized within the genus *Prototheca: P. stagnosa*, *P. wickerhamii*, and *P. zopfii*; a fourth species, *P. salmonis*, has been proposed. Of these three species, *P. wickerhamii* and *P. zopfii* have demonstrated pathogenicity. *Prototheca* spp. are ubiquitous in nature and are found in sewage systems, soil, lakes, rivers, ponds, and in feces. The organism has been documented to cause disease in dogs and cats and a variety of other species. *P. wickerhamii* is the causative organism in virtually all instances of cutaneous protothecosis, and *P. zopfii* is the causative organism in most instances of disseminated disease.[108]

223.4.5.1.2 Pathophysiology

Cutaneous infection with granuloma formation is the most common manifestation of protothecosis in most species, including cats and humans. Dissemination does not readily occur in cats or humans, but the infection readily disseminates to distant sites in dogs.

223.4.5.1.3 Clinical examination

Of the 26 canine cases reported in the veterinary literature, 20 either had ocular signs on presentation or developed them later.[108] Sixteen cases had GI signs, usually colitis-type diarrhea, vomiting, and weight loss. Six cases had neurologic signs in the form of paresis, head tilt, cervical pain, circling, and ataxia. *P. zopfii* accounts for most of the cases of canine disseminated protothecosis.

223.4.5.1.4 Diagnosis

Contrast radiography or abdominal ultrasonography may reveal diffuse colonic wall thickening or obstruction, but these are nonspecific findings. Fecal parasitologic examination is generally of little use in demonstrating the organism, but exfoliative cytology, histology, or both readily identifies the organism.[109] Aqueous or vitreous centesis can also be performed in dogs with ocular pathology and is generally useful in documenting organisms in the ocular fluid.

223.4.5.1.5 Treatment

The management of systemic protothecosis has been challenging in all animal species. Amphotericin B and itraconazole (5 mg/kg orally, twice a day for 1 month and then 5 mg/kg orally, once a day thereafter) have been used in several patients. Short-term improvement was reported in only two dogs.

223.4.5.1.6 Prognosis

Like pythiosis, the prognosis for protothecosis is grave. The course of the disease is so insidious that, by the time a definitive diagnosis has been reached, the organism has often disseminated throughout the body.

223.4.6 Bacteria

223.4.6.1 Brachyspira pilosicoli

223.4.6.1.1 Cause

Brachyspira spp., formerly *Serpulina* spp. or *Treponema* spp., are intestinal spirochetes of dogs, pigs, guinea pigs, rodents, nonhuman primates, and humans.[110] In pigs, they cause two important diarrheal syndromes: (1) *B. hyodysenteriae* causes swine dysentery and (2) *B. pilosicoli* causes porcine intestinal spirochetosis. The consequences of colonization by intestinal spirochetes in animals other than pigs and in humans is controversial. Some investigators believe the bacteria may be responsible for various GI disturbances, whereas others have questioned their clinical importance and claimed that shedding of large numbers of spirochetes in connection with diarrhea may be blamed on dislodgment from the crypts by diarrhea induced by other causative agents.

Intestinal spirochetes have been found in both healthy and diarrheal dogs. In a recent study it was suggested that canine intestinal spirochetes consist of *B. pilosicoli* and a group of nonpathogenic

spirochetes, provisionally designated *Brachyspira* (*Serpulina*) *canis*.[111] Infection with *B. pilosicoli* in the colon of dogs might be subclinical, but massive infection, which may occur in environments with poor hygiene or in dogs with a compromised intestinal function because of concurrent causative factors, may cause diarrhea.[111] *B. pilosicoli* may be associated with diarrhea in colony[112] and pet shop dogs.[113]

223.4.6.1.2 Pathophysiology

Severity of clinical signs appears to be associated with attachment of spirochetes to the epithelial surface of the colon, persistence of *B. pilosicoli* in the cecal and colonic crypt lumina, chronic inflammation caused by spriochetal invasion into the lamina propria, and translocation to extraintestinal sites.[114]

223.4.6.1.3 Clinical examination

Infected animals have clinical signs consistent with large bowel-type diarrhea.

223.4.6.1.4 Diagnosis

Brachyspira infections can be diagnosed by fecal culture, colonic histopathology, and PCR of fresh fecal samples. *Brachyspira* spp. are most effectively grown on either trypticase soy agar with 5% sheep blood or selective BJ agar at 42°C under anaerobic conditions. PCR amplification of the 16S rRNA gene has been used to further clarify natural infections.[111]

223.4.6.1.5 Treatment

The best treatments for *Brachyspira* spp. infection have not yet been identified.

223.4.6.1.6 Prognosis

The prognosis for health and recovery appears to be quite favorable.

223.4.6.2 Campylobacter

223.4.6.2.1 Cause

Campylobacter jejuni, *C. coli*, *C. upsaliensis*, and *C. helveticus* are commensal organisms found in the GI tract of healthy dogs and cats throughout the world.[115–117] The high prevalence of these organisms in healthy nondiarrheic dogs (*C. jejuni,* 49%; *C. coli,* 5%; *C. upsaliensis,* 19%) and cats (*C. jejuni,* 46%; *C. coli,* 1%; *C. upsaliensis,* 5%; *C. helveticus,* 22%) complicates diagnosis.[118–121] Under certain conditions, however, *Campylobacter* can induce significant GI tract pathology. Young age, immunoincompetence, concurrent GI infections, prior therapeutic interventions (e.g., antibiotics), and poor hygienic conditions appear to be the greatest risk factors for the development of infection.[122]

1390 1391

223.4.6.2.2 Pathophysiology

At some point, *Campylobacter* organisms become enteroinvasive and induce the host inflammatory response. *C. jejuni* localizes in mucus-filled crypts of the intestine and colon where it induces a superficial erosive enterocolitis.[122,123] Colonic epithelial glands undergo hyperplasia and thickening with exfoliation of the brush border and goblet cells. The colonic epithelium becomes cuboidal, crypt height is reduced, and crypt abscess is present. Shallow crypts and blunt irregular villi are features of the ileum response to infection.

223.4.6.2.3 Clinical examination

Clinical signs are watery diarrhea, often containing mucous and blood pigments, tenesmus, anorexia, fever, and vomiting.[123,124] Concurrent infections with *Salmonella*, *Giardia*, or parvovirus cause more severe disease.

223.4.6.2.4 Diagnosis

Direct examination of a fresh fecal sample is the method of diagnosis in many instances. Large numbers of curved, highly motile bacteria along with increased numbers of leukocytes is presumptive evidence of *Campylobacter* infection. With Gram staining, large numbers of faintly staining gram-negative, slender, curved (gull wing shaped) rods are evident. Fecal cultures or PCR are the most conclusive ways to determine the presence of *Campylobacter*.[118,120] *C. jejuni* is best cultured microaerophilically at 42°C for 48 hours on special *Campylobacter* blood agar plates.

223.4.6.2.5 Treatment

Erythromycin is the treatment of choice, although tetracyclines, aminoglycosides, clindamycin, and quinolones are also effective. Post-treatment cultures should be performed to confirm eradication. Pet owners should be advised on the importance of proper hygiene.

223.4.6.2.6 Prognosis

The prognosis for recovery and cure are generally excellent unless an underlying immunosuppressive condition has increased the susceptibility to infection.

223.4.6.3 Clostridium perfringens

223.4.6.3.1 Cause

C. perfringens is a gram-positive, spore-forming, obligate anaerobic rod-shaped bacterium that contributes to the microbial ecology and nutrition of the colon in healthy dogs and cats.[27] Under certain conditions, proliferation and sporulation of *C. perfringens* permits enterotoxin A (or CPE) production which may then induce mucosal damage, fluid secretion and large bowel-type diarrhea. Evidence for and against a role for *C. perfringens* in the pathogenesis of large bowel diarrhea has been put forward.

Enterotoxigenic *C. perfringens* has been associated with canine nosocomial diarrhea,[125] hemorrhagic enteritis,[115] and acute and chronic large bowel diarrhea.[126,127] On the other hand, many dogs harbor *C. perfringens* and CPE in the GI tract without developing clinical signs.[116,117,122] Until more definitive evidence is obtained, including the fulfillment of Koch's postulates, *C. perfringens* should probably be considered as a suspected pathogen in large bowel diarrhea.

223.4.6.3.2 Pathophysiology

The presumed pathogenicity of *C. perfringens* requires an anaerobic environment, sporulation, and enterotoxin production. However, problems exist with this hypothesis: enterotoxin may be demonstrated in the feces without sporulation, and enterotoxin may be found in the feces of healthy dogs. *C. perfringens* isolates are classified as one of five toxigenic types (A to E) based on the production of one or more of four major (α, β, ε, ζ) and seven minor (δ, θ, κ, λ, μ, ν, and sialidase) toxins.[128] Although all five types of *C. perfringens* are capable of producing CPE, the majority is produced by type A strains. As with enterotoxigenic *E. coli* (ETEC) strains, CPE is believed to induce crypt epithelial cell secretion.

223.4.6.3.3 Clinical examination

Clostridium perfringens-associated colitis is believed to be a major cause of acute, nosocomial, chronic large bowel diarrhea. Acute nosocomial diarrhea often begins within 1 to 5 days of boarding or kenneling. Affected dogs develop diarrhea, often with blood pigments, mucous, and tenesmus. These diarrheas are usually self-limiting and may resolve with supportive care alone. Chronic large bowel diarrheas associated with *C. perfringens* are similar to other large bowel-type diarrheas (i.e., chronic, intermittent, and recurring signs of colitis).

223.4.6.3.4 Diagnosis

No gold standard exists for the diagnosis of *C. perfringens*–associated diarrhea. Ideally, the diagnosis would be made on the basis of positive test results with Gram staining, fecal culture, ELISA enterotoxin (CPE) assay, PCR enterotoxin (*cpe*) genotyping, and rule-out of other colonic diseases on colonoscopy and biopsy.[129–132] Compared with normal dogs (without diarrhea), diarrheic dogs are more often CPE ELISA and *cpe* PCR positive, but many normal dogs are positive on both assays.

223.4.6.3.5 Treatment

Recent *in vitro* antimicrobial susceptibility testing suggests that *C. perfringens* should be susceptible to ampicillin, erythromycin, metronidazole, and tylosin.[133] These antibiotics have also been used in vivo with good success. It should be emphasized that many of the same patients respond to supportive care, including intravenous fluids, intestinal protectants, and bland or fiber-supplemented diets.

223.4.6.3.6 Prognosis

Affected animals usually respond to appropriate therapy within a matter of days. The prognosis for recovery is excellent.

223.4.6.4 Clostridium difficile

Clostridium difficile is believed to share many ecological factors with *Clostridium perfringens*,[134,135] but the role of this organism as a pathogen in dogs and cats has not been firmly established. Compared with normal dogs (without diarrhea), diarrheic dogs are more often toxin A ELISA positive, even though they may be *toxin A* PCR negative.[132] As with *C. perfringens*, many healthy dogs and cats carry *C. difficile* without developing clinical signs. In one recent study, it was difficult to experimentally infect dogs with this organism, and those that were infected did not develop clinical signs.[136] Antibiotic-associated diarrheas develop in dogs and cats, but they may have a pathogenesis other than *C. difficile*.

223.4.6.5 Escherichia coli

223.4.6.5.1 Cause

Most strains of *E. coli* are true commensal organisms that are not associated with clinical signs. Strains of *E. coli* that cause diarrhea in animals can be grouped into five main categories: (1) enterotoxigenic (ETEC), (2) enteroinvasive (EIEC), (3) enteropathogenic (EPEC), (4) enterohemorrhagic (EHEC), and (5) enteroadherent (EAEC) organisms.[137] Identification of pathogenic strains requires modern molecular technology such as bioassays, DNA hybridization, and PCR amplification.

223.4.6.5.2 Pathophysiology

Infection may result in enteritis, colitis, or both.[138] Enterotoxigenic (ETEC) strains adhere to the surface of epithelial cells and produce toxins that are heat labile, heat stable, or both, and that induce crypt epithelial cell secretion. EIEC strains of *E. coli* invade, replicate in, and destroy epithelial cells. EPEC strains are neither enterotoxigenic nor enteroinvasive, but they do attach to and efface the brush border of the enterocytes. EHEC strains produce verocytotoxins that induce hemorrhagic ileitis and colitis. EAEC strains of *E. coli* also induce enterocyte pathology, but their mechanism of action is poorly understood. Enterotoxigenic, enteropathogenic, and enterohemorrhagic *E. coli* have all been isolated from dogs and cats with diarrhea. *E. coli* endotoxin colonic absorption of water and sodium and contributes to the diarrhea seen during and after episodes of sepsis.[139]

1391

1392

223.4.6.5.3 Clinical examination

Affected animals typically have diarrhea and hematochezia with clinical signs relevant to the small intestine, colon, or both.

223.4.6.5.4 Diagnosis

E. coli can be grown from the feces of healthy dogs and cats, so a positive culture does not necessarily reveal the identity of an underlying pathogen. In addition to positive culture, diagnosis may require enterotoxin assays and DNA hybridization and PCR amplification.[140–144]

223.4.6.5.5 Treatment

Antibiotics should be used only in those cases in which firm evidence of bacterial infection exists. Fluoroquinolones appear to be a very effective classification for the treatment of enteric *E. coli* infections.

223.4.6.5.6 Prognosis

The prognosis is generally good for recovery and cure if infection is recognized early in the clinical course.

223.4.6.6 Salmonella

223.4.6.6.1 Cause

Salmonella spp. are predominantly motile, gram-negative facultative anaerobic rod-shaped bacteria found in the feces of normal and diarrheic animals.[116–117] As with many other commensal organisms of the GI tract, the high prevalence of these organisms complicates diagnosis. From 1% to 30% of the fecal samples or rectal swabs taken from healthy domestic pet dogs, 16.7% of dogs boarded in kennels, and 21.5% of hospitalized dogs were found to be positive on bacteriologic culture for *Salmonella*. From 1% to 18% of healthy cats and 10.6% of random source research colony cats are also culture-positive for *Salmonella* (summarized in reference 122). Despite these findings, several species of *Salmonella* have been impugned in the pathogenesis of acute enterocolitis in dogs and cats. *S. typhimurium* is the species most commonly isolated from diarrheic feces of dogs and cats, although other species have been identified.[145–147]

223.4.6.6.2 Pathophysiology

Those most at risk for *Salmonella* infection are young and immunoincompetent animals, those with concurrent GI infections (e.g., parvoviral or parasitic infections), and those animals who have had prior therapeutic interventions (e.g., antibiotics or glucocorticoids).[122] *Salmonella* is an enteroinvasive organism that induces an acute inflammatory response resulting in enterocolitis, mucosal sloughing, and secretory diarrhea. Most *Salmonella* infections are resolved via the local immune response, but bacterial translocation and septicemia may evolve into SIRS and multiple organ dysfunction syndromes (MODS) in some patients. Early recognition is important in preventing this sequela.

223.4.6.6.3 Clinical examination

The main clinical signs of *Salmonella* enterocolitis are anorexia, lethargy, fever, vomiting, diarrhea with mucous and blood pigments, dehydration, abdominal pain, and tenesmus. With bacterial translocation and septicemia, affected animals may have evidence of pale mucous membranes, weakness, tachycardia, tachypnea, and vascular collapse.

223.4.6.6.4 Diagnosis

Culture, serotyping, and PCR are the best methods of diagnosing *Salmonella* infections.[145]

223.4.6.6.5 Treatment

Treatment varies according to the severity of the clinical signs. Mild, self-limiting forms of enterocolitis may in fact resolve with little more than supportive therapy. Antibiotic therapy in such cases may prolong fecal shedding and encourage development of the carrier state. In animals with severe hemorrhagic diarrhea, history of immunosuppression, suspected or documented septicemia, evidence of SIRS, or a combination of these symptoms, parenteral antibiotics should definitely be used. If culture results are unavailable, therapy should include enrofloxacin, amoxicillin, or trimethoprim-sulfa, all of which are effective against *Salmonella*. Post-treatment cultures should be performed to confirm eradication, and pet owners should be advised of the public health importance of the disease.

223.4.6.6.6 Prognosis

The prognosis for recovery in nonsepticemic patients is generally good, although some animals may remain chronic carriers with recrudescence during periods of stress or unrelated disease. The prognosis for the septicemic patient is more guarded.

223.4.6.7 Yersinia enterocolitica

Y. enterocolitica is a commensal organism of the GI tract of some dogs and cats that may be a rare cause of acute colitis.[148] It is a motile, gram-negative facultative anaerobic coccobacillus bacterium that may be transmitted to animals via ingestion of raw pork[149] or contaminated water. If suspected, animals should be treated with cephalosporins or trimethoprim-sulfa. The prognosis is unknown because of the paucity of case reports.

223.5 INFLAMMATION

223.5.1 Inflammatory Bowel Disease

223.5.1.1 Cause

IBD may be defined using clinical, histologic, immunologic, pathophysiologic, and genetic criteria.

223.5.1.2 Clinical criteria

IBD has been defined clinically as a spectrum of GI disorders of an unknown cause that is associated with chronic inflammation of the stomach, intestine, or colon.[40] A clinical diagnosis of IBD is considered only if affected animals have: (1) persistent (> 3 weeks in duration) GI signs (anorexia, vomiting, weight loss, diarrhea, hematochezia, mucosy feces), (2) failure to respond to symptomatic therapies (parasiticides, antibiotics, GI protectants) alone, (3) failure to document other causes of gastroenterocolitis by thorough

diagnostic evaluation, and (4) histologic diagnosis of benign intestinal inflammation.[50] Small bowel and large bowel forms of IBD have been reported in both dogs and cats, although large bowel IBD appears to be more prevalent in the dog.

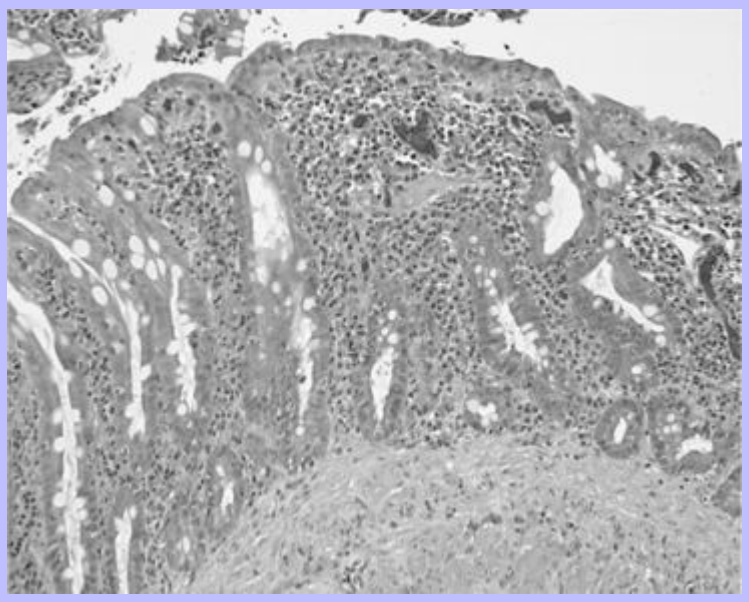
223.5.1.3 Histologic criteria

IBD has been defined histologically by the type of inflammatory infiltrate (neutrophilic, eosinophilic, lymphocytic, plasmacytic, granulomatous), associated mucosal pathology (villus atrophy, fusion, crypt collapse), distribution of the lesion (focal or generalized, superficial or deep), severity (mild, moderate, severe), mucosal thickness (mild, moderate, severe), and topography (gastric fundus, gastric antrum, duodenum, jejunum, ileum, cecum, ascending colon, descending colon).[11] Typical histologic changes associated with IBD are shown in Figure 223-7. As with small intestinal IBD, subjective interpretation of large intestinal IBD lesions has made it difficult to compare tissue findings between pathologists. Subjectivity in histologic assessments has led to the development of several IBD grading systems.*

1392

1393

Figure 223-7 Histologic appearance of inflammatory bowel disease (IBD) of the canine colon. Crypts are separated from adjacent crypts by edema, fibrosis, and inflammatory cells. Increased numbers of lymphocytes are present in the lamina propria, and reduced goblet cells are present in the epithelium. (Photomicrograph courtesy of Dr. Mattie Hendrick, University of Pennsylvania.)



* References 3, 11, 13, 36, 37, 38, 150, 151.

223.5.1.4 Immunologic criteria

IBD has been defined immunologically by the innate and adaptive response of the mucosa to GI antigens. Although the precise immunologic events of canine and feline IBD remain to be determined, a prevailing hypothesis for the development of IBD is the loss of immunologic tolerance to the normal bacterial flora or food antigens, leading to abnormal T cell immune reactivity in the gut microenvironment.[152] Genetically engineered animal models (e.g., IL-2, IL-10, T cell receptor knockouts) that develop IBD involve alterations in T cell development, function, or both, suggesting that T cell populations are responsible for the homeostatic regulation of mucosal immune responses.[153] Immunohistochemical studies of canine IBD have demonstrated an increase in the T cell population of the lamina propria, including CD3+ cells and CD4+ cells, macrophages, neutrophils, and IgA-containing plasma cells. Many of the immunologic features of canine IBD can be explained as an indirect consequence of mucosal T cell activation. Enterocytes are also likely involved in the immunopathogenesis of IBD. Enterocytes are capable of behaving as antigen-presenting cells, and interleukins (e.g., IL-7, IL-15) produced by enterocytes during acute inflammation activate mucosal lymphocytes. Up-regulation of Toll-like receptor 4 (TLR4) and Toll-like receptor 2 (TLR2) expression contribute to the innate immune response of the colon.[154] Thus the pathogenesis and pathophysiology of IBD appears to involve the activation of a subset of CD4+ T cells within the intestinal epithelium that overproduce inflammatory cytokines with concomitant loss of a subset of CD4+ T cells and their associated cytokines, which normally regulate the inflammatory response and protect the gut from injury. Enterocytes, behaving as antigen-presenting cells, contribute to the pathogenesis of this disease.[155]

223.5.1.5 Pathophysiologic criteria

IBD may be defined pathophysiologically in terms of changes in transport, blood flow, and motility. The clinical signs of IBD, whether small or large bowel, have long been attributed to the pathophysiology of malabsorption and hypersecretion, but experimental models of canine IBD have instead related clinical signs to the emergence of abnormality motility patterns.

223.5.1.6 Genetic criteria

IBD may be defined by genetic criteria in several animal species. Crohn's disease and ulcerative colitis are more common in certain human genotypes, and a mutation in the NOD2 gene (nucleotide-binding oligomerization domain2) has been found in a subgroup of patients with Crohn's disease.[155] Genetic influences have not yet been identified in canine or feline IBD, but certain breeds (e.g., German shepherds, boxers) appear to be at increased risk for the disease.

223.5.1.7 Pathophysiology

The pathophysiology of large intestinal IBD is explained by at least two interdependent mechanisms: (1) the mucosal immune response and (2) accompanying changes in motility.

223.5.1.7.1

Immune responses

A generic inflammatory response involving cellular elements (B and T lymphocytes, plasma cells, macrophages, and dendritic cells), secretomotor neurons (e.g., vasoactive intestinal polypeptide, substance P, cholinergic neurons), cytokines and interleukins, and inflammatory mediators (e.g., leukotrienes, prostanoids, reactive oxygen metabolites, nitric oxide [NO], 5-HT, IFN-γ, TNF-α, platelet-activating factor) is typical of canine and feline IBD.[156,157] Many similarities exist between the inflammatory response of the small and large intestine, but recent immunologic studies suggest that IBD of the canine small intestine is a mixed Th1 and Th2 response,[40,158,159] whereas IBD of the canine colon may be more of a Th1 type response with elaboration of IL-2, IL-12, INF-γ, and TNF-α[160] (Figure 223-8). Other studies of canine colonic IBD have demonstrated increased numbers of mucosal IgA-and IgG-containing cells,[36,161–163] nitrate,[162] CD3+ T cells, NO,[164] and inducible nitric oxide synthase (iNOS)[164] in the inflamed colonic mucosa (Table 223-5). Increases in the $CD3^{+}$ positive T cell population of the inflamed colon are consistent with changes reported in the inflamed canine intestine. Thus important similarities exist, as do differences between small (Chapter 222) and large bowel IBD.

223.5.1.7.2

Motility changes
